LIST OF CONTRIBUTORS.

-
- EDMUND ATKINSON, Ph.D. F.C.S.
Professor of Chemistry at the Royal Military College, Sandhurst.
- FRANCIS T. CONINGTON, M.A. F.C.S. (the late)
Fellow of Corpus Christi College, Oxford, and Examiner in Natural Science at that University;
Author of a 'Handbook of Chemical Analysis.'
- WILLIAM DITTMAR, Esq.
Principal Assistant in the Chemical Laboratory of the University of Edinburgh.
- FREDERICK FIELD, F.R.S. F.R.S.E.
(lately) Professor of Chemistry at St. Mary's Hospital.
- GEORGE C. FOSTER, B.A. F.C.S.
Professor of Physics at University College, London.
- MICHAEL FOSTER, M.D.
Professor of Physiology at Trinity College, Cambridge.
- EDWARD FRANKLAND, Ph.D. F.R.S.
Professor of Chemistry at the Royal School of Mines.
- FREDERICK GUTHRIE, Ph.D. F.C.S.
Professor of Physics at the Royal School of Mines.
- M. L'ABBÉ A. HAMY,
Paris.
- MICHAEL HANHART, Esq.
Lithographer.
- A. W. HOFMANN, LL.D. F.R.S. V.P.C.S.
Professor of Chemistry at the University of Berlin.
- WILLIAM S. JEVONS, M.A.
Cobden Professor of Political Economy at Owens College, Manchester; (lately) Gold Assayer in the Sydney Royal Mint.
- CHARLES E. LONG, Esq. F.C.S. (the late)
Analytical Chemist.
- WILLIAM ODLING, M.B. F.R.S.
Professor of Chemistry at the Royal Institution of Great Britain, Author of a 'Manual of Chemistry.'
- BENJAMIN H. PAUL, Ph.D. F.C.S.
Consulting Chemist.
- THOMAS RICHARDSON, Ph.D. F.R.S. &c. (the late)
Reader in Chemistry at the University of Durham.
- HENRY E. ROSCOE, Ph.D. F.R.S. F.C.S.
Professor of Chemistry at Owens College, Manchester.
- WILLIAM J. RUSSELL, Ph.D. F.C.S.
Professor of Chemistry at St. Bartholomew's Hospital.
- J. A. WANKLYN, F.R.S.E. F.C.S.
(lately) Professor of Chemistry at the London Institution.
- C. GREVILLE WILLIAMS, F.R.S.
Author of a 'Handbook of Chemical Manipulation.'
- ARTHUR WINCKLER WILLS, Esq.
Analytical and Manufacturing Chemist, Wolverhampton.

DICTIONARY OF CHEMISTRY.

H.

HEMAPHEIN. *Blood-brown.* (Simon, *Medicin. Chem.* i. 328; Handw. d. Chem. 2^a. Aufl. ii. [2] 167.) A brown substance, probably a product of the decomposition of hæmatin, obtained from blood by the following process:—Dried blood is repeatedly exhausted with boiling water, warm ether, and lastly with alcohol containing sulphuric acid, and the latter solution, after supersaturation with ammonia, is evaporated to dryness. The residue is exhausted with alcoholic ammonia, the solution is again evaporated to dryness, and the residue is exhausted with ether, and then repeatedly with water, in which the hæmaphein dissolves. To free it from still admixed hæmatin, it is dried, dissolved in boiling alcohol, separated again by evaporation, then dissolved in cold alcohol, and the alcohol is evaporated. The product thus obtained is a brown mass difficult to pulverise, soluble with brown-red colour in cold alcohol, less soluble in water and in ether. It does not melt when heated, but burns with a bright flame, without leaving any ash. The solution in dilute alcohol forms brown precipitates with lead, copper, mercurous and silver salts. Sanson obtained a body of similar colour to the above by treating blood successively with alcohol and water.

HÆMATEIN. $C^4H^{12}O^4$, or $C^4H^{10}O^3$. (Erdmann, *Ann. Ch. Pharm.* xlv. 294.—Hesse, *ibid.* cix. 232.)—A substance produced from hæmatoxylin by abstraction of 2 at. hydrogen, a change which takes place by the action of oxygen under the influence of alkalis. The best mode of preparing it is to sprinkle about 20 grms. of hæmatoxylin in a basin with sufficient ammonia to dissolve it, stirring continually, and warming the liquid gently as long as the hæmatoxylin remains in excess. It must now be exposed to the air, and ammonia added from time to time by small quantities, so that the liquid may always smell of it, care being however taken not to add too much ammonia, as it would cause decomposition. The liquid after a little while assumes a dark red colour, appearing almost black when viewed in a stratum of moderate depth. It then contains hæmateate of ammonium, and on being slightly supersaturated with acetic acid, deposits hæmatein in the form of a bulky brown-red mass, like ferric hydrate, which by drying acquires a deep green colour and metallic lustre: its powder in thin layers, exhibits a red colour.

Hæmatein dissolves slowly in cold, more readily in boiling water. On quickly evaporating a solution prepared at the boiling heat, it becomes covered with shining green scales, which sink to the bottom and are gradually replaced by others. Sometimes also the solution solidifies in a gelatinous mass, which yields micaceous lamellæ when suspended in water. Hæmatein likewise dissolves in alcohol and very easily in ether. It dissolves with red-brown colour in the mineral acids, less easily in acetic acid. Sulphydic acid decolorises it, but does not convert it into hæmatoxylin, which is carbonised by heat.

Hæmatein unites readily with bases. *Potash* dissolves it, forming a fine solution which turns brown on exposure to the air. *Ammonia* dissolves it with a fine purple colour, which likewise turns brown in the air.

The last-mentioned solution contains hæmateate of ammonium, which is likewise formed when a solution of hæmatoxylin in ammonia is exposed to the air. The salt deposited by gradual evaporation is a dark violet, granular powder, which when examined by the microscope, appears to be composed of transparent, violet, four-sided prisms. It contains, according to Erdmann's analysis, 66.26 per cent. C, 5.17 H and 6.72 N (mean), whence Gerhardt (*Traité*, iv. 303) deduced the formul $C^{16}H^{10}(NH^4)O^8$ (67.5 C, 5.4 H, and 8.3 N). Hesse, by leaving the solution to stand for two or three days in a cool place, obtained crystals in which he found 51.87 C, 5.7 H, and 3.55 N (mean), agreeing nearly with the formula $C^{16}H^{10}(NH^4)O^8.4H^2O$, which requires 51.75 C, 5.66 H, and 3.77 N. Hæmateate of ammonium dissolves readily in water and alcohol. The alcoholic solution is red-brown, but becomes purple on addition of water. The salt gives off water and ammonia at 100° C. and must therefore be dried over sulphuric acid at ordinary temperatures; even then it sometimes decomposes. Over sulphuric acid in vacuo, it gives off all its ammonia and leaves hæmatein (Erdmann). According to Hesse, it gives off all its water and ammonia at 130° C. leaving hæmatein as a very hygroscopic powder, having a blackish violet colour with green iridescence.

Hæmatein thus obtained contains, according to Hesse's analysis, 67.66 per cent. carbon, and 3.60 hydrogen, agreeing nearly with the formula $C^{16}H^{10}O^8$, which requires 68.08 C and 3.54 H. Erdmann found in his hæmatein 62.66 per cent. C and 4.1 H (mean), whence he deduced the formula $C^{16}H^{10}O^{10}$. Gerhardt (*Traité*, iv. 303) proposed the formula $C^{16}H^{12}O^8$, which, however, does not agree very well with Erdmann's analyses, requiring 64.0 per cent. C and 4.0 H. Hesse suggests that Erdmann hæmatein may be a dibasic acid, $\left. \begin{matrix} C^{16}H^{10}O^8 \\ H^2 \end{matrix} \right\} O^2$, and the product, $C^{16}H^{10}O^8$, obtained by himself, the corresponding anhydride; on this supposition, the two ammonium-salts above mentioned are, perhaps, $\left. \begin{matrix} C^{16}H^{10}O^8 \\ (NH^4)^2 \end{matrix} \right\} O^2$ and $\left. \begin{matrix} C^{16}H^{10}O^8 \\ H.NH^4 \end{matrix} \right\} O^2.3H^2O$.

The solution of hæmateate of ammonium forms coloured precipitates with many metallic salts: with acetate of lead it produces a deep blue precipitate; with sulphate of copper, violet-blue; with protochloride of tin, violet; with iron-alum, black. With chloride of barium it forms a dark purple liquid, which becomes brown on exposure to the air. It reduces nitrate of silver, but has no action on mercuric chloride. According to Hesse, it forms with chloride of barium, chloride of calcium, and especially with chloride of sodium, precipitates of various colours; no precipitate with hypsulphite of sodium; with acid sulphite of ammonium, a gelatinous precipitate, which disappears on boiling.

HÆMATIN or HÆMATOSIN. The red colouring matter of the blood-corpuscles. (See Blood, i. 607.) Lehmann (*Compt. rend.* xl. 385) first showed that it may be obtained in the crystalline state. R. Schwarz (*Zeitschr. f. die ges. Naturwissensch.* xi. 225) prepares it in this state by submitting the comminuted clot of ox-blood freed as much as possible from serum, to pressure, and agitating the expressed liquid by small portions with a saturated solution of oxalic acid, with addition of alcohol and a large quantity of ether. The clear dark brown solution, decanted after a few minutes and left to stand for some weeks over chloride of calcium, deposits the hæmatin in small black nodules made up of cubes, which may be freed from admixed oxalate of calcium by means of dilute hydrochloric acid. Less distinct crystals may be obtained by leaving the ethereal solution to evaporate freely; but the quantity is always small. A solution of hæmatin obtained as above from horse-blood, yielded, on standing, small rush-shaped or spindle-shaped crystals, red-brown by transmitted light. Hæmatin may be obtained in the amorphous state by distilling off about a third of the ether from the solution, and mixing the residue with a large quantity of water. The black flock thus precipitated are washed with water by decantation; then boiled with strong acetic acid, to free them from albuminous compounds, as long as the liquid is rendered turbid by ferrocyanide of potassium; and, lastly, the precipitate is boiled with water, alcohol, and ether in succession, and then again treated with water. The crystallised compound may be subjected to the same treatment without undergoing any alteration. Hæmatin thus prepared is tasteless and inodorous, insoluble in water, cold alcohol, and ether; partially (?) soluble in hot alcohol, easily in acidulated alcohol, whence it is precipitated by water. The solution in acidulated alcohol is decolorised by peroxide of lead. Hæmatin likewise dissolves easily in slightly alkaline liquids, but not in strong sulphuric or hydrochloric acid. Silver, lead, and copper-salts form precipitates in the ammoniacal solution. Hæmatin, when burnt, leaves a residue of ferric oxide mixed with small quantities of calcic phosphate.

The following analyses of hæmatin by Schwarz, give results not differing greatly from those formerly obtained by Mulder (whence the latter deduced the formula $C^{16}H^{12}FeN^4O^8$), but agreeing better with the formula $C^{16}H^{12}FeN^4O^8$.

Calculation.	Schwarz:		Mulder.	
	Amorphous.		Crystallised from horse-blood.	
C ⁷²	66.35	64.12	63.89	64.03
H ⁷²	5.28	5.31	5.28	5.60
Fe	6.73	6.36	.	.
N ⁸	10.10	10.19	.	10.17
O ⁸	11.54	11.00	.	11.85
Phosphate of calcium }	3.02	.	.	.
	100.00	100.00	100.00	100.00

When an alcoholic solution of crystallised hæmatin is boiled with nitric acid, the whole of the nitrogen of the hæmatin is removed, and a non-azotised acid is formed, together with a substance which reduces cupric oxide in alkaline solution, and ferments with yeast, yielding alcohol and carbonic acid.

The name *hæmatin* is sometimes also used as a synonyme of HÆMATOXYLIN.

HÆMATINONE. A red glass known to the ancients, and used for mosaics, ornamental vases, &c.; it is mentioned by Pliny, and occurs pretty frequently among the ruins of Pompeii. Its colour is a fine red, intermediate between red lead and vermilion. It is opaque, harder than common glass, takes a fine polish, has a conchoidal fracture, and a specific gravity of 3.5. The red colour, which is due to red oxide of copper, is completely destroyed by fusion, and cannot be restored by any addition whatever. The fused mass has a greenish black colour, which reducing agents merely convert into a muddy brown-red. Hæmatinone contains no tin, and no colouring substance except cuprous oxide.

This antique glass may be exactly imitated by the following process, discovered by Pettenkofer (Dingl. pol. J. cxlv. 122):—100 pts. of silica, 11 lime, 1 magnesia, 33 litharge, and 50 carbonate of soda, are fused together, and to the clear white glass thus produced are added 25 pts. of scale oxide of copper, somewhat later 2 pts. of scale oxide of iron, and, lastly, a small quantity of charcoal. On leaving the fused mass to cool slowly, a liver-coloured glass is obtained, which, when further heated (for 6 to 12 hours) till it softens, is converted into hæmatinone of a splendid red colour, in consequence of the separation of a red cuprous compound within its mass.

A more fusible glass, made by melting together 100 pts. silica, 10 lime, 0.5 magnesia, 40 litharge, 60 carbonate of soda, 30 scale oxide of copper, 2 alumina, and 3 scale oxide of iron, exhibits, after once slow cooling in the air-furnace, a great number of red points, diffused through a yellowish vitreous mass; on cutting and polishing this glass, the red points appear as beautiful tufts of needle-shaped crystals.

When part of the silica in hæmatinone is replaced by boric anhydride (by adding borax to the melted mass), a dark-coloured, dichroitic, crystalline compound is obtained, called *astralite* (i. 429).

Pettenkofer is of opinion that the same crystalline cuprous compound (whether pure cuprous oxide, or more probably cuprous silicate) which imparts the red colour to hæmatinone, constitutes likewise the crystalline spangles contained in *aventurin glass* (i. 477), which in fact he has produced by fusing hæmatinone with a quantity of iron filings, sufficient to reduce about half the copper contained in it to the metallic state (the metal then settling down in the form of a regulus, and leaving a deep greenish black, scarcely transparent glass above), heating this glass for some time to the temperature at which it softens, and then leaving it to cool very slowly. (Jahresb. d. Chem. i. 1061; ix. 798.)

HÆMATITE. Native sesquioxide of iron. (See IRON, OXIDES OF.)

HÆMATO-CRYSTALLIN. A crystalline substance obtained from blood (i. 606). It has the composition of the albuminoids, and if quite pure would probably be colourless, but it has never yet been obtained perfectly free from hæmatin.

HÆMATO-GLOBULIN. Syn. with HÆMATO-CRYSTALLIN.

HÆMATOIDIN. A crystalline substance often found in extravasated blood (i. 607). It appears to be produced by the decomposition of hæmatin; but the nature of the transformation has not been exactly made out. According to Verdeil and Dollfus (Compt. rend. xxx. 306), crystals resembling hæmatoidin may be obtained from ox-blood by filtering it after coagulation by heat; evaporating the solution to a syrup, and mixing it with alcohol; strongly concentrating the liquid filtered from the resulting precipitate; and mixing it, when cold, with dilute sulphuric acid. Fat globules then separate on the surface of the liquid, and sometimes red crystals resembling hæmatoidin.

HÆMATOSIN — HÆMATOXYLIN.

Robin (Compt. rend. xli. 506) found a considerable quantity of hæmatoïdin in an hepatic cyst, forming hard, brittle prisms of 118° and 62° , and of a bright, orange-brown colour. According to Valentiner (Jahresb. f. Chem. 1859, p. 666), gall-stones, bile, and the livers of persons affected with jaundice, yield, when treated with chloroform, a crystalline substance differing from all previously known ingredients of bile, and agreeing in all respects with hæmatoïdin.

HÆMATOSIN. See HÆMATIN.

HÆMATOXYLIN, also called *Hæmatin*. $C^{16}H^{10}O^6$. (Chevreul, Ann. Chim. lxxx. 128.—Golfier-Besseyre, Ann. Ch. Phys. [2] lxx. 272.—Erdmann, Ann. Ch. Pharm. xlv. 292.—Leblanc, *Traité de Chimie* de Dumas, viii. 102.—O. Hesse, J. pr. Chem. lxxv. 218; Ann. Ch. Pharm. cix. 332.)—A crystalline substance contained in logwood (*Hæmatoxylin Campechianum*), and the source of the colouring properties of that well-known dye. In the pure state, however, it has little or no colour, but is converted into a colouring matter under the influence of alkalis and oxygen.

It is prepared by leaving the commercial extract of logwood—previously mixed with quartz-sand to prevent agglomeration—in contact with 5 or 6 times its volume of ether (not anhydrous) for several days, agitating from time to time; then decanting the brownish-yellow solution; distilling off the ether; mixing the syrupy residue with water; and leaving it to itself in a loosely covered vessel. If no water were added, the liquid would simply dry up to a gummy mass; but, if a sufficient quantity of water is present, the hæmatoxylin crystallises in the course of a few days. The crystals are washed with water and freed from adhering mother-liquor by pressure between filtering paper. The mother-liquor mixed with the wash-water yields another crop of crystals by spontaneous evaporation. A kilogramme of logwood treated several times with ether yields from 100 to 120 grms. of hæmatoxylin. (Erdmann.)

Hæmatoxylin thus prepared has more or less of a yellow colour, but by recrystallisation from water containing a little sulphite of ammonium, it may be obtained in colourless crystals. (Hesse.)

Hæmatoxylin forms two kinds of crystals containing respectively 3 and 1 at. water. The trihydrated crystals, $C^{16}H^{10}O^6 \cdot 3H^2O$, obtained as above, belong to the dimetric system. Ordinary combination $\infty P\infty$. P, with $P\infty$ subordinate. Length of principal axis = 0.63 (nearly). Angle of the terminal edges of the primitive octohedron, $P = 124^{\circ}$. The crystals are transparent, generally very brilliant, and sometimes of considerable length. They give off their water (15.1 per cent.) in vacuo at ordinary temperatures.

The monohydrate, $C^{16}H^{10}O^6 \cdot H^2O$ (containing 5.6 water), is obtained by leaving a solution supersaturated at mean temperature to stand for some time, in crystals of considerable size, with smooth and sometimes curved faces, and consisting, according to a preliminary determination by Naumann, of hemihedral trimetric combinations, $oP \cdot \frac{P}{2} \cdot mP\infty$. The same hydrate is obtained in granular crystals, by pouring a

solution of hæmatoxylin, supersaturated at the boiling heat, into a cold vessel containing a small quantity of solution of acid sulphite of ammonium. (Hesse.)

Dehydrated hæmatoxylin contains, according to Erdmann's analyses, 63.17—63.66 per cent. carbon, and 4.65—4.70 hydrogen, whence Erdmann deduced the formula $C^{16}H^{10}O^6$. Gerhardt, however (*Traité*, iv. 299), suggested the more probable formula, $C^{16}H^{10}O^6$, which requires 63.5 per cent. C, 4.5 H, and 31.9 O.

Hæmatoxylin dissolves slowly and sparingly in cold water, easily in alcohol and ether (Erdmann). It dissolves in a saturated solution of borax more easily than in pure water, forming a neutral or slightly acid liquid, which exhibits a bluish fluorescence, and from which the borax is not precipitated by alcohol. This solution, mixed with hydrochloric, acetic, or sulphuric acid, solidifies to a dense mass, in which granular crystals of monohydrated hæmatoxylin quickly form; but on addition of solution of chloride of sodium, potassium, or ammonium, ferrocyanide of potassium, or acid sulphite of ammonium, it deposits hæmatoxylin as a white amorphous mass. When acid sulphite of ammonium is added by drops to the same solution, hæmatoxylin is at first deposited in the form of an amorphous gummy precipitate, which re-dissolves on boiling the liquid, and reappears on cooling; but on continuing the addition of the acid sulphite to the syrupy liquid, a point is at length attained at which the amorphous hæmatoxylin disappears, and crystals of hæmatoxylin are soon afterwards obtained. When amorphous hæmatoxylin is dissolved in boiling water, and a drop of hydrochloric acid added to the solution, crystals of hæmatoxylin, generally the monohydrate, are soon deposited. (Hesse.)

Hæmatoxylin dissolves abundantly in a warm solution of hyposulphite of sodium, forming a purple liquid, which deposits amorphous hæmatoxylin on cooling. It dis-

solves with some difficulty in solution of *chloride of sodium*, more easily in a saturated solution of *chloride of barium* (this solution at first depositing crystals of the trihydrate, which gradually give place to those of the monohydrate), very abundantly in solution of *ordinary phosphate of sodium*, forming a liquid which behaves like the solution of hæmatoxylin in borax above mentioned, excepting that it exhibits a basic reaction. (Hesse.)

Hæmatoxylin has a strongly saccharine taste, like that of liquorice, very persistent, and without astringence or bitterness. Its solutions turn the plane of polarisation to the right. It reduces cupric oxide in an alcoholic solution containing alkali.

An aqueous solution of hæmatoxylin is not altered by contact with pure air or oxygen gas; but if the slightest trace of *ammonia* is present in the air, the liquid acquires a yellowish red colour, arising from the formation of hæmateate of ammonium; probably thus:

Hæmatoxylin melts in its water of crystallisation when moderately heated, and is completely carbonised at higher temperatures. *Chlorine* converts it into an uncrystallisable mass: With *nitric acid* it forms oxalic acid. *Sulphuric* and *hydrochloric acids* have but little action upon it.

With *bases*, hæmatoxylin forms compounds which, on exposure to the air, are converted into hæmateates. *Baryta-water*, added to a solution of hæmatoxylin freed from air by boiling, forms a white precipitate which soon turns blue if the air has access to it. *Potash* imparts to the solution a violet colour, quickly changing to purple and brown. With acetate of *lead*, neutral or basic, the solution yields a white precipitate, which quickly turns blue; with *cupric acetate* or *sulphate*, a greenish grey precipitate, which soon becomes dark blue with a coppery lustre. *Dichloride of tin* forms a rose-coloured precipitate, which does not change colour. *Iron alum* forms, after a while, a slight blackish violet precipitate. *Common alum* colours the solution light red, but does not produce a precipitate. *Chloride of barium* first colours the liquid red, and then forms a red precipitate. The solution of hæmatoxylin quickly reduces nitrate of *silver* and *chloride of gold*.

HÆMIN. A crystallised, intensely red substance, which may be prepared from blood in various ways, but is difficult to obtain in the pure state, and has therefore not been analysed. The crystals are obtained immediately on mixing blood, either fresh or boiled, with strong acetic acid. No crystals are formed, however, when blood coagulated by boiling is first washed with water and then treated with acetic acid (Teichmann, Pfeuffer and Henle's Zeitschr. f. rat. Medicin, iii. 367; viii. 141). According to Krauss (Jahresb. f. Chem. 1861, p. 792), human blood may be distinguished with certainty from that of the ox, sheep, pig, mouse, or poultry, by the characters of the hæmin-crystals obtained from it.

HAFREFJORDITE. Oligoclase from Hafrefjord, in Iceland.

HAIDINGERITE. A hydrated arsenate of calcium, $2Ca''HA_2O^4 \cdot 3H^2O$, supposed to be from Baden or Joachimsthal, associated with pharmacolite. Occurs in minute crystals belonging to the trimetric system, mostly congregated in botryoidal forms and drusy crusts. Specific gravity 2.848. Hardness 1.5 to 2.5. Lustre vitreous. Colour white. Streak white. Transparent or translucent. Sectile; their laminae slightly flexible. (Dana, ii. 413.)

Crystals having the form and composition of haidingerite may be produced artificially by digesting carbonate of calcium at ordinary temperatures with excess of aqueous arsenic acid. (Debray, Ann. Ch. Phys. [3] lxi. 419.)

HAIR. Hair consists of a cylindrical tube clothed with minute scales, having their points directed towards the free extremity. The tube is filled with an oil, which gives the colour to the hair; in white hair this oil is colourless.

In the normal state hair is insensible, strongly electric, and a bad conductor of heat. In contact with the air, it swells and absorbs moisture, but does not putrefy. Chlorine first bleaches and then converts it into a resinous matter resembling turpentine.

Hair is insoluble in water. Heated with water in a sealed tube, it is decomposed, with liberation of sulphydric acid. A similar decomposition takes place with aqueous potash. Nitric acid turns it yellow, forming oxalic acid, sulphuric acid, and a peculiar bitter substance. Hydrochloric and sulphuric acids dissolve it, forming rose-coloured solutions. Alkalis dissolve it. Many salts and metallic oxides, and likewise certain organic substances, change the colour of red or white hair to black. A solution of nitrate of silver in ether, or the same salt mixed with lard, oil, slaked lime, or pyrogallie acid is commonly used for blackening hair.

Hair, when heated, becomes hard, swells and emits an odour of burnt horn, and in the open air, takes fire, burns with a bright flame, and leaves a residue of charcoal. By dry distillation it yields oily and ammoniacal products.

According to Von Laer, human hair contains 49·8 per cent. carbon, 6·4 hydrogen, 17·1 nitrogen, 5·0 sulphur, and 26·7 oxygen. It leaves by calcination from 0·32 to 1·86 per cent. of ash, consisting of 0·17 to 0·93 soluble matter, 0·658 to 0·390 oxide of iron, and 0·000 to 0·628 earthy salts. (Pelouze et Frémy, *Traité*, vi. 244.)

HAIR-SALT. A term applied to native *sulphate of aluminium*, $\text{Al}^2(\text{SO}^4)^3 \cdot 9\text{H}^2\text{O}$, and to *iron-alum*, $\text{Al}^{10}\text{Fe}(\text{SO}^4)^2 \cdot 12\text{H}^2\text{O}$, these salts sometimes occurring in delicate fibrous masses. (See **ALUM** and **SULPHATES**.)

HALLITE. Basic sulphate of aluminium, $2(\text{Al}^2\text{O}^3 \cdot \text{SO}^4) \cdot 3\text{H}^2\text{O}$. (Syn. with **WEBSTERITE**.)

HALLOYSITE or **HALLOTTE.** A hydrated silicate of aluminium containing a larger proportion of water than ordinary clay, which it otherwise resembles. After drying in the air at ordinary temperatures, it retains nearly $2\text{H}^2\text{O}$, but by drying in the kiln, the proportion of water is reduced to nearly that of common clay, viz. $\text{Al}^2\text{O}^3 \cdot \text{SiO}^2 + \text{H}^2\text{O}$. It occurs in white, soft, smooth masses, with conchoidal waxy fracture, adhering to the tongue, opaque or translucent at the edges only. When immersed in water, it does not fall to pieces but becomes more translucent. It is readily decomposed by sulphuric acid. The following are analyses:—

(Gm. iii. 417.)

HALOGEN. The electro-negative radicle of a haloïd-salt.

HALOÏD SALTS. Berzelius applied this term to salts consisting of a metal united with an electro-negative radicle, viz. *chlorides, bromides, iodides, cyanides, &c.*, designating by the term, **AMPHID-SALTS**, those which were supposed to result from the union of two binary compounds containing a common element, viz. the oxygen-salts, sulphur-salts, selenium-salts, and tellurium-salts. The distinction between these two classes of salts is no longer retained, but the term *haloïd* is still occasionally applied to the chlorides, bromides, iodides, fluorides, and cyanides.

HALOTRICHINE. A silky iron-alum, from the Solfatara, near Naples. (See **SULPHATES**.)

HALOTRICHITE. A name applied sometimes to native iron-alum, sometimes to native hydrated sulphate of aluminium. (See **SULPHATES**.)

HAMATHIONIC ACID. An acid produced by the action of sulphuric acid on euxanthic acid. Its composition has not been exactly determined. The barium-salt contains 31·4 per cent. baryta; the lead-salt, 61·6 to 62·4 oxide of lead. (See **EUXANTHIC ACID**, ii. 610.)

HAMPSHIREITE. (See **STREATITE**.)

HARDNESS OF MINERALS. A harder body is distinguished from a softer, either by attempting to scratch one with the other, or by trying each with a file. To give a definite character to the results thus obtained, Mohs introduced a scale of hardness, consisting of ten minerals, gradually increasing in hardness from 1 to 10, viz.:

1. *Talc*: common laminated, light-green variety.
2. *Gypsum*: a crystallised variety.
3. *Calc-spar*: transparent variety.
4. *Fluor-spar*: crystalline variety.
5. *Apatite*: transparent variety.

- 5.5 *Scapolite*: crystalline variety.
6. *Felspar*: (orthoclase); white cleavable variety.
7. *Quartz*: transparent.
8. *Topaz*: transparent.
9. *Sapphire*: cleavable varieties.
10. *Diamond*.

The hardness of any given mineral may be determined by attempting to scratch it with some of the above minerals, or by trying to scratch a smooth surface of the successive members of the scale with a sharp corner of the substance to be examined; thus, if it scratches fluor-spar and is scratched by apatite, the hardness is between 4 and 5.

Or again, the relative hardness of a mineral may be determined by abrading one of its edges with a file. If the file abrades the mineral under trial with the same ease as fluor-spar, and produces an equal depth of abrasion with the same force, the hardness is said to be 4. If the mineral is abraded more easily than fluor-spar, but less easily than apatite, the hardness may be 4.25 or 4.5. In making these comparative trials, care must be taken to apply the file to edges of equal obtuseness. That part also of the specimen should be selected which has not been altered by exposure, and has the highest degree of transparency and compactness of structure. The pressure for determination should be rather heavy, and the file should be passed three or four times over the specimen.

Certain varieties of some minerals give a low degree of hardness under the file, owing either to impurities or imperfect aggregations of particles, whilst they scratch a harder species, showing that the particles are hard, but loosely aggregated; this peculiarity is exhibited by certain varieties of chialtolite, spinel, and sapphire.

Many minerals—kyanite and mica, for example—present different degrees of hardness on dissimilar faces. This inequality, like difference of colour, lustre, &c., in the faces, is confined to those primary forms which are developed upon unlike axes. (Dana, i. 180.)

HARMALA, ALKALOIDS OF. (Gerh. iv. 9.—Handw. d. Chem. iii. 769.)—

The seeds of the *Peganum Harmala*, a plant growing abundantly on the steppes of Southern Russia, especially in the Crimea, contain two organic bases called harmaline and harmine, probably in the form of phosphates; they are found in the seed-coating, not in the kernel. To obtain these alkaloids, the pulverised seeds are exhausted in a percolating apparatus with water acidulated with acetic or sulphuric acid; and the brownish yellow extract, which contains the bases in the form of acetates, together with earthy phosphates, colouring matter, &c., is mixed with a solution of common salt, whereupon the hydrochlorates of the alkaloids, which are insoluble in that liquid, are precipitated together with colouring matter. Nitrate of sodium may also be used instead of the chloride, provided care be taken that the extract of the seeds does not contain free sulphuric acid, as the nitric acid which would then be liberated might decompose the alkaloids. The precipitate is collected on a filter, and washed with brine until the whole of the mother-liquor is removed; then dissolved on the filter with cold water, which leaves part of the colouring matter undissolved. The solution, treated with animal charcoal, and then at a temperature of 50° to 60° C. with ammonia added by small portions, yields the alkaloids in the pure state, nearly the whole of the harmine being thrown down before the harmaline begins to separate. As soon as the latter body makes its appearance,—which may be known by examining the precipitate from time to time with the microscope, harmine crystallising in needles, while harmaline forms leafy scales,—the solution must be filtered hot, and the harmaline precipitated from it by ammonia.

The seeds contain about 4 per cent. of alkaloids, of which one-third consists of harmine, and two-thirds of harmaline.

HARMALA RED. The seeds of harmala contain also a red colouring matter, which may be extracted by digesting them with alcohol for 8—14 days. It is insoluble in water, easily soluble in ether, and dissolves in all proportions in absolute alcohol. It unites with acids, forming red salts, and dyes wool or silk mordanted with acetate or sulphate of alumina, from the lightest rose-colour to the deepest scarlet. The colours do not, however, appear to be very fast. (Gm. xvi. 119.)

HARMALINE. C_8H_9NO .—Discovered by Göbel in 1837 (Ann. Ch. Pharm. xxxviii. 363); afterwards more minutely examined by Fritzsche (*ibid.* lxi. 360; lxxiii. 351, 355; lxxii. 306; lxxviii. 327). It is colourless when pure; if it has a yellowish or brownish tint, it may be purified by suspending it in water, adding acetic acid in sufficient quantity to dissolve it, filtering to separate colouring matter, then precipitating with chloride or nitrate of sodium, or hydrochloric acid, washing the precipitate on a filter with a dilute solution of the reagent employed, dissolving it in tepid

water, treating the solution with animal charcoal till it exhibits a light yellow colour, and precipitating by caustic potash.

Harmaline crystallised from alcohol forms octahedrons belonging to the trimetric system, modified by the faces ∞P_{∞} , ∞P_{∞} , and P_{∞} . Ratio of the vertical to the horizontal axes, 1 : 1.804 : 1.415. Angles of the terminal edges in $P = 116^{\circ} 34'$ and $131^{\circ} 18'$; of the lateral edges in the same $= 83^{\circ} 54'$. It is sparingly soluble in water and ether, moderately soluble in cold alcohol, and very freely in boiling alcohol. It has a faint bitter taste; and colours the saliva yellow.

Harmaline, when heated, melts, gives off white vapours and becomes carbonised. Heated in a tube, it yields a white mealy sublimate. Oxidising agents, under certain circumstances, convert it into a red colouring matter, insoluble in water, soluble in alcohol. By some oxidising agents, however, harmaline is converted into harmine by loss of 2 at. of hydrogen; this change takes place when the acid chromate of harmaline is heated to 120°C ., or when harmaline is heated with hydrochloric acid and alcohol, to which a little nitric acid is added. When nitrate of harmaline is heated with alcoholic hydrochloric acid, the harmaline is converted into harmine. Harmaline, boiled with excess of *nitric acid*, yields, first, nitroharmaline, then, by longer boiling, nitroharmine: with boiling *nitromuriatic acid*, it forms chloronitroharmine.

The salts of harmaline are yellow, have a bitter taste, and are for the most part easily soluble and crystallisable.

The *acetate* is obtained by spontaneous evaporation of a solution of harmaline in acetic acid, in the form of a syrup which becomes crystalline after a while. A solution of the acetate, mixed with acid carbonate of potassium, yields *acid carbonate of harmaline*, in the form of a precipitate composed of fine needles. The neutral alkaline carbonates either form no precipitate with the salts of harmaline, or merely throw down the base.

The *neutral chromate* is a sparingly soluble, yellow, crystalline salt, which may be obtained by adding acetate of harmaline drop by drop to a solution of neutral chromate of potassium, saturated in the cold, filtering from the precipitate of harmaline first produced, and adding more acetate of harmaline to the filtrate. The *acid chromate*, $2\text{C}^{12}\text{H}^{14}\text{N}^2\text{O} \cdot \text{H}^2\text{O} \cdot 2\text{CrO}_3$, is produced by adding acid chromate of potassium to a dilute solution of harmaline, and separates immediately in oily drops, which, after a while, become crystalline. When heated to 120°C ., it is rapidly decomposed, yielding a sublimate of *harmine* and leaving a dark-coloured residue containing chromium.

The *hydrochlorate*, $\text{C}^{12}\text{H}^{14}\text{N}^2\text{O} \cdot \text{HCl} \cdot 2\text{H}^2\text{O}$, forms long prismatic needles containing 12.3 per cent. water of crystallisation. It is moderately soluble in water and in alcohol. The *chloroplatinate*, $2(\text{C}^{12}\text{H}^{14}\text{N}^2\text{O} \cdot \text{HCl}) \cdot \text{PtCl}_4$, is a yellow precipitate.

The *hydrocyanate* forms a peculiar alkali. The *hydroferrocyanate* is a brick-red crystalline powder; the *hydroferricyanate* forms long dark green prisms. The *sulphocyanate* forms silky needles, sparingly soluble in cold, more soluble in boiling water.

Nitrate of harmaline, obtained by precipitating the acetate with dilute nitric acid or nitrate of ammonium, forms needles sparingly soluble in pure water, and almost insoluble in water containing nitric acid.

Oxalates.—When aqueous oxalic acid is boiled with excess of harmaline, crystals of the neutral salt separate on cooling; and oxalic acid, added to the solution of these crystals, precipitates the acid oxalate of harmaline.

Sulphates.—By digesting dilute sulphuric acid with excess of harmaline, and evaporating the filtrate, the neutral sulphate is obtained as a yellow resin, which, when left over oil of vitriol, changes to a radio-crystalline mass.

Sulphite.—The solution of harmaline in aqueous sulphuric acid dries up to a yellow resin, exhibiting no traces of crystallisation.

Sulphydrate.—By mixing concentrated solutions of sulphydrate of ammonium and acetate of harmaline, slender prisms are obtained which quickly decompose on exposure to the air, after separation of the mother-liquor.

Hydrocyan-harmaline, $\text{C}^{12}\text{H}^{14}\text{N}^2\text{O} = \text{C}^{12}\text{H}^{14}\text{N}^2\text{O} \cdot \text{HCy}$, is a base containing the elements of harmaline and hydrocyanic acid. It is obtained by dissolving harmaline in dilute boiling hydrocyanic acid and filtering hot, being then deposited in crystals on cooling; or by pouring a solution of cyanide of potassium into a solution of a salt of harmaline, or caustic potash into a solution of a salt of harmaline previously mixed with hydrocyanic acid. From aqueous solutions it is deposited in amorphous flocks, which give off hydrocyanic acid when dried in the air; the decomposition may, however, be prevented by dissolving the powder, while yet moist, in hot alcohol. If it still contains harmaline, it may be purified by suspending it in water and adding acetic acid, which readily dissolves the harmaline, but exerts little or no action on the hydrocyan-harmaline.

This base, when pure, forms thin rhomboidal tables, which, when dry, undergo no alteration by exposure to the air, or in vacuo, or even at 100°C . At a higher tem-

perature, or when boiled with water or alcohol, it is resolved into harmaline and hydrocyanic acid. Suspended in water and boiled with a large excess of nitric acid, it is decomposed, giving off red vapours, and yielding a purple solution which deposits non-crystalline grains of a fine red colour, changed to green by ammonia. Hydrocyan-harmaline, heated with hydrochloric acid and chloride of potassium, yields a resinous product.

The salts of hydrocyan-harmaline are even less stable than those of harmaline. The base does not appear to combine with all acids. The hydrochlorate, $C^{12}H^{12}N^2O.CyH.HCl$, is a crystalline powder composed of small octahedrons with a rhombic base and secondary faces, whereas hydrochlorate of harmaline, when examined by the microscope, appears like an aggregation of long yellow prisms. The *nitrate* and *sulphate* are also crystalline.

Nitroharmaline. $C^{12}H^{12}N^2O^2 = C^{12}H^{12}(NO^2)N^2O$. *Chrysoharmine*.—This body, which is derived from harmaline by the substitution of 1 at. nitryl, NO^2 , for 1 at. hydrogen, may be prepared:—1. By suspending 1 pt. of harmaline in 6 or 8 pts. of alcohol of 80 per cent., adding 2 pts. of strong sulphuric acid, and, when the solution is complete, 2 pts. of moderately concentrated nitric acid; heating the mixture on the water-bath; and as soon as the reaction, which is very brisk, is over, cooling it quickly to prevent secondary decompositions. The liquid then deposits sulphate of nitroharmaline, which is to be washed with alcohol containing sulphuric acid, then dissolved in warm water, and precipitated by dilute potash or ammonia. If the nitroharmaline thus precipitated contains harmine or undecomposed harmaline, it may be freed therefrom by means of sulphurous acid, which forms a sparingly soluble salt with nitroharmaline, but very soluble salts with the other two bases.—2. By a process exactly similar to that which will be hereafter described for the preparation of nitroharminine, excepting that the nitric acid used must be weaker, viz. of specific gravity 1.12 instead of 1.40.

Nitroharmaline, precipitated from its salts by an alkali, is an orange-coloured powder composed of microscopic prisms; larger crystals are deposited from the alcoholic solution. It is but sparingly soluble in cold water, to which, however, it imparts a yellow colour; boiling water dissolves it much more freely. It is more soluble in alcohol than harmine or harmaline; sparingly soluble in cold ether, more soluble in hot ether. It dissolves in oils, both fixed and volatile; also in hot rock-oil. It melts at $120^\circ C$.

Heated with ammoniacal salts it decomposes them, expelling the ammonia. Nitric acid converts it into nitroharminine.

The salts of nitroharmaline are yellow. The *hydrochlorate*, $C^{12}H^{12}(NO^2)N^2O.HCl$, crystallises in small prisms; its solution, mixed with tetrachloride of platinum, yields the *chloroplatinate*, $2(C^{12}H^{12}(NO^2)N^2O.HCl).PtCl_4$, as a yellow precipitate, which ultimately assumes the form of minute prisms.

The *nitrate* crystallises in yellow needles, rather sparingly soluble in water, especially if it contains a little nitric acid. A perfectly neutral solution of this salt, mixed with ammoniacal nitrate of silver, yields a yellowish red flocculent precipitate, consisting of *argento-nitroharmaline*, $C^{12}H^{12}Ag(NO^2)N^2O.H^2O$.

A compound of *nitroharmaline* with *nitrate of silver* is obtained in light yellow crystalline flakes on mixing an alcoholic solution of nitroharmaline with nitrate of silver.

The *neutral sulphate* is obtained as a crystalline precipitate on saturating a solution of the acetate with sulphate of ammonium. The *acid sulphate*, $C^{12}H^{12}(NO^2)N^2O.H^2SO^4$, is produced by dissolving the base in excess of sulphuric acid, mixed with alcohol, or by dissolving it in strong sulphuric acid, and pouring the solution, drop by drop, into cold water. It is a pale yellow crystalline powder, nearly insoluble in cold water.

The *sulphite* is very little soluble in cold water, especially if acidulated with sulphurous acid.

The *acetate* is soluble; the *oxalate* crystallisable. The *hydroferrocyanate* is a yellow crystalline precipitate. The *hydroferricyanate* separates in oily drops, which solidify, after a while, to a crystalline powder. The *sulphocyanate* forms sparingly soluble microscopic needles.

Hydrocyano-nitroharmaline, $C^{12}H^{12}(NO^2)N^2O.CyH$, is obtained by dissolving nitroharmaline in a hot alcoholic solution of hydrocyanic acid; also, by leaving a concentrated solution of acetate of nitroharmaline, mixed with hydrocyanic acid, to evaporate; or by adding ammonia to a salt of nitroharmaline containing hydrocyanic acid. It forms slender yellow needles, which give off the odour of ammonia when moist, but are permanent when dry. By boiling with water, it is resolved into nitroharmaline and hydrocyanic acid. Decomposed also by strong ammonia or potash. It dissolves in strong sulphuric acid, and the solution, poured into a small quantity of water, yields needles, apparently consisting of an insoluble sulphate.

HARMINE. $C^{12}H^{12}N^2O$. (Fritzsche, *loc. cit.*, p. 7).—This alkali, which contains 2 at. H less than harmaline, may be obtained either directly from the seeds of *Peganum harmala*, in the manner already described, or as a product of the oxidation of harmaline. Acid chromate of harmaline, heated to $120^{\circ} C$, decomposes suddenly with evolution of heat, and produces harmine, part of which volatilises and condenses on the sides of the vessel. A better process is to heat harmaline with a mixture of equal parts of hydrochloric acid and alcohol, to which a little nitric acid is added. The conversion of the harmaline is complete soon after the liquid begins to boil, and on cooling, hydrochlorate of harmaline is abundantly deposited in slender needles. The solution of this salt, decomposed by ammonia, yields the base.

Harmine forms rhomboidal prisms of $124^{\circ} 18'$, and $55^{\circ} 42'$, nearly insoluble in water, very sparingly soluble, at ordinary temperatures, in alcohol and in ether. It is a weaker base than harmaline; nevertheless it expels ammonia from its salts at the boiling heat.

The salts of harmine are colourless, and mostly crystalline; their solutions have a yellow tint when concentrated, bluish when dilute. Alkalis and alkaline carbonates decompose them, precipitating the base.

The acid chromate, $2C^{12}H^{12}N^2O.H^2O.2Cr^2O^3$, is always formed on mixing an acid solution of harmaline with a soluble chromate. It is decomposed by heat, yielding a peculiar base.

The hydrochlorate, $C^{12}H^{12}N^2O.HCl$, forms needles containing 12.38 per cent. water, which they give off at $100^{\circ} C$. From alcohol, the salt is deposited in the anhydrous state. The chloroplatinate, $2(C^{12}H^{12}N^2O.HCl).PtCl^4$, is a flocculent precipitate, becoming crystalline when heated. The chloromercurate is deposited as a curdy precipitate from cold solutions, and crystalline from hot solutions. The hydrobromate and hydriodate resemble the hydrochlorate.

The hydroferrocyanate and hydroferricyanate are obtained as yellow precipitates.

The nitrate forms yellow needles, sparingly soluble in cold water, still less in water acidulated with nitric acid.

The neutral oxalate is a crystalline precipitate. The acid oxalate, $C^{12}H^{12}N^2O.C^2H^2O^4$. H^2O forms radiating needles, containing 5.67 per cent. water, which they give off at $100^{\circ} C$.

The neutral sulphate, $2C^{12}H^{12}N^2O.H^2SO^4.2H^2O$, obtained by dissolving an excess of harmine in dilute sulphuric acid and evaporating, forms concentrically grouped needles containing 6.57 per cent. of water. The acid sulphate, $C^{12}H^{12}N^2O.H^2SO^4$, obtained by adding excess of sulphuric acid to a solution of harmaline in boiling alcohol, forms crystals similar in form, but anhydrous.

The sulphocyanate is obtained by precipitation in yellow needles.

Substitution-derivatives of Harmine.

Dichlorharmine. $C^{12}H^{10}Cl^2N^2O$. (Fritzsche, Petersb. Acad. Bull. v. 12).—Produced by the action of hypochlorous acid on harmine. To prepare it, a very dilute solution (containing $1\frac{1}{2}$ to 2 per cent.) of hydrochlorate of harmine is heated to boiling; 10 to 15 per cent. of strong hydrochloric acid is then added to it, and afterwards, the solution being still kept boiling, chlorate of potassium is thrown in, by small quantities at a time, until the brownish red colour which the liquid assumes at first, is changed to pure yellow. The ebullition is maintained a little while longer, so as to destroy a coloured product; the solution is then allowed to cool; and the crystals of dichlorharmine which separate are washed with dilute hydrochloric acid, or with solution of chloride of sodium, and purified by crystallisation from alcohol, or re-solution in water and precipitation by hydrochloric or nitric acid. On redissolving the hydrochlorate of dichlorharmine in a large quantity of hot water, and boiling it for several hours with a great excess of soda-ley, crystals of dichlorharmine are deposited, which must be recrystallised from alcohol.

Dichlorharmine forms soft white needles, insoluble in cold, very slightly soluble in boiling water. It dissolves in alcohol, ether, benzene, and sulphide of carbon, much more easily when heated than in the cold.

Dichlorharmine forms a compound with iodine, corresponding to di-iodide of nitro-harmine (p. 11), and containing 46.45 per cent. iodine.

With acids it forms crystallisable salts, which, like those of harmine, are very difficultly soluble in water containing acids or salts. The mono-acid (neutral) salts are decomposed to a certain extent, with separation of dichlorharmine, when a large quantity of water is poured upon them. Ammonia throws down dichlorharmine from their solutions, as an amorphous, colourless jelly; solution of soda acts in the same way, but in this case the precipitate becomes crystalline when long boiled with a great excess of soda solution. Dichlorharmine displaces a trace of ammonia from a boiling solution of sal-ammoniac; part of the dissolved dichlorharmine separates out on cooling, but the rest only on addition of ammonia to the filtrate.

Hydrochlorate of Dichlorharmine is obtained by dissolving the base in water containing hydrochloric acid, and precipitating by excess of hydrochloric acid. It crystallises from water in needles, from alcohol in larger crystals; chloride of sodium separates it from its solution in the form of a jelly which turns to needle-shaped crystals. It contains 2 at. water, which it gives off at 100° C., but reabsorbs 1 at. if exposed to moist air. When heated much above 100° , it becomes yellow and loses hydrochloric acid; between 180° and 200° it melts to a brown-yellow liquid, which dissolves in water and contains a newly formed base.

The *nitrate* is precipitated as a jelly, which afterwards changes to crystalline needles, by addition of excess of nitric acid to a solution of dichlorharmine in water containing nitric acid. It is anhydrous and less soluble in water than the hydrochlorate. When melted it gives off acid vapours and yields a brown mass, from the solution of which in aqueous alkalis acids throw down brown flocks.

Nitrate of dichlorharmine precipitates from *oxide of argentammonium*, a pale greenish jelly, containing silver. When hydrochlorate of dichlorharmine is mixed with nitrate of silver, a jelly is precipitated, without formation of chloride of silver, but, on adding nitric acid to the jelly, chloride of silver is formed.

Nitroharmine. $C^{12}H^{11}(NO^2)N^2O$. *Nitroharmidine*. (Fritzsche, Petersb. Acad. Bull. xii. 33, 225; Ann. Ch. Pharm. lxxviii. 328; xcii. 330.)—Produced by the action of nitric acid on harmaline or nitroharmaline. It does not appear to be formed by the action of nitric acid on harmine. To prepare it, 1 pt. of harmaline is dissolved in 2 pts. of water, and the requisite quantity of acetic acid, and to the solution 12 pts. of nitric acid of specific gravity 1.40 are added in a thin stream. A violent evolution of red vapours takes place; and if the liquid be kept in a state of ebullition till the action is over, then cooled quickly, and treated with excess of caustic alkali, nitroharmine is deposited in the form of a deep yellow precipitate, while a resinous matter, formed at the same time, remains in solution. The product is purified by converting it into a hydrochlorate, and decomposing that salt with ammonia. Nitroharmine forms yellow needles, tasteless, sparingly soluble in cold, more soluble in boiling water. From boiling alcohol it separates in deep yellow octahedrons, which soon change into needles. Ether dissolves it but sparingly. It dissolves in rock-oil and in coal-tar naphtha. Heated with a solution of sal-ammoniac, it slowly eliminates ammonia. It unites with iodine, but is decomposed by chlorine and bromine.

The salts of nitroharmine have a slightly bitter taste, and mostly crystallise in yellow needles. The *hydrochlorate*, $C^{12}H^{11}(NO^2)N^2O.HCl + 2H^2O$, obtained by adding hydrochloric acid in excess to a solution of the base in acetic acid, or in hot water acidulated with a few drops of hydrochloric acid, crystallises in slender needles, which may be purified by recrystallisation from boiling alcohol. The *chloroplatinate* is soluble and crystallises in needles.

The *neutral nitrate* is but sparingly soluble in water, still less in dilute nitric acid: hence nitric acid gradually precipitates nitroharmine from the solutions of its other salts. It crystallises in yellow needles, which, if left in the acid liquor, gradually change to granular and rhomboidal crystals of a deeper yellow colour. There appears also to be a *basic nitrate*, somewhat more soluble in water.

The hydrocyanate does not appear to exist by itself, but a double compound of *hydrocyanate of nitroharmine and mercuric cyanide* is deposited in granular crystals when cyanide of mercury is added to a boiling solution of acetate of nitroharmine and the liquid left to cool.

The *hydroferrocyanate* and *hydroferricyanate* are obtained by precipitation, the former in brown microscopic prisms, the latter in yellow grains. The *sulphocyanate* forms nearly colourless needles, sparingly soluble in cold, more soluble in hot water.

Di-iodide of Nitroharmine, $C^{12}H^{11}(NO^2)N^2O.I_2$, separates in yellowish brown agglomerated microscopic needles, on mixing the boiling solutions of iodine and nitroharmine in alcohol or coal-tar naphtha. It is nearly insoluble at ordinary temperatures in water, alcohol, ether, and coal-tar naphtha; slightly soluble at higher temperatures. It may be heated to 100° C. without decomposition. It is resolved into iodine and nitroharmine by boiling with alcohol, and more quickly with dilute sulphuric acid. It appears to form a crystalline salt with hydrochloric acid. It dissolves also in acetic and hydrocyanic acids, and these solutions yield crystalline compounds.

BROMONITROHARMINE. $C^{12}H^{11}BrN^2O^3 = C^{12}H^{11}Br(NO^2)N^2O$. *Bromonitroharmidine*.—When bromine-water is added to a very dilute solution of a salt of nitroharmine, the smell of bromine disappears immediately, and on addition of ammonia, bromonitroharmine is precipitated and may be purified by recrystallisation from alcohol. It resembles chloronitroharmine, forms salts with acids, and unites with bromine and iodine.

The *tribromide*, $C^{12}H^{11}Br^3N^2O^3.Br^2$, is formed on adding bromine-water in moderate excess to a solution of bromonitroharmine in weak alcohol, and separates on cooling and stirring the liquid, in yellow microscopic needles.

CHLORONITROHARMINE. $C^{12}H^{10}ClN^2O^3 = C^{12}H^{10}Cl(NO^2)_2N^2O$. *Chloronitroharminine*. (Fritzsche, Petersb. Acad. Bull. xii. 225; Ann. Ch. Pharm. xcii. 330).—Produced by the action of chlorine on nitroharminine, or of nitromuriatic acid on harmaline.

Preparation.—1. When chlorine-water is added to aqueous hydrochlorate or acetate of nitroharminine, or chlorine gas is passed into the solution till the smell of chlorine becomes permanent, chloronitroharminine separates in the form of a jelly. If the action of the chlorine be too long continued, a yellow resin is produced. The mixture is heated to boiling, and the resulting solution is precipitated by the cautious addition of ammonia, drop by drop, with constant stirring. A more or less crystalline product is thus obtained, whereas, from cold solutions, a jelly is precipitated, which is difficult to wash.—2. A solution of 1 pt. harmaline in 2 pts. water and the requisite quantity of acetic acid, is poured into 12 pts. of boiling nitric acid of specific gravity 1.40, and 2 pts. of fuming hydrochloric acid are added to the mixture; or the harmaline solution is poured into the boiling mixture of the two acids. The liquid becomes red-brown, froths up strongly, and evolves a volatile substance which attacks the eyes, but deposits nothing but resin on cooling. In order to separate the dissolved chloronitroharminine, a solution of sal-ammoniac, cooled by placing lumps of ice in it, is poured into the liquid; this is diluted with about an equal bulk of water; and caustic soda is then added, until it smells strongly of ammonia, whereby an abundant precipitate of impure chloronitroharminine is thrown down. The product is washed with dilute hydrochloric acid and heated with water; the solution freed by filtration from undissolved resin, and precipitated by gradual addition of ammonia; and the precipitate purified by crystallisation from hot alcohol. The crude chloronitroharminine may also be dissolved in boiling water, with addition of just the necessary quantity of nitric acid, and precipitated as nitrate from the cooled filtrate by addition of nitric acid in excess; this salt, after being washed, may be dissolved in hot water, and pure chloronitroharminine precipitated from the boiling filtered solution by means of caustic ammonia.

Chloronitroharminine forms a bright yellow, brittle mass, composed of very fine needles, which cannot be distinctly perceived, even under a magnifying power of 300. Ammonia precipitates it from cold solutions, as an almost transparent, deep yellow, very bulky jelly, which shrinks very much on drying. It is tasteless in the solid state, slightly bitter and rough in solution. It gives off 11.4 per cent. water at 100° C. (2 at. = 10.98 per cent.), and becomes orange-yellow. It dissolves but slightly in cold water; more abundantly in boiling water, forming a yellow solution; with moderate facility in boiling alcohol; slightly in ether; abundantly in boiling coal-tar naphtha, and in rock-oil.

Chloronitroharminine dried at 100° C. leaves a reddish-yellow residue when alcohol or coal-tar naphtha is poured upon it, but dissolves completely when boiled with dilute nitric acid.—*Solution of iodine* converts it into di-iodide of chloronitroharminine. When mixed with solution of iodide of potassium, and then with nitric acid, it deposits a deep blue precipitate.

Chloronitroharminine unites with acids, forming yellow salts. When boiled with solution of sal-ammoniac, it slowly displaces a trace of ammonia.

The *hydrochlorate*, obtained by adding hydrochloric acid in excess to a solution of the base in hot alcohol, forms fine capillary crystals moderately soluble in water. It is precipitated from its aqueous solution by a large excess of hydrochloric acid, as a yellow jelly; by chloride of sodium in white flocks. On mixing the hot alcoholic solutions of this salt and tetrachloride of platinum, *chloroplatinate of chloronitroharminine*, $2(C^{12}H^{10}ClN^2O^3.HCl)PtCl_4$, is deposited on cooling in fine yellow prisms.

The *nitrate* forms stellate groups of slender needles. A perfectly neutral solution of this salt mixed with ammonio-nitrate of silver, yields a precipitate consisting of a compound of chloronitroharminine with nitrate of silver.

Sulphates.—A solution of chloronitroharminine in warm alcohol containing sulphuric acid deposits the *neutral sulphate* on cooling, in spherical groups of capillary needles. From a hot aqueous solution the salt is deposited in light yellow gelatinous flocks. The *acid sulphate* separates slowly in needles from a hot concentrated alcoholic solution of the neutral salt mixed with excess of sulphuric acid.

Di-iodide of Chloronitroharminine, $C^{12}H^{10}ClN^2O^3.I_2$, separates in slender needles resembling di-iodide of nitroharminine, from a mixture of the hot solutions of iodine and chloronitroharminine in alcohol or in coal-tar naphtha. It is more soluble in alcohol than the di-iodide of nitroharminine, and dissolves easily in warm alcoholic hydrocyanic acid, separating in rounded granules on cooling.

HARMOTOME. This term includes two isomorphous mineral species, identical in crystalline form, viz.: *Baryta-harmotome*, and *Lime-harmotome*.

Baryta-harmotome, also called *Cross-stone*, *Stauroilite*, *Andrealite*, *Andreabergolite*, *Moruenite*.—Crystals belonging to the trimetric system, being generally

rectangular prisms with four-sided summits set upon the lateral edges. Ordinary combination, $P. \infty P_{\infty}. \infty P_{\infty}. P_{\infty}$ (like fig. 528), often without P_{∞} . Ratio of the axes: $a:b:c = 0.9781:1:0.684$. For P , the angle of the terminal edges in the brachydiagonal section = $121^{\circ} 28'$, in the macrodiagonal section, = $120^{\circ} 1'$; and the angle of the lateral edges (in a section parallel to the base) is $88^{\circ} 44'$. Cleavage most distinct parallel to ∞P_{∞} . The crystals are generally twins, inserted crosswise into

Fig. 528.

Fig. 529.

one another, as shown in fig. 529, in which the faces ∞P_{∞} are denoted by n , and ∞P_{∞} by m . For distinctness, the faces of one of the crystals are shaded (Kopp, *Krystallographie*, p. 263). Rarely massive. Specific gravity = 2.39 to 2.498. Hardness = 4.6. Lustre vitreous. Colour white, passing into grey, yellow, red, or brown. Streak white. Subtransparent to translucent. Fracture uneven, imperfectly conchoidal. Brittle. Melts without intumescence before the blowpipe, forming a white globule. When finely pounded it is decomposed completely, though with difficulty, by hydrochloric acid.

The following are analyses of baryta-harmotome:— a , from Oberstein; b , from Strontian (Köhler, Pogg. Ann. xxxvii. 561); c , from Strontian (Connell, Ed. N. Phil. J., 1832, July, p. 33); d , *Morvenite*, from the same (Damour, Ann. Min. [4] ix. 339); e , from Andreasberg; f , from Strontian (Rammelsberg, *Mineralchemie*, p. 821).

	a .	b .	c .	d .	e .	f .
SiO_2	46.65	46.10	47.04	47.60	48.74	48.49
Al_2O_3	16.64	16.41	15.24	16.39	17.65	16.35
Fe_2O_3			0.24	0.65		
BaO	19.12	20.81	20.85	20.86	19.22	20.08
CaO	1.10	0.63	0.10			
K_2O			1.72	1.55		2.07
Na_2O	1.10	0.90				
H_2O	15.25	15.11	14.92	14.16	14.66	13.00
	99.76	99.96	100.11	101.21	100.27	99.99

These analyses agree pretty nearly with the formula $\text{BaO}.\text{Al}_2\text{O}_3.5\text{SiO}_2 + 5\text{H}_2\text{O}$ (Rammelsberg), which requires 46.65 per cent. silica, 15.58 alumina, 23.79 baryta, and 14.00 water (the other constituents being regarded as adventitious), and by substituting $\text{al} = \frac{1}{2} \text{Al}$, and regarding 2 at. hydrogen as basic, this formula becomes $(\text{Ba}.\text{al}^{\frac{1}{2}}\text{H})\text{SiO}_3.4\text{H}_2\text{O}$, which is reducible to $\text{M}^2\text{SiO}_3.\frac{1}{2}\text{H}_2\text{O}$, the formula of a metasilicate.

The composition of the mineral has, however, been hitherto generally represented by the formula $\text{BaO}.\text{Al}_2\text{O}_3.3\text{SiO}_2 + 6\text{H}_2\text{O}$, or $2(\text{BaO}.\text{Al}_2\text{O}_3).9\text{SiO}_2 + 10\text{H}_2\text{O}$; but this formula gives only 44 per cent. silica, which is considerably below that of all analyses which have been made of the mineral.

Baryta-harmotome occurs at Oberstein in Zweibrücken, in siliceous geodes; at Andreasberg in the Hartz; at Strontian in Argyleshire; in Norway on gneiss; and in simple crystals with analcime, in the amygdaloid of Dumbartonshire. The variety called *Morvenite*, distinguished by the greater brilliancy of its crystals, is also found at Strontian. (Dana, ii. 323; Gm. iii. 446.)

Lime-harmotome, or *Potash-harmotome*, *Phillipsite*, *Christianite*.—Isomorphous with the preceding, occurring also in twins. Specific gravity = 2.2 to 2.213. Hardness = 4 to 4.6. Lustre vitreous. Colour white, sometimes reddish. Streak uncoloured. Translucent—opaque. Before the blowpipe it intumesces slightly, gives off water, and melts to a translucent glass. Hydrochloric acid decomposes it easily, with separation of gelatinous silica.

The following are analyses of lime-harmotome:— a , from Annerode near Giessen

HARRINGTONITE—HAUYNE.

(Wernerkink, *Gilb. Ann.* lxxvi. 171, 336); *b*, from Stempel near Marburg (L. Gmelin *Leonh. Zeitschr. f. Min.* 1826, i. 8); *c*, from the same; *d*, from Habichtswalde, near Cassel (Köhler, *Pogg. Ann.* xxxvii. 561); *e*, from the Giant's Causeway (Connell *Edinb. Phil. J.* xxxv. 373).

	<i>a</i> .	<i>b</i> .	<i>c</i> .	<i>d</i> .	<i>e</i> .
SiO ₂	48.36	48.51	50.44	48.22	47.35
Al ₂ O ₃	20.00	21.76	21.78	23.33	21.80
Fe ₂ O ₃	0.41	0.99	3.70
CaO	5.91	6.26	6.50	7.22	4.85
K ₂ O	6.41	6.33	3.95	3.89	5.55
BaO	0.46	Na ₂ O
H ₂ O	17.09	17.23	16.81	17.56	16.96
	98.64	101.08	99.48	100.22	100.21

The composition of lime-harmotome has been represented by several different formulæ. The quantities of calcium and potassium contained in it are somewhat variable, but its composition appears to be, for the most part, that which is expressed by the formula $2\text{CaO} \cdot 3\text{Al}_2\text{O}_3 \cdot 12\text{SiO}_2 + 15\text{H}_2\text{O}$ (50.2 per cent. SiO₂, 21.3 Al₂O₃, 7.0 CaO, 6.5 K₂O, and 15.0 water), which, by substitution of *al* for $\frac{3}{2}\text{Al}$, as before, becomes $(\text{Ca}^2\text{K}^2\text{al}^3)\text{Si}^{12}\text{O}^{36} \cdot 15\text{H}_2\text{O}$, and is reducible to the general formula $\text{M}^2\text{Si}^{12}\text{O}^{36} \cdot 15\text{H}_2\text{O}$, or $\text{M}^2\text{SiO}_3 \cdot 4\text{H}_2\text{O}$, which is that of a metasilicate, and differs from the general formula of baryta-harmotome only in its amount of water.

Lime-harmotome occurs in the amygdaloid of the Giant's Causeway, in large transparent crystals. It is also found in Iceland; among the Vesuvian lavas; in sheaf-like aggregations at Capo di Bove, near Rome; and in long radiating crystals at Acì Castello in Sicily, and other localities. (Dana, ii. 324; Rammelsberg, *Mineralchemie*, p. 811.)

HARRINGTONITE. See NATROLITE.

HARRISITE. A variety of cuprous sulphide, Cu₂S, occurring in the Canton mine, Georgia, in crystals belonging to the regular system, and cleaving parallel to the faces of a cube (Shepard, *Jahresb. f. Chem.* 1857, p. 656). Genth (*Sill. Am. J.* [2] xii. 449) regards it as a pseudomorph of copper-glance after galena.

HARTIN. C¹⁰H¹⁰O. *Psatyrin*.—A fossil resin resembling hartite. Massive, but crystallises from rock-oil in needles belonging to the trimetric system. White; destitute of taste and smell. Pulverises between the fingers. Melts at 210° C., and distils at 260°. Slightly soluble in ether. Gives, by analysis, 78.06 per cent. C, 10.92 H, and 11.02 O. It is found in the lignite of Oberhart, Austria. (Schrötter, *Pogg. Ann.* liv. 45.)

HARTITE. C¹⁰H⁸.—Another fossil resin from the lignite of Oberhart. Oblique prisms belonging to the monoclinic system. Cleavage only in traces. Specific gravity 1.046. Hardness = 1. White, with a somewhat greasy lustre. Translucent. Brittle. Melts at 74° C., and distils at higher temperatures. Dissolves easily in ether, less readily in alcohol, and crystallises from each solution by evaporation (Haidinger, *Pogg. Ann.* liv. 261). Gives, by analysis, 87.47 per cent. C and 12.05 H. (Schrötter.)

HATCHETTIN or *Mineral Tallow*, a fossil resin occurring in the coal measures of Glamorganshire; crystallised and amorphous in thin laminæ; like wax or spermaceti in consistence. Specific gravity 0.916 at 15.5° C. White and transparent, with nacreous lustre, but becomes black and opaque by long exposure. Greasy to the touch. Melts at 46° C. Distils without change when cautiously heated. Dissolves sparingly in boiling alcohol, and separates on cooling; sparingly also in cold ether, more easily in hot ether. Gives, by analysis, 85.9 per cent. carbon and 14.6 hydrogen (= 100.6). (Johnston, *Phil. Mag.* xii. 338.)

A similar substance is found at Rossitz, in Moravia. Specific gravity, 0.892. Hardness = 1. A variety from Loch Fyne, near Inverness, melts at 47° C. Another allied mineral from Merthyr Tydvil, melts at 76.6° C.

HAUSERITE. Native disulphide of manganese, MnS₂, found at Kalinka, in Hungary. (See MANGANESE, SULPHIDES OF.)

HAUSMANNITE. Native manganoso-manganic oxide, MnO.Mn₂O₃, or Mn³O₄, found at Ilmenau in Thuringia, at Ilfeld in the Hartz, and one or two other localities. (See MANGANESE, OXIDES OF.)

HAUYNE. A mineral consisting of silicate of aluminium, sodium, and calcium, with sulphate of calcium, occurring in the lavas of Vesuvius, on Somma, and on the basalt of Niedermendig, near Andernach, on the Rhine. It crystallises in rhombic dodecahedrons, with cleavage parallel to the faces, sometimes distinct; commonly in

crystalline grains. Specific gravity 2·4 to 2·5. Hardness 5·5. Lustre varying from vitreous to greasy. Colour bright blue, occasionally asparagus-green. Streak bluish-white. Subtransparent to translucent. Fracture flat-conchoidal to uneven. Before the blowpipe it decrepitates and fuses slowly to an opaque white or greenish-blue glass. Effervesces with borax, and forms a glass which is yellow when cold. The finely pulverised mineral dissolves completely in hydrochloric acid, the liquid depositing gelatinous silica when evaporated.

The composition of hauyne has been variously stated. From the analysis of the mineral from Mont Albano, Whitney (Pogg. Ann. lxx. 431) deduced the formula $3(\text{Na}^2\text{O} \cdot \text{Al}^2\text{O}^3 \cdot 2\text{SiO}^2) + 2(\text{CaO} \cdot \text{SO}^4)$, or $3(\text{Naal}^3)\text{SiO}^4 \cdot \text{CaSO}^4$; from that of hauyne from Somma, Rammelsberg calculates the formula $2(\text{Na}^2\text{O} \cdot \text{Al}^2\text{O}^3 \cdot 2\text{SiO}^2) + (\text{CaO} \cdot \text{SO}^4)$, or $4(\text{Naal}^3)\text{SiO}^4 \cdot \text{CaSO}^4$. The following table exhibits the numbers deduced from these formulae, together with the results of the corresponding analyses:

Mont Albano.	(Whitney.)	Somma.	(Rammelsberg.)
	Calc.	Analysis.	Calc. Analysis.
6SiO ² . .	32·20	32·48	4SiO ² . . 34·29 34·06
2SO ³ . .	14·31	12·98	SO ³ . . 11·43 11·25
3Al ² O ³ . .	26·83	27·75	2Al ² O ³ . . 28·57 27·64
2CaO . .	10·02	9·96	CaO . . 8·00 10·60
3Na ² O . .	16·64	14·24	2Na ² O . . 17·71 11·79
K ² O	2·40	K ² O . . 4·96
	100·00	99·81	100·00 100·30

According to these formulae, hauyne is allied to nosean, sodalite, and ittnerite, all of which are silicates of the form $\text{M}^2\text{O} \cdot \text{Al}^2\text{O}^3 \cdot 2\text{SiO}^2$, easily reducible to an orthosilicate, $(\text{Mal}^3)\text{SiO}^4$ [$\text{al}^3 = \frac{1}{3}\text{Al} = 9 \cdot 1$]. The formulae of these minerals are in fact:

Hauyne from Niedermendig contains, according to Whitney, 33·90 SiO²; 12·01 SO³; 28·07 Al²O³; 7·50 CaO and 19·28 Na²O = 100·73, and is composed of 1 molecule of nosean and 2 molecules of the Albano hauyne. The blue colour of hauyne appears to arise from a small quantity of a metallic sulphide similar to that which gives the colour to ultramarine. All specimens of hauyne, when treated with hydrochloric acid, give off at least a trace of sulphydric acid. (Dana, ii. 230; Handw. J. Chem. iii. 832.)

HAUYNOPHYR. A name applied to the lava of Melfi on the Vulture. This lava is black or brown, and contains hauyne of various colours, and augite in slender needles. It is strongly attacked by acids. When it is treated with an equal weight of a mixture of 2 pts. hydrochloric acid and 1 pt. water, 30·2 per cent. remains undecomposed, consisting mainly of augite containing a large proportion of iron. The hauyne amounts to 22 per cent. (Rammelsberg, Jahresb. 1860, p. 807.)

HAYDENITE. Yellowish chabasite, from Jones's Falls, Maryland. (See CHABASITE.)

HAYESINE. (Syn. with BOROCALCITE.)

HAYTORITE. Pseudomorphous quartz, from the mine of magnetic iron at Hay Tor, in Devonshire. It has the form of datholite, and contains 98·5 per cent. silica and 0·2 ferric oxide.

HEAT. The word Heat is used in common language, both as the name of a particular kind of sensation, and to denote that condition of matter in which it is capable of producing this sensation in us. Any influence whereby external objects are rendered *hot*, or capable of exciting the sensation of heat, causes them at the same time to undergo other changes, which, being independent of the varying condition of our bodies, afford much more certain and more exact indications as to the condition of heat than is furnished by the sense of touch. Indeed, strictly speaking, our sensations bear no direct testimony with regard to the absolute degree of hotness of external objects, but rather to the fact of their imparting heat to our bodies, or removing heat from them. When these effects are produced in a moderate degree, we experience the sensations of heat and cold respectively; when the loss or gain of heat by our bodies is more rapid, it no longer produces any sensation to which a definite name can be assigned, but simply a feeling of pain; and the very rapid passage of heat either into or out of our bodies, causes a wound which is of the same kind in either case. The direct evidence of our senses with respect to the heat of external objects is therefore confined within comparatively narrow limits. Moreover, it is not always of the same

kind, even with respect to bodies in the same condition, as is easily proved by putting one hand into hot water and the other into cold water, and after a short time removing both and plunging them into lukewarm water, which will then feel cold to the hand which was previously in hot water, but warm to the other.

The most important of the other properties of the condition of matter constituting heat, besides producing the sensation denoted by the same word, are the following:

1. Heat imparted to any body raises its *temperature*, that is, it not only causes the body to produce the sensation of heat in a more marked degree, but its tendency to impart the property of so doing—in other words, its tendency to impart heat—to other bodies is increased.

2. It modifies the relations between the density and elasticity of substances, the general law being, that the hotter a body is, the less is its *elasticity of figure*, or tendency to preserve a definite form and arrangement of parts, and the greater is its *elasticity of volume*, or tendency, if solid or liquid, to preserve a definite volume, and if gaseous to expand indefinitely.

3. Heat causes solid bodies to become liquid, and liquid bodies to become gaseous. The amount of heat required to produce these changes in any body varies with its special nature and with other circumstances, but they take place always and without exception, in the same order; that is, the solid state always corresponds to the lowest degree of heat, the gaseous state to the highest degree, and the liquid state to an intermediate degree.

4. Heat causes changes in the chemical composition of bodies, and also in their electrical, magnetic, and optical properties.

The capacity of heat thus to effect changes characterises it as a form of energy, capable of being measured and expressed as a quantity, in terms of one or other of the directly measurable effects which it produces. When thus expressed as a quantity, the condition of heat is found to be subject, like other forms of energy (mechanical energy, for example), to a law of conservation; that is, if in any system of bodies, no heat is expended or produced through changes other than changes of temperature, then the total quantity of heat in the system cannot be changed by the mutual actions of the bodies, but what one loses another gains; and if there are changes other than changes of temperature, then if by those changes the total heat of the system is changed in amount, that change is compensated exactly by an opposite change in some other form of energy. (See Rankine, *A Manual of the Steam Engine and other Prime Movers*, ed. 1861, § 196, pp. 224, 225.)

Hence it follows that heat may be produced by the reversal of its effects: as, for instance, by the conversion of a liquid body into a solid, or of a gas into a liquid; by the compression of a gas, so as to make it occupy a smaller bulk; by the transmission, through the point of junction of two dissimilar metals, of an electric current opposite in direction to that which would be produced by the application of heat at the same point; by the union of oxygen and hydrogen so as to form water, the effect of heat upon water being to resolve it into oxygen and hydrogen gases, &c. &c.

Similarly, heat may be caused to disappear—in other words, cold may be produced—when a change, such as heat is capable of producing, is brought about by other means: as when a solid is liquefied by solution, or when a liquid is vaporised; when a gas is expanded; when, through the point of junction of two dissimilar metals, an electric current is transmitted in the same direction as that which would be produced by the application of heat at the same point, &c. &c.

The reversal of any of its effects does not, however, necessarily and under all circumstances, cause heat to be produced: instead of it an equivalent of some other form of energy may be generated; thus, in Grove's gas-battery (ELECTRICITY, ii. 430) the primary result of the combination of oxygen and hydrogen gases is not the evolution of the quantity of heat which would be required to decompose the water formed, but of an equivalent amount of electrical energy. Neither is the disappearance of heat always a necessary consequence of the production, by other means, of changes such as might be brought about by the action of heat itself: for example, in the decomposition of water by the electric current, there is no disappearance of heat, but there is expended an amount of electrical energy, equivalent to the heat which would otherwise have been required to effect the same decomposition. Further, the most familiar and most practically important processes by which heat is produced, such as combustion, friction, and percussion, are not such as can be directly reversed by the action of heat.

On the other hand, heat being a form of energy, every source or store of energy may be considered as, directly or indirectly, a source of heat. The sources of heat available to man may therefore be classified as follows:

1. The *Sun*. According to Pouillet, the total heating effect of the sun's rays falling perpendicularly during 1 minute upon one square centimetre of the earth's surface, including the portion absorbed by the atmosphere, amounts to 1·7633 times the quan-

tity of heat required to raise the temperature of 1 grm. of water 1 degree centigrade, or to 1.7633 gramme-degrees. The mean heating effect on each square centimetre of the earth's surface, for every minute during 24 hours, is therefore = 0.4408 gramme-degree; or the total effect during one year is 232,000 gramme-degrees.* According to these data, the whole quantity of heat received by the earth from the sun in one year would be sufficient to melt a layer of ice over the whole surface of the earth of 32 metres (or 36 yards) in thickness. The whole of this supply of heat (which is less than the 2,300 millionth part of the total heat emitted by the sun) is not, however, directly available as such. According to Pouillet, nearly one-half is absorbed by the atmosphere, and of the heat so absorbed a considerable proportion goes to supply the mechanical energy of air in motion, or wind, and thus ceases, at least for a time, to exist as heat. Another portion is expended in causing the evaporation of water from the ocean and from the moist surface of the land: as will be shown in the sequel, a great part of this heat reappears when the evaporated water is returned to the earth as rain or otherwise; but the remainder is retained in a modified form in water which is deposited at a higher level than that from which it was evaporated, and so furnishes the mechanical energy, or water-power, of rivers and falling water. Still another portion of the total energy of the sun's rays is absorbed by growing plants, enabling them to convert carbonic acid and water into woody fibre: our ordinary modes of obtaining artificial heat—namely, by the combustion of wood and coal—are processes in which the heat thus absorbed is liberated by the reversal of the chemical changes which take place in plants while living. The warmth and mechanical force of animals are also derived, through the vegetable food which they consume, from the same source, whence are likewise derived, directly or indirectly, our chief supplies of electrical energy.

2. The *internal heat* of the earth. This we may consider as of two kinds: the actual heat, of which there is evidence in hot springs and volcanoes, as well as in the comparatively high temperature of deep mines; and the potential heat stored up in combustible minerals. By far the most important store of potential heat, namely, coal, represents, as we have already seen, a portion of the energy of the sun's rays which reached the earth during the growth of the plants from which it has been formed.

3. The *tidal wave*, caused by the earth's diurnal rotation, combined with the mutual motions of the earth, moon, and sun, is a source of heat which might be rendered practically available, by causing water-wheels, driven by the tidal waters, to generate heat by friction.

4. The *fall of meteoric stones* is a source of heat, practically insignificant, so far as the earth is concerned, but which has been supposed to play an important part in the maintenance of the heat of the sun.

(On the possible sources of energy available to man, see W. Thomson, Phil. Mag. [4] iv. 259.)

ON THE MEASUREMENT OF HEAT.

Before we can proceed further in the study of the properties and effects of heat, it is necessary that we should have some means of measuring and comparing different quantities of it. As already stated, quantities of heat may be expressed in terms of any of its directly measurable effects; but that one which is usually the most easily and accurately observable is alteration of temperature, and hence quantities of heat are commonly defined by stating the extent to which they are capable of altering the temperature of a known weight (such as 1 grm.) of a known substance (for instance, water). Accordingly, the unit of heat which will be employed in this article is the quantity, already spoken of as a gramme-degree, which is required to raise the temperature of 1 gramme of water from 0° to 1° centigrade. Heat is, however, capable of causing other alterations in the condition of bodies, such as the liquefaction of solid substances, without at the same time causing any alteration in their temperature; hence, another way in which a quantity of heat may be defined is by stating the amount of some known solid (ice, for example) which it is capable of liquefying, without causing any change in its temperature. Quantities of heat can also be expressed in terms of the mechanical or electrical energy to which they are equivalent; but as neither motion nor electricity can be generated by heat without the simultaneous expenditure of a greater or less quantity in causing a rise of

* The total quantity of heat received in a minute by a hemisphere of the earth's surface is the same as that which would fall on the great circle forming the projection of that hemisphere—that is to say, $1.7633 \pi R^2$ gramme-degrees (the radius being measured in centimetres). Hence, supposing the heat to be uniformly distributed over this surface, the quantity received in a minute by each square centimetre of surface is

$$\frac{1.7633 \pi R^2}{4 \pi R^2} = 0.4408 \text{ gramme-degrees;}$$

and as the earth performs its rotation in 24 hours and the year contains 365 days, it follows that the mean amount of heat received in a year by each square centimetre of the earth's surface is $0.4408 \times 60 \times 24 \times 365$, or in round numbers, 232,000 gramme-degrees.

temperature in material substances, and since, therefore, the whole of a given quantity can never be transformed without loss into these other forms of energy, they cannot serve for the direct measurement of heat. And in fact, whatever mode of measurement is adopted, it is always necessary to take account of the temperature of the bodies whose heat is to be estimated, and of those which are influenced by them, in order that we may know the extent to which their temperature is altered; or on the other hand, that we may convince ourselves that no such alteration takes place. The measurement of temperature, or *thermometry*, is therefore a necessary preliminary to the measurement of heat, or *calorimetry*.

Thermometry.—Temperature, or hotness, has already been defined as the tendency of one portion of matter to part with heat to other portions, and has been stated to depend on the quantity of heat which the portion of matter in question contains. For the purpose of defining different temperatures, it is obviously necessary to adopt two standard points, separated by a known and constant interval, which may serve as a measure by which to estimate the interval between any other two temperatures. The standard points usually adopted are the temperature of melting ice, and the temperature of pure water boiling freely under a barometric pressure of 760 millimetres (= 29.92 inches) of mercury (measured at the melting point of ice). When a quantity of mercury is allowed to attain equilibrium of temperature with melting ice, and afterwards with water boiling under the conditions above mentioned, it is found that its bulk in the latter case always exceeds its bulk in the former case by a certain constant amount. The expansion of the mercury is here a measure of the quantity of heat which the boiling water imparted to it after it had come to such a condition that an interchange of heat no longer took place between it and the melting ice; and since, as already observed, the mercury always expands by the same proportion of its bulk at the temperature of melting ice, we may conclude that the quantity of heat which boiling water can impart to a given mass of matter, exceeds that which melting ice can impart to the same mass, by a constant proportion; in other words, that the temperature of boiling water is higher than the temperature of melting ice, and that the interval which separates them is always the same.

It is upon this principle that the use of the mercurial thermometer, and of other instruments in which expansion is employed to indicate temperature, depends. The construction and use of this instrument in its various forms are fully described in the article THERMOMETER, to which the reader is referred. It will be sufficient here to state, that there are in frequent use three different modes of designating the two standard points of temperature, and of subdividing the interval between them: namely, the *centigrade* scale of Celsius employed in this Dictionary, in which the temperature of melting ice is denoted by zero, and the temperature of boiling water by 100; Réaumur's scale, in which the temperature of melting ice is likewise denoted by zero, but that of boiling water by 80; and Fahrenheit's scale, in which the former temperature is marked 32, and the latter 212. The melting point of ice is therefore indicated by any of the following expressions:—

0° C., 0° R., and 32° F.;

and the boiling point of water by any of the following:—

100° C., 80° R., and 212° F.;

accordingly, 100 degrees centigrade are equivalent to 80 degrees Réaumur, and to 180 (= 212 - 32) degrees Fahrenheit, or 5 degrees C. = 4 degrees R. = 9 degrees F. The simplicity of these relations makes it easy, when a temperature is expressed according to any of the three scales, to find an equivalent expression according to either of the other two. (See further the article THERMOMETER.)

Besides the mercurial thermometer, and the spirit thermometer, which is quite similar to it in principle and in the manner in which it is used, there are some other instruments, which are advantageously employed in special cases, for the measurement of temperature, and must therefore be briefly described here.

The Weight-thermometer.—This is a mercurial thermometer which differs from the common one, inasmuch as the expansion of the mercury consequent upon rise of temperature is not read off directly from a divided scale, but is calculated from the weight of mercury which escapes from the instrument. It consists of a cylindrical glass reservoir, closed at one end, and terminated at the other by a short capillary glass tube which is so bent that, when the thermometer is placed in the position in which it is to be used, its open end points vertically downwards. The mode of using it is as follows: The thermometer is weighed while empty, and the reservoir and tube are then completely filled with pure mercury, the whole of the air being carefully expelled by boiling, and allowing the instrument to cool while the open end of the capillary tube dips under the surface of mercury, as in the usual process of filling a barometer or thermometer.

By surrounding the thermometer with melting ice, the instrument itself, as well as the mercury contained in it, is brought to the temperature of 0° C.: when this temperature has been reached by every part of it, the vessel of mercury is removed from under the open end of the capillary tube, and is replaced by a small tared capsule. The ice is now removed, and the outside of the thermometer is carefully dried. As the mercury contained in it returns to the temperature of the air (supposed above 0° C.), it expands, and, consequently, some of it escapes by the capillary tube into the tared capsule. The thermometer, and the capsule containing the mercury which has escaped from it, are now placed together in the balance and weighed; by deducting from the gross weight so obtained the weight of the instrument when empty, and that of the capsule, we obtain the weight W , of the quantity of mercury which fills the thermometer at 0° C.

The instrument is next heated to 100° C., by immersing it in the steam of boiling water, the same precautions being taken as in fixing the boiling point of the ordinary graduated thermometer (see THERMOMETER), and the mercury which escapes is collected in the tared capsule and weighed. Let w be the weight of the whole quantity of mercury which escapes from the thermometer when it is heated from 0° C. to 100° C.; then the coefficient of apparent expansion (see below, *Expansion of Liquids*) of the mercury contained in the thermometer will be

$$\delta = \frac{w}{(W - w)100} \dots \dots \dots (a)$$

Similarly, if w_1 be the weight of mercury which escapes from the thermometer when it is heated to any other temperature, t° , which it is required to determine, we have

$$\delta = \frac{w_1}{(W - w_1)t}; \dots \dots \dots (b)$$

hence we get

$$\frac{w_1}{(W - w_1)t} = \frac{w}{(W - w)100}$$

or—

$$t = \frac{w_1}{w} \cdot \frac{W - w}{W - w_1} \times 100$$

The value of δ , deducible from equation (a), was found by Dulong and Petit (who were the first to employ the weight-thermometer) to be equal to $\frac{1}{24100}$, and by substituting this value in equation (b) the value of t is given independently of the preliminary experiment above described, in which the thermometer is heated to 100° C.; but some uncertainty is thus introduced into the determination, inasmuch as the value of δ varies to a slight extent with the kind of glass of which the thermometer is made.

The weight-thermometer is capable of giving very accurate results when employed to indicate the mean temperature of any considerable space, such as an oil- or water-bath, the temperature of which changes so slowly that it may be assumed, at any given instant, to be the same as that of the thermometer. The size of the instrument depends upon the purpose for which it is to be employed: it is well that it should be of such a length as to reach from one end to the other of the space whose temperature has to be measured, and its capacity ought to be such that the weight of mercury driven out by the smallest rise of temperature which it is required to estimate may be capable of being accurately determined by the balance. An obvious precaution in the use of this instrument is to keep the open end constantly under the surface of the mercury in the capsule, so that no air can enter in consequence of a diminution of temperature.

Regnault's *Air-thermometer* is an instrument which is applicable in the same kind of cases as the weight-thermometer, but has the advantage of giving accurate results at all temperatures below that at which glass softens, whereas the indications of the weight-thermometer are obviously confined to temperatures below the boiling-point of mercury. In construction, it closely resembles the latter instrument, and consists of a cylindrical glass reservoir about 2 centimetres (0.8 inch) in diameter and about 12 or 15 centimetres (4.8 or 6 inches) long, terminated at one end by a narrow glass tube of 1 or 2 millimetres internal diameter, which is bent at a right angle, at a short distance from the end farthest from the reservoir, and drawn out to a fine point. In this state, the instrument is placed in the space of which it is desired to know the temperature; and as soon as the instant arrives for which this temperature is required, the draw-out point is sealed by fusion with the blowpipe, the height of the barometer and its attached thermometer (1. 512) being observed at the same time. The thermometer thus closed is then supported in a vertical position, the narrow tube downwards, and with the bent and sealed extremity of the latter under the surface of mercury; it is next opened by breaking off, under the mercury, as small a piece as possible of the point; and the reservoir is completely surrounded with melting ice. Owing to the contraction of the air in the thermometer as it cools, the mercury rises in the tube and

partially fills the reservoir; and, when the temperature of the thermometer and its contents has been reduced to 0°C ., the height of the surface of the mercury in the reservoir, above that of the mercury outside the instrument, is measured by a cathetometer, the height of the barometer being carefully noted at the same time. The open end of the tube is now closed, while still under mercury, by pressing against it a pellet of soft wax; the ice is removed from the reservoir; and the instrument is taken out of the support, inverted, and weighed together with the mercury contained in it. The thermometer is next completely filled with mercury at 0°C . and weighed again, and lastly the weight of the instrument itself when empty is determined.

Let W be the weight of mercury which completely fills the thermometer, and let w be the difference between this weight and that of the mercury contained in it at the first weighing. These two weights then bear to each other the same proportion as the total capacity of the thermometer at 0°C . bears to the volume occupied—at 0°C . and under the atmospheric pressure diminished by the column of mercury read off by the cathetometer—by the air which the thermometer contained at the moment when it was sealed with the blowpipe. They may therefore be taken to represent respectively these volumes: we shall then have

$$W(1 + \kappa t) = w \frac{h}{H} (1 + \alpha t),$$

$$\text{or—} \quad t = \frac{W - w \frac{h}{H}}{w \frac{h}{H} \alpha - W \kappa};$$

where t is the temperature required;

H , the atmospheric pressure at the moment of sealing the thermometer with the blowpipe;

h , the pressure supported by the air in the thermometer at the moment of closing it with the pellet of wax = the barometric pressure observed at the same moment — the column of mercury read off with the cathetometer;

α , the coefficient of expansion of air for $1^{\circ}\text{C} = 0.00366$;

κ , the coefficient of cubical expansion of the glass of which the thermometer is made = 0.0000305 , between 0° and 300°C ., for common glass, and = 0.0000233 for crystal-glass from Choisy-le-Roi. (Regnault.)

(For the derivation of the above formula, see the section *Expansion of Gases* in this article; for further details of the air-thermometer, see Regnault, *Cours élémentaire de Chimie*, éd. 1864, iv. 64.)

Dewille and Troost's iodine-pyrometer.—For the measurement of temperatures above that at which glass softens, Dewille and Troost employ a method which depends on essentially the same principles as the use of the air-thermometer, although the mode of experimenting differs considerably. Their apparatus consists of a globular flask of Bayeux porcelain of 280 or 300 c.c. capacity, with a neck 11 centimetres long and 4 mm. in internal diameter. A quantity of iodine is put into the flask, and the neck is nearly closed by a small plug of porcelain which lies loosely in the opening. When the flask is now exposed to a high temperature, the iodine is vaporised and the greater part escapes by the neck, driving out at the same time nearly the whole of the air. After the flask has been exposed for about twenty minutes to the temperature that is to be measured, the flame of an oxy-hydrogen blowpipe is allowed to play for an instant upon the porcelain plug lying in the neck: the plug is thus melted and closes the flask hermetically. When cold, the flask is cleaned and carefully weighed; the end of the neck is broken under boiled water or mercury, and the flask is weighed, together with the water or mercury which enters; it is then completely filled with water or mercury and weighed again; lastly, the flask is weighed when empty. From the weights thus obtained it is easy to calculate the capacity of the flask, and the volume of air which the iodine-vapour has failed to expel: the first weighing gives directly the excess of the weight of the flask and iodine-vapour over that of the empty flask. The observations which require to be made in each experiment are the following:—

Temperature of the balance	= t°
Atmospheric pressure	= h mm.
Excess of weight of flask after being heated and sealed full of iodine-vapour over weight of flask filled with air previous to the experiment	= g grm.
Capacity of flask	= v c. c.
Residual air	= u c. c.

Besides these data, the following constants are required in order to calculate the temperature at which the flask was sealed:—

Weight of 1 c. c. air at 0° and 760 mm. pressure	=	0.001293 gm.
Density of iodine-vapour referred to air as unity	=	8.716
Coefficient of expansion of air for 1° C.	=	0.00366
Coefficient of cubical expansion of Bayeux porcelain for 1° C.	=	0.000108

The required temperature, T , can now be calculated as follows:

let I_w (= $\frac{(v-a) \cdot 0.001293}{1 + 0.00366 T} \cdot \frac{h}{760} + i$) be the total weight of iodine-vapour contained in the flask at the moment of sealing, then

$$\frac{I_w}{0.001293 \times 8.716} \cdot \frac{(1 + 0.00366 T) 760}{h} = I_v$$

will be the volume of this vapour at the same moment; but

$$I_v + \frac{a(1 + 0.00366 T)}{1 + 0.00366 T} \cdot \frac{760}{h} = v(1 + 0.000108 T)$$

and from this equation, in which T is the only unknown quantity, its value is easily found.

It is obvious that this method is applicable only for the measurement of maximum temperatures which can be maintained stationary for some time; but in cases where these conditions can be fulfilled, as in determining the boiling points of difficultly volatile substances (e.g. sulphur, cadmium, zinc) it is capable of yielding very accurate results.

A porcelain globe filled with air may be employed as a thermometer in the same way: the advantage of using iodine is that given differences of temperature correspond to greater differences of weight.

(See further Deville and Troost, Ann. Ch. Phys. [3] lviii. 267, 275, 285, 293.)

Mercury-pyrometer.—This instrument, proposed by Regnault (Ann. Ch. Phys. [3] lxiii. 40), is composed of a bottle made of cast or wrought iron, platinum or porcelain, having a capacity of 500 to 1000 c. c., and provided with a perforated lid which lies flat upon the neck of the bottle, the under surface of the lid (which has a considerably greater diameter than the neck) and the upper surface of the neck being ground together, so that by sliding the lid a little to one side, the bottle can be almost completely closed without removing it from the furnace, or other space whose temperature is to be determined. Before beginning the experiment, 10 or 15 grms. of pure mercury are put into the bottle, and it is then placed in the furnace, the lid being laid on so that the hole through it forms a continuation of the orifice of the neck; when the bottle has been in the furnace long enough to have thoroughly assumed the temperature of the latter, it is closed by drawing the lid sideways, then removed from the furnace, and quickly cooled. The mercury remaining in the bottle is poured out (it can be completely detached from the bottle by shaking a little water round in it), and weighed, either in the metallic state, or, when necessary, after solution in an acid and precipitation. When the following data are known, namely—

- v = capacity of the bottle in c. c. at 0° C.;
- κ = coefficient of cubic expansion of the substance of the bottle;
- h = atmospheric pressure at the moment of withdrawing the bottle from the furnace;
- d = density of mercury-vapour at temperatures at which it has the properties of a perfect gas;
- p = weight of mercury remaining in the bottle;

the required temperature, T , can be calculated.

The weight of mercury-vapour which fills the bottle at T° is

$$= v \cdot \frac{1 + \kappa T}{1 + 0.00366 T} \cdot 0.0012932 \cdot d \cdot \frac{h}{760} = p;$$

hence

$$\frac{1 + \kappa T}{1 + 0.00366 T} = \frac{760}{v \cdot 0.0012932 \cdot d} \cdot \frac{p}{h} = M \cdot \frac{p}{h},$$

in which last expression M is a quantity which remains constant for the same bottle: we have therefore

$$T = \frac{1 - M \frac{p}{h}}{M \cdot 0.00366 \frac{p}{h} - \kappa}$$

Regnault's *Hydrogen-pyrometer* (Ann. Ch. Phys. [3] lxxiii. 42) is an instrument whereby the temperature of a furnace or other heated space can be quickly determined at any required instant. It consists of a wrought iron tube one or two inches wide, and long enough to reach from one side of the furnace to the other, terminated at each end by a capillary tube of the same material, provided with a three-way cock. When the temperature of the furnace is to be determined, a current of pure and dry hydrogen is caused to enter the iron tube at one end, and allowed to issue freely into the air at the other; when the current of gas has been continued long enough to displace all the air, and to reduce any oxide that may have formed in the inside of the tube, it is stopped; the free end of the iron tube is connected with a copper tube filled with oxide of copper, and heated to redness by a row of gas-jets; the current of hydrogen is then replaced by a slow current of dry air, which sweeps forward the hydrogen into the copper tube, where it is completely converted into water. The water thus formed passes on to a weighed U-tube containing pumice-stone and sulphuric acid, and from its weight the temperature of the furnace can be calculated upon the same principle as when the mercury pyrometer is used. (For further details, and for figures of this apparatus and of that last described, see Regnault, *loc. cit.*)

The *Thermomultiplier*.—This instrument consists of a thermo-electric pile, connected with a delicate galvanometer; its construction, and the principles upon which its action depends, have already been explained in the article *ELECTRICITY* (ii. 413 and 443, 444). As a thermoscope, or instrument for rendering sensible heat of very low intensity, this apparatus is much more delicate than any other that has been devised, the heat given out by the human body producing a perceptible effect upon it, even at a distance of ten yards or more (Daguin, *Traité de Physique*, 2nd edit. ii. 34). As a differential thermometer, it is capable of giving accurate results, when the intervals of temperature to be measured are sufficiently small. But, since the direct indications of the instrument are not generally proportional to these intervals of temperature, it is necessary to construct, for each thermomultiplier, a table showing the interval of temperature to which each degree read off upon the instrument really corresponds. The following account of the method recommended by Melloni for constructing these tables is given by Tyndall (*Heat as a Mode of Motion*, p. 355), being translated by him from 'La Thermocroce,' p. 59:—

"Two small vessels are half-filled with mercury, and connected separately by two short wires, with the extremities of the galvanometer. The vessels and wires thus disposed make no change in the action of the instrument; the thermo-electric current being freely transmitted, as before, from the pile to the galvanometer. But if, by means of a wire, a communication be established between the two vessels, part of the current will pass through this wire and return to the pile. The quantity of electricity circulating in the galvanometer will be thus diminished, and with it the deflection of the needle.

"Suppose, then, that by this artifice we have reduced the galvanometric deviation to its fourth or fifth part; in other words, supposing that the needle being at 10 or 12 degrees, under the action of a constant source of heat, placed at a fixed distance from the pile, that it descends to 2 or 3 degrees when a portion of the current is diverted by the external wire; I say that by causing the source to act from various distances, and observing in each case the *total* deflection and the *reduced* deflection, we have all the data necessary to determine the ratio of the deflections of the needle, to the forces which produce these deflections.

"To render the exposition clearer, and to furnish, at the same time, an example of the mode of operation, I will take the numbers relating to the application of this method to one of my thermomultipliers.

"The external circuit being interrupted, and the source of heat being sufficiently distant from the pile to give a deflection not exceeding 5 degrees of the galvanometer, let the wire be placed so as to connect the two vessels of mercury; the needle falls to 1.5. The connection between the two vessels being again interrupted, let the source be brought near enough to obtain successively the deflections:—

5°, 10°, 15°, 20°, 25°, 30°, 35°, 40°, 45°.

Interposing after each the same wire, we obtain the following numbers:—

1.5°, 3°, 4.5°, 6.3°, 8.4°, 11.2°, 15.3°, 22.4°, 29.7°.

"Assuming the force necessary to cause the needle to describe each of the first degrees of the galvanometer to be equal to unity, we have the number 5 as the expression of the force corresponding to the first observation. The other forces are easily obtained by the proportion:—

$$1.5 : 5 = a : x = \frac{5}{1.5} a = 3.333a, *$$

* That is to say, one reduced current is to the total current to which it corresponds, as any other reduced current is to its corresponding total current.

where α represents the deflection when the exterior circuit is closed. We thus obtain

5, 10, 15·2, 21, 28, 37·3

for the forces corresponding to the deflections,

5°, 10°, 15°, 20°, 25°, 30°.

"In this instrument, therefore, the forces are sensibly proportional to the arcs up to nearly 15 degrees. Beyond this the proportionality ceases, and the divergence augments as the arcs increase in size.

"The forces belonging to the intermediate degrees are obtained with great ease, either by calculation or by graphical construction, which latter is sufficiently accurate for these determinations.

"By these means we find,

Degrees . . .	13°	14°	15°	16°	17°	18°	19°	20°	21°
Forces . . .	13	14·1	15·2	16·3	17·4	18·6	19·8	21	22·3
Differences . . .	1·1	1·1	1·1	1·1	1·2	1·2	1·2	1·3	
Degrees . . .	22°	23°	24°	25°	26°	27°	28°	29°	30°
Forces . . .	23·5	24·9	26·4	28	29·7	31·5	33·4	35·3	37·3
Differences . . .	1·4	1·5	1·6	1·7	1·8	1·9	1·9	2	

"In this table we do not take into account any of the degrees preceding the 13th, because the force corresponding to each of them possesses the same value as the deflection.

"The forces corresponding to the first thirty degrees being known, nothing is easier than to determine the values of the forces corresponding to 35, 40, 45 degrees, and upwards.

"The reduced deflections of these three arcs are,

15·3° 22·4°, 29·7°.

"Let us consider them separately; commencing with the first. In the first place, then, 15 degrees according to our calculation, are equal to 15·2; we obtain the value of the decimal 0·3 by multiplying this fraction by the difference 1·1; for we have evidently the proportion

$$1:1.1 = 0.3:x = 0.3$$

The value of the reduced deflection corresponding to the 35th degree, will not, therefore, be 15·3°, but $15·2° + 0·3° = 15·5°$. By similar considerations we find $23·5° + 0·6° = 24·1°$, instead of 22·4°, and $36·7°$ instead of 29·7° for the reduced deflections of 40 and 45 degrees.

"It now only remains to calculate the forces belonging to these three deflections, 15·5°, 24·1°, and 36·7°, by means of the expression 3.333α ; this gives us,

the forces, 51·7, 80·3, 122·3.
for the degrees, 35, 40, 45.

"Comparing these numbers with those of the preceding table, we see that the sensitiveness of our galvanometer diminishes considerably when we use deflections greater than 30 degrees."

When one face of the thermopile is exposed to the action of heat, the needle of the galvanometer, with which the pile is connected, immediately leaves its position of equilibrium and swings considerably beyond the new position in which, after a series of gradually diminishing oscillations, it ultimately comes to rest, if the pile continues exposed to the same source of heat; and when the source of heat is removed, the face of the pile only gradually loses the increased temperature which it had acquired while exposed to its action, so that the return of the galvanometer needle to its first position is likewise gradual. These two circumstances would occasion a very considerable loss of time in making a numerous series of observations with the thermomultiplier, were it necessary each time to allow the needle to become stationary at the point of ultimate deflection; but Melloni observed that the arc through which the needle swings in its first oscillation is always the same for an ultimate deflection of the same amount, and hence, by constructing what he calls a *Table of Impulses*, or table giving the ultimate deflection corresponding to a first swing, or impulse, of any given amount, this loss of time may be avoided. With such a table, it is only necessary to observe the arc described by the needle in its first movement, and then to refer to the table for the ultimate deflection corresponding thereto.

Siemens's Resistance Thermometer.—In this instrument the actual indications of temperature are made by an ordinary mercurial thermometer: its peculiarity consists in the fact that it enables the temperatures of spaces to be determined into which a thermometer could not be introduced, or where, if introduced, it could not be observed. Its action depends on the increased resistance which a metallic wire offers to the passage of an electric current when its temperature is raised. (*ELECTRICITY*, ii. 467.)

Two perfectly similar coils of insulated wire are enclosed in two hermetically sealed copper cases. One is placed in the space of which the temperature is required, the other in a bath of water; and the temperature of the bath is altered until the electrical resistance of the two coils is exactly equal, an equality which can be readily tested by a differential galvanometer. The temperature of the bath will then clearly be equal to that of the space where the first resistance coil is placed. The connections are made with very thick copper wire, so that their resistances shall have little or no influence upon the result. The wires are coiled on an open copper cylinder of considerable diameter and length, so as to expose a large surface to the air or water in which they are placed. They in consequence take the temperature of the surrounding medium with great rapidity. (*Report on Electrical Instruments in the International Exhibition of 1882*, by Fleeming Jenkin.—Jurors' Reports, Class xiii. p. 93.)

This instrument is obviously adapted for determining the temperature of different depths of the sea, or of borings on land, and for other similar purposes. Its sensibility may be considerably increased by adopting a suggestion of Dr. Esselbach's, and constructing one of the coils, that one which is placed in the bath of water, of a material whose resistance increases more slowly with rise of temperature than that of the substance of which the other coil is made. The temperature of the bath would then have to be varied more than one degree, in order to compensate the alteration of resistance caused by a variation of one degree in the temperature of the medium surrounding the other coil.

Besides the instruments for measuring temperature which are described above and in the article THERMOMETER, already referred to, a great number of others, of various degrees of utility, have been suggested from time to time. But it is believed that the instruments here noticed are those most likely to be found practically useful by the experimental chemist. A large number of the older contrivances for thermometric purposes are very fully described in the treatise on *The Thermometer and Pyrometer*, published by the Society for the Diffusion of Useful Knowledge. (Library of Useful Knowledge, Natural Philosophy, vol. ii. 1832.)

Calorimetry.—The cases in which quantities of heat require to be measured are very numerous, and different methods and apparatus are required in nearly every case. In relation to every one of the effects of heat the question arises: How much heat is needed to produce this effect with a given intensity? hence calorimetric measurements have to be made in the study of each of these effects, while the nature of each will determine the manner in which such measurements can best be made. We shall, therefore, consider the different problems into which calorimetry enters, one by one as they occur, and shall now pass at once to the

QUANTITATIVE STUDY OF THE EFFECTS OF HEAT.

The following order will be adopted in this part of the subject:—

1. Changes of Temperature produced by Heat.
2. Changes of Volume produced by Heat.
3. Changes of State of Aggregation produced by Heat.
4. Relations of Heat to Chemical Affinity.
5. Relations of Heat to Electricity.
6. Relations of Heat to Mechanical Energy.

1. *Changes of Temperature produced by Heat.*—**Specific Heat.**—When equal weights of two different substances, say a pound of water and a pound of mercury, are placed in two similar vessels, and exposed for the same length of time to the heat of the same lamp, or placed in front of the same fire, at equal distances from it, or otherwise treated so as to have an opportunity of taking up, each exactly as much heat as the other, it is found that, if of equal temperatures at the beginning of the experiment, they have no longer the same temperature at the end of it. The mercury is found to be much hotter than the water. Hence it is proved that a quantity of heat which is sufficient to raise the temperature of a given quantity of mercury through a given number of degrees, is only able to raise the temperature of the same quantity of water through a smaller number of degrees; in other words, more heat is required to raise the temperature of a given quantity of water one degree, than is required to raise the temperature of the same quantity of mercury one degree. Again, if we take two equal weights of water and mercury which have been heated to the same temperature, say to 100° C., and place them under such conditions that, in cooling down to the temperature of the atmosphere, each shall give out exactly as much heat in each second as the other, it will be found that the mercury will have cooled down to the temperature of the atmosphere long before the water; hence, when its temperature is lowered by a given number of degrees, water gives out more heat than an equal quantity of mercury does in undergoing a similar alteration of temperature. Extending similar experiments to other substances, we should find that the quantity of heat needed to effect a given

change of temperature is different for almost every substance. These quantities of heat, expressed relatively to the quantity of heat required to raise the temperature of an equal weight of water from 0° to 1° C., are called the specific heats of the various substances. Thus, for instance, the statement that the specific heat of lead is 0.0314, implies that the quantity of heat which would suffice to raise the temperature of any given quantity of lead from 0° to 1° C., would raise the temperature of an equal quantity of water only from 0° to 0.0314° .

The power of heat, then, to cause changes of temperature depends upon the nature of the substance upon which it acts, just as we shall see in the sequel, that its power to cause changes of volume, or changes of any other kind, varies with the nature of the bodies submitted to its action.

Three principal methods have been employed for measuring the specific heats of different substances. Of these, much the most accurate is that known as the method of mixtures; we shall, therefore, describe it first. It consists in heating a known weight of the substance, whose specific heat is to be determined, to a known temperature, then plunging into a known weight of water, also at a known temperature, and determining the temperature of the mixture which results. In an experiment of this kind, let T° be the temperature to which the substance was heated, t° the initial temperature of the water, and θ° the temperature of the mixture; and let the weight, in grammes, of the substance be W , and the weight of the water, w . Then it is plain that the heat which the substance has given out in cooling from T° to θ° is the same as that required to heat the water from t° to θ° . Calling the hitherto unknown specific heat of the substance x , we shall have for the former quantity of heat, the expression $W(T - \theta)x$, and for the heat taken up by the water (whose specific heat = 1), $w(\theta - t)$. Hence

$$W(T - \theta)x = w(\theta - t);$$

or

$$x = \frac{w(\theta - t)}{W(T - \theta)}.$$

The most accurate determinations of specific heat that have hitherto been published are probably those made by Regnault (Ann. Ch. Phys. lxxiii. 5; *Ibid.* [3] i. 129; ix. 322; xxvi. 261 and 268; xxxviii. 129; xli. 257; lxiii. 5), by the method of mixtures. Fig. 630 (see p. 26), which is copied from his latest memoir on this subject, shows the disposition of apparatus usually employed by this investigator. The substance to be examined is contained in a basket of fine brass wire, M, suspended in the middle of an upright cylinder, A, of thin metal. This cylinder is surrounded by a larger concentric cylinder, B, and this again by a third cylinder, C. By the ebullition of water in the boiler, V, the annular space between A and B is kept constantly full of steam, which passes thence through the openings, $o o$, near the top of B, into the outer annular space comprised between B and C, and hence by the waste-pipe ef to the condenser G, and so back to the boiler. That portion of the steam which is liquefied in the cylinders B and C, returns to the boiler in the form of water by the pipe c . The temperature of the substance in M is shown by the thermometer T, the bulb of which occupies a cylindrical space left for the purpose in the middle of the basket of brass wire. The water into which the substance is to be plunged is contained in the calorimeter H, a small vessel of very thin and highly polished brass, supported upon three points, and carried by a foot which slides along a groove, so that, by a rapid and smooth motion, it can be brought directly under A, or removed to the farther side of the sliding screen, pp' , so as to be protected from the influence of heat given out by the heating apparatus C. When in its place under A, the calorimeter is protected from heat radiated by the boiler by the double screen D, between the two coatings of which a continual circulation of cold water is kept up. The temperature of the calorimeter is indicated by the thermometer t , the bulb of which is long enough to reach from just below the surface of the water to very near the bottom.

At the commencement of an experiment, the calorimeter is drawn back outside the screen pp' , and the basket containing the substance to be examined is suspended in the middle of the cylinder A by a silk thread, the cylinder itself being closed at top and bottom by hollow plugs to prevent loss of heat, one of which is shown in its place at the upper part of the figure. Steam from the boiler being allowed to circulate about A, the substance at M is gradually heated to nearly the temperature of boiling water. After, in general, about two hours, the thermometer T becomes stationary; but, for greater certainty that the temperature of the substance is uniform throughout, the heating is continued for at least another hour. The temperature of the water in the calorimeter is then observed by reading the thermometer t through a telescope, the temperature of the air being read off at the same time upon another thermometer. The calorimeter is quickly pushed under the heating apparatus; the plug at the bottom of the cylinder A is removed; and by loosening the cork which supports the thermometer T.

the silk thread from which the basket *M* hangs is liberated, and this with its contents allowed to fall into the water contained in *H*. The calorimeter is again drawn back behind the screen *PP'*, and the basket is moved about in the water by an assistant, while the observer watches through the telescope the maximum temperature indicated

Fig. 530.

by the thermometer *t*. This maximum generally occurs one or two minutes after the immersion of the substance. Suppose that, in such an experiment, the following results were obtained:—

Weight of substance	<i>M</i> grm.
" " brass wire basket	<i>p</i> grm.
Temperature by thermometer <i>T</i> at moment of immersion	<i>T</i> °
Temperature by thermometer <i>t</i> at same moment	<i>t</i> °
Maximum temperature after immersion by thermometer <i>t</i>	<i>θ</i>
Weight of water in calorimeter, calorimeter and thermometer supposed included	<i>A</i>
Specific heat of brass	<i>c</i>

Then, calling the required specific heat of the substance C , we should have

$$MC(T - \theta) + pc(T - \theta) = A(\theta - t);$$

or

$$C = \frac{A(\theta - t) - pc}{M(T - \theta)} - \frac{pc}{M}$$

In giving the calculation in this very simple form, we are assuming that the constant A includes not merely the actual water in the calorimeter, but also the "water-equivalents" of the brass of which the calorimeter is composed, and of the glass and mercury composing the thermometer t , for these are all heated at the same time as the water, and to the same extent. If the weight of brass in the calorimeter were w , and the weights of glass and mercury in the thermometer t respectively w' and w'' , and if, further, the specific heats of brass, glass, and mercury be c , c' , and c'' , the "water-equivalent" of the calorimeter (or the quantity of water which would require the same quantity of heat to raise its temperature one degree) would be wc , and the "water-equivalent" of the thermometer t would be $w'c' + w''c''$. Hence if a be the weight of actual water in the calorimeter, the calorimetric value of the whole quantity of matter to which the heat of the body under experiment is imparted will be:

$$A = a + wc + w'c' + w''c''.$$

The values of the several terms making up the whole value of A must obviously be determined by preliminary experiments.

An additional correction, the value of which has also to be found by preliminary trials, is required to compensate the heating or cooling effect of the atmosphere upon the calorimeter and its contents during the course of an experiment. But as the difference between the two temperatures t and θ of the calorimeter seldom exceeds 4° or 6° , it is easy, by keeping the temperature of the instrument as much below the atmospheric temperature during the first half of the experiment as it is expected to exceed it in the second half, to render the error introduced by atmospheric heating or cooling, very small indeed: in Regnault's experiments, it amounted to only three or four hundredths of a degree, but was nevertheless carefully allowed for.

By means of the apparatus above described, the substance under examination can never be heated quite to the boiling point of the liquid in the boiler V , so that when this is water, the temperature of the substance never rises above 87° or 98° ; but any other temperature that may be desired can easily be attained by introducing into the boiler, in place of water, a liquid which boils at nearly the required temperature, and then raising or lowering its temperature of ebullition as much as may be needed, by connecting the tube h with a large reservoir of compressed or rarefied air.

In determining the specific heat of substances (such as phosphorus, for example) which could not be heated without causing them to melt or else to undergo other alterations which would interfere with the accuracy of the results, Regnault adopted an inverse process, and cooled them to a temperature considerably below that of the water in the calorimeter, and thus observed the diminution in the temperature of the latter which resulted from immersing the cooled substances in it. The apparatus employed for producing and maintaining constant a low temperature, resembles to some extent the heating apparatus already described and figured. It consists of a central tube, in the middle of which is suspended the substance to be cooled, surrounded by two larger concentric cylinders. The space between the central tube and the next is partially filled with ether or some other volatile liquid, and the space between this tube and the outside one is filled with air. By causing a rapid current of air to traverse the ether, its temperature is gradually lowered, and with an external temperature of 20° C. any temperature not lower than -12° can be maintained constant by properly regulating the flow of air; the lowest temperature that can be obtained under similar circumstances, by employing sulphide of carbon instead of ether is -8° . By the use of liquid ammonia, any temperature between -40° and -80° C. can be obtained.

In order to apply the above method to determinations of the specific heat of liquids, they must be enclosed in tubes of very thin glass, nearly filled and hermetically closed. These tubes are suspended, like the basket M , in the centre of the tube A , and afterwards let down into the calorimeter. In calculating the result, allowance must of course be made for the heat imparted to the calorimeter by the tube.

Another apparatus which serves for the determination of specific heats is represented in fig. 531. This apparatus, devised by Favre and Silbermann (*Ann. Ch. Phys.* [3] xxxvi. 33), consists of a glass globe, A , of about 1 litre capacity, in which are three openings. The first, b , admits a thin iron or platinum tube, closed at the lower end, about 1 inch ($2\frac{1}{2}$ to 3 centimetres) wide and 4 inches (10 or 11 centimetres) long, cemented at the top into the opening of the glass, and kept in its

place below by a piece of glass rod, one end of which is cemented against the upper side of the tube and the other end against the side of the glass globe. Within this tube, which is called the *muffle*, is placed another tube of very thin glass which serves to contain the substances under experiment. This is held in its place by a

Fig. 531.

cork which surrounds its neck and fits tightly in the mouth of the muffle; it is surrounded by about 100 grms. of mercury, intended to facilitate interchange of heat between it and the muffle.

The second opening, *c*, carries a horizontal capillary tube, *tt*, about 500 millimetres long, divided into millimetres, and terminated at the farther end by a small funnel. This tube, which should be perfectly cylindrical, is cemented to the glass globe by marine glue, so that, when needful, it can be easily removed and cleaned.

The third opening carries a steel piston, *d*, which, by means of a screw, can be raised or lowered so as to increase or diminish somewhat the capacity of the globe.

The globe itself is supported upon a thick ring of cork and enclosed in a box lined with wadding or swan's-down, and surrounded by a double casing filled with water. It is filled with mercury, with the precautions necessary to exclude any trace of air, and the extremity of the column of mercury is adjusted by moving the steel piston, *d*, up or down, so as to be exactly at the zero point of the divisions of the tube.

In using the instrument, the substance whose specific heat is to be determined, is introduced at a known temperature into the muffle, or into the glass tube inside it. The substance then parts with its heat to the mercury contained in the globe of the calorimeter, causing it to expand, and the expansion read off on the tube *tt* is a measure of the quantity of heat thus imparted to the mercury. In order, however, to compare the indications of this instrument with those of the water-calorimeter, it is needful to know the number of divisions of the tube *tt* which correspond to the effect of a unit of heat, or gramme-degree. For this purpose Favre and Silbermann graduated their instrument as follows:—A few scraps of platinum wire, and 4 or 5 grammes of distilled water, are placed in a pipette of the form shown in fig. 532. The

Fig. 532.

pipette is heated over a spirit-lamp until the water boils, the flame being occasionally passed along the point *a*, so as to heat it sufficiently to prevent the condensation of steam, and the drop of water is removed from the end by a piece of filter-paper, so that the steam may have free issue into the air at the moment of beginning the experiment.

The lamp is then removed for an instant; the ebullition ceases, and at the same moment the point of the pipette is rapidly introduced to the bottom of the tube contained in the muffle, the pipette being simultaneously turned round through 180° about the axis *ab*. The lamp is then again brought near the pipette, and the cork which closes the upper end is removed, so that no steam may follow the water into the muffle. As soon as the mercury-column in *tt* has reached the extreme point, the temperature of the water is taken by a small and sensitive thermometer; and the experiment is completed by weighing the glass tube with the water contained in it.

If the weight of water be *P*, and the number of degrees through which its temperature falls after being introduced into the tube of the muffle be *T*, the number of units of heat imparted to the calorimeter will be *PT*. If this quantity of heat causes the mercury to advance through *N* divisions of the tube *tt*, the amount of

expansion, C , expressed in the same divisions, corresponding to one unit of heat will be

$$C = \frac{N}{PT}.$$

Favre and Silbermann found that, in the instrument employed by them, one unit of heat caused the mercury to advance in tt by 0.3 millimetre.

In determining the specific heats of liquid substances by means of this apparatus, they are introduced into the tube of the muffle by means of the pipette *ad*, in the manner already described in the case of water, the weight employed being determined after the experiment.

Another method of ascertaining the specific heats of various substances consists in determining the quantity of ice which can be melted by the heat given off by a known weight of each while cooling through the same number of degrees. A known weight of the substance to be operated upon is heated to a determinate temperature, as 100° , and then placed in a cavity scooped out of a block of melting ice and covered by a second slab of ice. The temperature of the substance is thus brought down to that of melting ice, and a quantity of ice is melted—that is, a quantity of water is formed—proportionate to the quantity of heat which the substance gives out in cooling to this temperature.

This method, however, though very simple both in principle and in execution, cannot be made to give very accurate results; for there is great difficulty in determining with exactness the quantity of water formed, and a small error committed here will introduce a large error into the estimate of the quantity of heat given out by the body in cooling, since as will be seen hereafter, the quantity of heat needed to convert one part of ice into water would be sufficient to raise the temperature of $79\frac{1}{2}$ parts of water one degree.

A third method, called the method of cooling, was employed by Dulong and Petit. It consists in determining the length of time which the different substances to be examined require in order to cool in a vacuum from one known temperature to another, each being placed, as nearly as possible, under identical circumstances.

In order to realise the necessary conditions for determinations of this kind, the substances to be examined are all reduced to an impalpable powder, and filled successively into the same cylindrical silver vessel, gilded and highly polished externally, in the axis of which is the bulb of the thermometer by which the progress of the cooling is to be shown. The silver vessel, supported by the stem of the thermometer, is suspended in the middle of a large brass receiver, coated internally with lamp-black, from which the air can be completely removed. This is immersed in water at 40° C., and when the thermometer inside the apparatus marks 35° , it is transferred to melting ice. The thermometer is now watched through a telescope, and the instants at which it marks 20° , 15° , 10° , and 5° , are noted. If all other circumstances were the same, the time during which each substance underwent the same fall of temperature, would be a measure of the amount of heat given out in undergoing this change—that is, of the specific heat of the substance; but Regnault, who submitted this method to very careful examination (*Ann. Ch. Phys.* [3] ix. 327), found that it was impossible to obtain results of any value by its application in the case of solid bodies: with liquids, for which the same sources of error do not occur as for solids, it is capable of giving much more exact results.

The difficulties attendant on the exact determination of the specific heats of gases and vapours are very much greater than in the case of solids and liquids. An extensive series of experiments on this subject has been made by Regnault (*Mém. de l'Acad. des Sciences*, xxvi. 41) with elaborate care, the principle of his method being to observe the alteration of the temperature of water, surrounding a spiral tube, caused by the passage through the tube of a known quantity of gas which enters and issues from it at known temperatures. A description of the apparatus employed in these researches and of the methods of experimenting would occupy too much space to admit of its being given here; we must therefore refer for details to the paper already quoted. (A figure of the apparatus and a tolerably full account of the method of experimenting are also given in Daguin's *Traité de Physique*, 2nd edit. ii. 275–280.) The principal results obtained are enumerated below (p. 35).

In the following Table are given the specific heats of a considerable number of the elementary bodies, according to the results obtained by Regnault by the method of mixtures. When the specific heat of the same element has been determined by him several times, the most recent result is given in the Table. The third column gives the temperatures between which the specific heats given in the second column were observed; the numbers contained in the fourth and fifth columns will be referred to presently. The specific heats of the gaseous elements are not included in this table, but will be found in a subsequent one, together with the specific heats of some other gases (see p. 35).

SPECIFIC HEAT OF INORGANIC COMPOUNDS. 31

The following short table gives the specific heats of a few substances which require to be taken into account in calculating the results of the experiments from which the numbers in the foregoing and subsequent tables are deduced:—

Name of Substance.	Specific heat.	Temperatures between which the specific heat was observed.
Brass	0.09391	98° and 12°
Glass	0.19768	99 " 14
Oil of turpentine	0.42593	98 " 15
Water	1.00800	98 " 13

Numerous determinations have been made by Regnault of the specific heats of inorganic compounds. A selection from his results, sufficient to show their general nature, is given in the next table. The temperatures between which the determinations were made are not given in the table, but were in all cases a temperature approaching 100° C., and a temperature near that of the atmosphere. In the case of substances which are soluble in water, or capable of being chemically acted on by it in any way, the calorimeter was filled with oil of turpentine. The different substances enumerated in the table are arranged in groups according to their chemical composition.

For a numerous series of determinations of the specific heats of the isomorphous sulphates of the magnesian group, see Pape (Pogg. Ann. cxx. 337).

With regard to alloys of two or more metals, Regnault found that, at temperatures considerably removed from their melting points, their specific heats are the means of the specific heats of their components. In the following table, the values given in the column headed "Calculated Specific Heats" are obtained by multiplying the specific heat of each constituent into the percentage amount of it contained in the alloy, and dividing the sum of all these products for each alloy by 100; these values, therefore, would exactly represent the specific heats of the respective alloys if the above rule were rigorously true; the correspondence between them and the results of direct observation is sufficient to show that the rule is, at least, a close approximation to the truth.

Specific Heat of Alloys.

In the case of alloys which, at the temperature of observation, were approaching their melting points, the observed specific heat was always considerably higher than that calculated as above.

The specific heats of a few liquids are included in the tables already given (pp. 30 and 32): we append here the results obtained by Person (Ann. Ch. Phys. [3] xxi. 333; xxiv. 136), H. Kopp (Pogg. Ann. lxxv. 98) and Favre and Silbermann (Comptes rend. xxiii. 624; also Ann. Ch. Phys. [3] xxxvii. 464-470) for some additional liquids, simple and compound. Favre and Silbermann's experiments were made by cooling the liquids in the mercurial calorimeter (p. 28), from their respective boiling points to temperatures nearly equal to that of the surrounding atmosphere.

The specific heat of water at different temperatures has been determined by Regnault (*Mém. Acad. Sciences*, xxi. 729) from whose experiments it appears that the quantity of heat expressed in *heat-units* which one gramme of water loses in cooling down from t° to 0° C. is given by the formula,—

$$Q = t + 0\cdot00002 t^2 + 0\cdot0000003 t^3;$$

and the specific heat C at the temperature t° , that is to say, the quantity of heat required to raise one gramme of water from t° to $(t + 1)^\circ$, by the formula,—

$$C = 1 + 0\cdot00004 t + 0\cdot0000009 t^2.$$

From this formula, the following numbers are obtained :

Specific Heat of Water.

<i>t.</i>	<i>Q.</i>	<i>C.</i>	<i>t.</i>	<i>Q.</i>	<i>C.</i>
0°	0·000	1·0000	150°	161·462	1·0262
50	50·087	1·0042	200	203·200	1·0440
100	100·500	1·0130	230	234·708	1·0568

The specific heat of ice is considerably less than that of liquid water. According to Regnault's experiments, it is 0·474 between -78° and 0° C., and 0·504 between -20° and 0° , according to the experiments of Person and of Desains.

It results from Regnault's determinations of the specific heats of gases and vapours, made in the manner already mentioned (p. 29), that the specific heat of a given *weight* of a gas which obeys Boyle's law (*Gases*, ii. 820) does not alter with variations either of temperature or of pressure. This was found to be true of atmospheric air

between the temperatures of -20° and $+225^{\circ}$, and at pressures varying from 1 to 12 atmospheres. Consequently the specific heat of a given volume of air, or other non-condensable gas, varies directly as its density. In gases which do not follow Boyle's law, this regularity does not exist: thus the specific heat of carbonic anhydride is found to increase perceptibly as its temperature rises, being 0.18427 between -30° and 10° , and 0.20246 between 10° and 100° , and 0.21692 between 10° and 210° , as compared with that of an equal weight of water.

The following table gives the specific heats of the various gases and vapours examined by Regnault, compared, first, with an equal weight of water taken as unity, secondly, with that of an equal volume of air referred as before to its own weight of water as unity. The latter series of numbers is obtained by multiplying the numbers expressing the specific heats of equal weights of the various gases or vapours, by their respective densities referred to that of air as 1.

Table of Specific Heats of Gases and Vapours. (Regnault.)

Name.		Specific heats.	
		Equal weights.	*Equal volumes.

	Chloride of titanium1290	.8564

Comparing these values with those given for some of the same substances in previous tables, it appears that the specific heat of the same body is commonly greater in the liquid than in the solid state, and always less in the gaseous than in the liquid state.

On examining the numbers above given for the specific heats of different bodies, it will be seen that the specific heat of a substance is not altogether an absolute and unchangeable property: on the contrary, it will be evident that this property, in one and the same substance, is capable of considerable variation, depending (a) on the

physical structure of the substance, (b) on its temperature, (c) on its state of aggregation. In illustration of this remark, it will be sufficient to refer to the specific heats of carbon, silicon, selenium, sulphur, phosphorus, alumina, and carbonate of calcium, as given in the foregoing tables, in evidence of the influence of differences of physical condition; to the specific heats of lead, phosphorus, water, and ice, in evidence of the effect of differences of temperature; and to those of bromine, mercury, tin, lead, bismuth, water, &c., in the solid and liquid states, in evidence of the effect of the state of aggregation.

In reference to the connection between specific heat and temperature, it may be remarked that this property varies to a greater extent, for a given interval of temperature, near the temperatures at which changes in the state of aggregation occur, than at a distance from those temperatures. Thus, the specific heat of lead, an easily fusible metal, is considerably greater between 10° and 100° C. ($=0.0314$) than it is between 10° and -78° C. ($=0.0306$); and that of phosphorus, a still more fusible substance, shows even a greater difference when compared between 10° and 30° (specific heat $=0.1887$) and between -71° and 10° C. (specific heat $=0.1740$); while the specific heat of platinum, one of the most infusible of all the metals, varies to a scarcely perceptible extent at temperatures below 100° C., and only slowly at temperatures considerably higher. The mean specific heat of this metal between 0° C. and the temperatures enumerated below, was in fact found by Pouillet to be represented by the numbers contained in the second line of the following table.

Specific Heat of Platinum.

Interval of temperature	0° and 100°	0° and 300°	0° and 500°	0° and 700°	0° and 1000°	0° and 1200°
Mean specific heat	0.0335	0.03434	0.03518	0.03602	0.03728	0.03808

The specific heat of solid bodies therefore increases with rise of temperature, up to their melting points, and at this temperature there is generally a further sudden increase of specific heat of a considerable amount.

It may be further noticed that in the table of the specific heats of the elements (p. 30), the elements are arranged nearly in the order of their specific heats, beginning with lithium (specific heat $=0.941$) and ending (if we disregard for the present the three elements carbon, boron, and silicon, which are placed together after the rest) with bismuth (specific heat 0.031); and that this order is also exactly the inverse order of their atomic weights, as given in the fourth column, the atomic weight of lithium ($=7$) being less than that of any other element included in the table, and that of bismuth ($=210$) being greater than that of any other element. In fact, not only do those elements whose atomic weight is lowest possess, as a rule, the greatest specific heat, and *vice versa*, but the specific heats of the elements (in the solid state) are, within comparatively narrow limits, inversely proportional to their atomic weights, when these are taken as having the values given in the fourth column of the table; so that the product of the specific heats of the elements into their atomic weights is nearly a constant quantity; as shown by the numbers in the fifth column of the table. These numbers may be taken to represent the *atomic heats* of the elements, or the relative quantities of heat which must be imparted to, or removed from, atomic proportions of the several elements, in order to cause in them equal alterations of temperature. The table shows that the atomic heats of the elements are not represented by an absolutely constant quantity; but when it is considered that the two factors (atomic weight and specific heat) of which they are made up, vary in the proportion of $1:30$, it cannot be denied that they are comprised between comparatively very narrow limits: for (taking those determinations only which refer to comparable conditions of the several elements, and which there is reason to believe were made upon nearly pure substances) we find that they are nearly all included between 5.9 (aluminium, rhodium) and 6.9 (iodine), the greater number not differing much from 6.5 . (The high atomic heat of uranium, 7.4 , is doubtless to be explained by the impurity of the metal operated upon.) The general accordance is amply sufficient to indicate the existence of a general law, although the individual results show the effect of some one or more disturbing causes. And even if it be admitted that the true atomic heats of the elements under consideration are really identical, under comparable circumstances, there are several reasons why the experimental atomic heats, deduced like those in the foregoing table, cannot be expected to exhibit the same identity. The most important of these reasons are: the unavoidable experimental errors attaching to the determination of the specific heats; the imperfect purity of some of the elements examined; the circumstance that, although most of the determinations were made at nearly the same absolute temperatures—namely, between a temperature near 100° and that of the atmosphere—the different elements

are not, in regard to their specific heats, under comparable circumstances at these temperatures, some being much nearer to their melting point than others, and therefore having in general relatively higher specific heats (see p. 36); lastly, in a few cases, the uncertainty of the experimental data used in fixing the atomic weights.

The relation of approximate equality among the atomic heats of the elements exists, however, only when their atomic weights are allowed to have the values given in the table: these values are in very many cases the double of those given in the table of atomic weights, vol. i. pp. 464, 465, and employed in the first edition of *this work*. If the latter scale of atomic weights be adopted, the elements would have to be divided into two classes: those whose atomic heat is approximately 6.5, and those whose atomic heat is approximately 3.2. The fact that, by doubling the atomic weights of the latter class of elements, their atomic heats would be brought into harmony with those of the former class, is in itself a strong argument in favour of such a change; and by reference to the articles ATOMIC WEIGHTS (i. 468-473) and CLASSIFICATION (i. 1008, 1009, foot-note) and the article ATOMICITY in the SUPPLEMENT, it will be seen that it is supported by many other considerations, both chemical and physical. In any case it is certain that the numbers in the column headed "Atomic Weights," in the table on p. 30, represent quantities of the various elements which are calorimetrically comparable; and it is therefore best to assume those numbers as really representing those weights of the elements which, in relation to the phenomena of heat, possess the properties of atoms. Whether the chemical atoms of the elements are always identical with the calorimetric atoms, is a question that is perhaps still open to discussion.

It is very important, however, not to overlook the fact that the atomic heats of boron, carbon, and silicon form unquestionable exceptions to the general rule, and cannot be brought into harmony with it, by the adoption of any atomic weights to which the present state of chemical knowledge lends any serious support.

The examples which have been given (pp. 31-33) of the specific heats of compound bodies, show that, within certain classes of allied compounds, the same kind of relation subsists between their specific heats and molecular weights, as has been pointed out between the specific heats and atomic weights of the elements. Consequently, the molecular heats of the substances comprised in each such class, or the products of their specific heats into their molecular weights (see the last column of the table), are approximately equal. In calculating these molecular heats, the atomic weights of the elements are taken as having the values which may be deduced from their specific heats; those values, namely, which are given in the previous table. Adopting these atomic weights, it will be seen that, as a rule, the molecular heat of solid compound bodies increases with the number of atoms contained in their molecule. For instance, the molecular heat of the oxides MO enumerated in the table averages about 11; that of the oxides MO_2 , about 14; that of the oxides MO_3 , about 19; that of the oxides M_2O_3 , about 25.5.

An extensive series of determinations of the specific heats of solid bodies has been made by H. Kopp, but the individual results have not yet been published (1864); we shall, therefore, instead of discussing any further the relations between specific heat and chemical composition which might be deduced from Regnault's experiments already given, reproduce here the substance of the remarks which Kopp (Ann. Ch. Pharm. cxxvi. 362), with his own results before him, makes upon this subject.

This new investigation has brought to light a considerable number of additional examples of solid compounds which, having an analogous atomic constitution, possess also approximately the same molecular heat. Among these, particular interest attaches to the case in which an analogy of constitution is apparent only when the atomic weights of the elements are admitted to have the values assigned to them in the foregoing tables, and where the formulæ previously adopted and the old atomic weights of the elements would never have caused any such relations between specific heat and molecular weight to be suspected. Just as the molecular heats of carbonates and silicates, M^*CO_3 and M^*SiO_3 , and of nitrates and chlorates, MNO_3 and $MClO_3$, are approximately equal, so also are the molecular heats of the permanganates and perchlorates, $MMnO_3$ and $MClO_4$, and of the sulphates and chromates, M^*SO_4 and M^*CrO_4 . The new investigation, however, also furnishes some additional examples to the previously known exceptions to the general rule, and thus supplies further evidence of the fact that it is possible for bodies of analogous constitution to differ considerably in their molecular heats.

The molecular heat of a compound appears to be governed only by its empirical, and not by its rational constitution. Analogous compounds, in one of which a complex group occupies the place of an elementary atom, were found, even when isomorphous,

to have unequal molecular heats; thus the molecular heats of the ammonium-compounds are considerably greater than those of the corresponding potassium-compounds, and those of the cyanogen-compounds exceed those of the chlorine-compounds.

The atomic (or molecular) heat of any body which is contained in a compound, or may be assumed as one of its constituents, may accordingly be ascertained indirectly, by deducting from the molecular heat of the compound that of whatever other constituents it contains in addition to the body in question. For instance, if we deduct from the molecular heat of a compound of the form $M^xM''O^y$ (chromate of lead, tungstate of calcium, &c.)—which, it may be remarked, is twice as great as that of compounds of the form M^xO^y (stannic oxide, titanian anhydride, &c.)—the molecular heat of the base $M''O$, we get as remainder the molecular heat of the anhydrous acid M^xO^y ; and the same remainder is obtained by deducting, from the molecular heat of acid chromate of potassium, $K^2Cr^2O^7$, that of the neutral chromate, K^2CrO^4 . Again: the molecular heats of hydrated compounds admit of being regarded as made up of the molecular heat of the respective anhydrous substances, together with that of the water contained in them in the solid form.

Such indirect determinations of the atomic heat of a substance are nevertheless somewhat uncertain: not only because it occasionally happens that analogous compounds, which there is every reason to expect would possess equal molecular heats, do nevertheless, according to the experimental determinations of their specific heats, show important differences in their molecular heats; but also, and more particularly, because the total uncertainty attaching to the determination of the molecular heat, both of the original compound and of the element or group which has to be deducted from it, is accumulated upon the relatively small remainder. But when such inferential determinations are made for whole series of corresponding bodies, and not merely for individual cases, the results may be regarded as sufficiently trustworthy to render such considerations as arise from them worthy of notice.

This is especially the case with regard to the inferred specific and atomic heats of certain elements. As already pointed out, nearly all the elements, when examined in the solid state, are found to have approximately the same atomic heat—on the average, about 6.4. It is now very generally admitted that this—the so-called law of Dulong and Petit—holds good for *all* the elements, and a scale of atomic weights of the elements is considered as satisfactorily established if the products of these atomic weights into the specific heats are nearly equal. In the case of some elements, however, it results, both from the older determinations of their specific heats and from Kopp's newer determinations, that this rule is inapplicable; for example, the specific heats of carbon, boron, and silicon, are such, that the products, obtained by multiplying them into the respective atomic weights—when any values are adopted for these which can possibly be deduced from chemical considerations—are always decidedly smaller than the corresponding products in the case of other elements whose specific heats in the solid state can be investigated.

But these exceptional or accidental results acquire additional interest when taken in connection with the conclusions which may be drawn from the molecular heats of compounds. Compounds of those elements which obey Dulong and Petit's law exhibit a regularity in their molecular heats (*A. H.*): such, namely, that these are as many times greater than that of an element, as there are elementary atoms contained in the respective

compounds (that is to say, $\frac{A.H.}{n} = 6.4$ nearly, if n denotes the number of elementary atoms in one molecule of each compound). This regularity appears, not only in alloys containing atomic proportions of different metals, but also in the metallic chlorides, bromides, and iodides (see table, pp. 31, 32), and has been found by Kopp to extend likewise to compounds of which one molecule contains as many as seven, or even nine, elementary atoms (such as ZnK^2Cl^4 and PtK^2Cl^6). It is less distinctly recognisable in the case of the compounds of the metals with sulphur ($\frac{A.H.}{n}$ is here usually less than 6), and no longer exists for the metallic oxides, which, almost without exception, give for the quotient $\frac{A.H.}{n}$ a number decidedly less than 6, and smaller in proportion as the number of oxygen-atoms exceeds that of the atoms of metal. For water, considered of course in the solid state, this quotient is only about 3, and for the few organic compounds which Kopp has examined (such as tartaric acid and cane-sugar) it is still less.

The fact that this regularity is absent in so many compounds admits of only one explanation—namely, that they contain elements which, at least in these combinations, possess a different atomic heat from that which corresponds to Dulong and Petit's law.

It has often been assumed that the specific, and therefore the atomic, heat of an ele-

ment may be different in certain compounds from what it is in the free state, and that it may be different in one compound from what it is in another. But, according to Kopp, the only ground for such an assumption is that by means of it the calculated molecular heats of compound bodies can be brought into closer agreement with the results of experiment; for, as he remarks, the variations which the specific heat of an element must be supposed capable of undergoing when it enters into combination (if Dulong and Petit's law be taken as applicable to all elements in the free state) are much greater than the variations, dependent on differences of physical condition, which have ever been actually observed in the case of an accurately investigated element. On the contrary, it appears that, in many compounds, the elementary atoms of which they are composed retain the atomic heats which belong to them in the free state; and that, moreover, the atomic heats which can be indirectly calculated for certain elements, notwithstanding their disagreement with Dulong and Petit's law, accord very closely with the atomic heats which result from the direct investigation of the same elements in the free state. Kopp accordingly maintains that—although these last-mentioned facts render the calculation of the molecular heat, and thence of the specific heat, of compound bodies from the atomic heats of the elements much more difficult, and although they make the agreement between the results of calculation and those of direct observation much less complete—every element, when considered in the solid state, and at a temperature sufficiently removed from its melting point, possesses one essentially invariable specific heat, which it is true may vary somewhat with differences of physical condition—such as greater or less density, amorphous or crystalline structure, &c.—but not to such an extent as some of his determinations of specific heat would require, if Dulong and Petit's law were really applicable to all the elements; and further, that the specific heat of each element in the free state is essentially the same as that which it possesses in its compounds.

By deducting from the molecular heats of the various oxides the atomic heats of the metals contained in them, or by deducting from the molecular heats of the oxygen-salts those of the groups which are therein united with oxygen (taking away from the molecular heat of KClO_3 , for example, that of KCl , or from that of PbSO_4 the molecular heat of PbS), a remainder is obtained in every case which gives for the atomic heat of oxygen a number less than 6. For the reasons already stated (p. 38), the results thus arrived at do not agree so well as might be wished; nevertheless, Kopp gives it as his opinion that the atomic heat of oxygen cannot differ greatly from 4.

When the molecular heats of the carbonates M^2CO_3 and $\text{M}'\text{CO}_3$ are compared with the molecular heats of the oxides $(\text{M}'')^2\text{O}^3 (= 3\text{M}''\text{O})$ and $(\text{M}''')^2\text{O}^3$, the molecular heats of the carbonates are found to be decidedly smaller (according to Regnault's experiments, as given in the table, pp. 31–33, the molecular heats of the carbonates M^2CO_3 and oxides $3\text{M}''\text{O}$ are, on the average, about 29.4 and 32.85 respectively; those of the carbonates $\text{M}'\text{CO}_3$ and oxides $(\text{M}''')^2\text{O}^3$, about 21.7 and 25.5 respectively). Such comparisons show that the atomic heat of carbon in these combinations must be assumed to be about the same as that which has been directly found for free carbon in the form of diamond; namely, 1.8. Similar comparisons applied to other elements lead likewise to the adoption of atomic heats which are much smaller than what would correspond to the law of Dulong and Petit: for instance, to the atomic heat 2.3 (nearly) for hydrogen; for boron, to a number lying between 2 and 3; for silicon, to 4 (nearly); and for fluorine, also to a number which appears to be distinctly less than 6.4.

The specific and molecular heats of compound bodies calculated with the atomic heats thus arrived at for the elements, show, in very many cases, a very satisfactory degree of agreement with those deduced from direct experiment; in many other cases, however, they show important discrepancies. But equal discrepancies may likewise be observed among the molecular heats of analogous compounds, such even as contain elements as corresponding constituents which, when examined in the free state, gave nearly equal atomic heats. Regnault not unfrequently found this difference amount to one-tenth of the molecular heats in question; occasionally it was still greater.

Kopp considers that the results of his investigation confirm and widen the conclusion, already adopted by some philosophers, that Dulong and Petit's law does not hold good for all the so-called elements in the solid state. For a particular group of elements it is undoubtedly true; but if it is not a universal law, and if there are some elements to which it certainly does not apply, it may be considered doubtful with regard to individual elements, whether they ought to be looked upon as agreeing with or as departing from it. This may be said to be the case with sulphur, for which Kopp's determinations, made between 47° and the temperature of the atmosphere, give the atomic heat 6.2, nearly, which likewise agrees with the atomic heat of sulphur as indirectly deduced from the molecular heats of the metallic sulphides.

In general, the molecular heat of a compound increases with its degree of complexity, or with the number of elementary atoms contained in one molecule, and this more especially in the case of such as contain only elements which follow Dulong and Petit's law. Kopp points out that if the application of this rule be extended to the elements themselves, the fact that a large proportion of them have nearly the same atomic heat may be taken as an indication that, whether they be absolutely simple substances or no, they are at least bodies of a comparable degree of complexity; while, on the other hand, the smaller atomic heats of some elements would seem to show that they are of a lower degree of complexity, or approach more nearly to truly simple bodies, than the rest. It would thus appear to be possible for a substance which can be proved to be compound, to have the same atomic heat as a so-called element: for instance, a peroxide, XO , containing an element whose atomic heat was equal to that of hydrogen, namely, about 2.3, would have a molecular heat of about $2.3 + 4 = 6.3$, that is to say, the same as that of chlorine, iodine, or the metals.

With regard to the apparent improbability of two so-called elements, which are capable of mutually replacing each other in compounds, like hydrogen and the metals—or which even appear as corresponding constituents of isomorphous substances, like silicon and tin—having unequal atomic heats, it must be borne in mind that this is not in reality any more surprising or improbable than that an undecomposable substance and one known to be compound, such, for example, as hydrogen and peroxide of nitrogen, or potassium and ammonium, should replace each other in compound bodies without causing any alteration in their chemical characters, or should even be capable of appearing as corresponding constituents of isomorphous substances.

It still remains to consider, rather more particularly than has been done thus far, what it is that is measured under the name of the specific heat of solid, liquid, or gaseous substances, by the methods above described.

In all these methods of measurement, the heat imparted to the various bodies does something more than merely raise their temperature: it causes at the same time, as will be seen by what follows, an expansion or increase of their bulk; and when the bodies are again cooled, they contract, or diminish in bulk, to an equal amount. Hence the specific heats, measured as above, are not, strictly speaking, the relative quantities of heat required to raise the temperature of the various substances to the same extent, but the quantities required to do this, and at the same time to cause a greater or less increase of bulk. It is therefore a question for further investigation, what proportion of the total specific heat of a substance goes to raise its temperature, and what proportion to cause it to expand, or possibly to modify it in other ways.

The expansion which accompanies a given rise of temperature is inconsiderable in the case of solids and liquids, compared with that which takes place in gases; but it would be incorrect to conclude that the proportion of the total specific heat of solid, liquid and gaseous substances respectively, which is expended in causing expansion, is in proportion to the amount of expansion actually produced in each case. On the other hand, although no data exist which make it possible to form a very definite estimate of the ratio of the *real* specific heat to the *total apparent* specific heat of solids or liquids (see, however, p. 44), it is certain that they oppose a much greater resistance to any force tending to alter their bulk than gases do, and hence the comparatively small amount of expansion which they undergo may require the expenditure of as much or more heat than the relatively great expansion which takes place in gases: there is, therefore, no reason to believe that the ratio of the two specific heats, in the case of solid and liquid substances, is a magnitude of a different order from what it is in the case of gases.

The ratio of the apparent to the real specific heat of a gas, is the ratio of its specific heat under constant pressure (when, therefore, it expands as its temperature rises) to its specific heat when kept at a constant volume. It is, of course, the specific heat under constant pressure which is determined by the method already described (p. 29), and which is given for several gases in one of the preceding tables (p. 36). That the specific heat of a gas kept at a constant volume is less than its specific heat under a constant pressure, is obvious from the following considerations. Suppose a quantity of gas to have had its temperature raised t° , while the pressure to which it was exposed remained constant: the increase of temperature will have been accompanied by a corresponding increase of volume. Now, suppose the gas to be compressed, so as to restore it to its original bulk: the result of this compression will be to raise its temperature t' more. The gas will now be in the same condition as it would have been if the same quantity of heat had been imparted to it without its being allowed to expand: hence it is evident that the same quantity of heat that, is required to raise the temperature of a given weight of gas t° , while the pressure remains constant, will suffice to raise the temperature of the gas $t + t'$ degrees if it

is kept at a constant volume. The specific heat, c' , corresponding to a constant pressure, is therefore to the specific heat, c , corresponding to a constant volume, as $t + t'$ to t . One gramme of air has its temperature raised 1°C . when there is imparted to it 0.2374 of a unit (gramme-degree) of heat, and it expands at the same time, if the pressure remains unaltered, by $\frac{1}{273}$ of its bulk at 0°C . Accordingly, if the elevation of temperature consequent on compressing a gas by $\frac{1}{273}$ of its bulk at 0° be α° , it is evident that the ratio

$$\frac{1 + \alpha}{1} = \frac{c'}{c} = k$$

is the ratio of the specific heat under constant pressure to that at constant volume. Clement and Desormes found by direct experiments upon air the value 0.34° for α , but it is plain that the unavoidable loss of heat attending such experiments must cause the result to be too low.

A less direct, but far more accurate means of determining the ratio $k = \frac{c'}{c}$, not only for air but for several other gases also, is afforded by the theory of the propagation of sound. The velocity with which a wave-motion, such as that which constitutes sound, is propagated through a homogeneous medium whose elasticity is the same in all directions, depends only upon the elasticity, e (see ii. 370), and the density, d , of the medium, according to the equation

$$v = \sqrt{\frac{e}{d}}.$$

This expression, applied to the movement of a sound-wave through the air, becomes

$$v = \sqrt{\frac{e}{d}} = \sqrt{\frac{gH\sigma}{s}} \cdot k(1 + \alpha t);$$

where g denotes the accelerating force of gravity ($= 9.808$ metres $= 32.18$ feet); $H = 760$ mm. $= 29.92$ inches; σ the weight of 1 cub. cent. of mercury at $0^\circ = 13.596$ gm.; s the weight of 1 cub. cent. of air at 0° and under a pressure of 760 mm. mercury $= 0.001293$ gm.; t the temperature of the air, α its coefficient of expansion under constant pressure ($= 0.00367$), and k the required ratio $\frac{c'}{c}$. Now the velocity of sound in air at 0° has been experimentally found to be $= 333$ metres, or 1092.6 feet per second; hence the above equation gives

$$333 = \sqrt{\frac{9.808 \times 0.76 \times 13.596}{0.001293}} \cdot k$$

or $k = 1.414$.

The physical reason for the presence of the magnitude k in the formula for the velocity of sound, is that that velocity, being dependent upon the elasticity of the air, varies with every variation of the elasticity, and that the alternate heatings and coolings, caused respectively by the alternate condensations and rarefactions which constitute the waves of sound, are equivalent, in their effect upon the velocity of transmission of the waves, to an increase in the elasticity of the air in the proportion of $1 : k = 1 : 1.414$.

In the above formula the magnitudes g , H , σ , t , and α are all independent of the particular nature of the gas (at least in the case of perfect gases; for imperfect gases the value of α varies slightly), hence if v and v' represent the velocities with which sound traverses two different gases, s and s' their densities, and k and k' the ratios of the two specific heats of each, we have

$$v : v' = \sqrt{\frac{k}{s}} : \sqrt{\frac{k'}{s'}},$$

$$\text{or} \quad \sqrt{\frac{k}{s}} = \frac{v}{v'} \sqrt{\frac{s'}{s} \cdot k};$$

so that the ratio k' for any gas may be deduced from that of air, provided the density of the gas and the velocity with which it is traversed by sound are known.

Hence the investigation of this ratio is reduced to that of the real velocities of sound in different elastic fluids. For any other gas than atmospheric air, it is useless to think of measuring directly the velocity of propagation of a sound wave; recourse must obviously be had to indirect means. The theory of wind instruments suggested a mode, which was first indicated and put in practice by Laplace and Jacquin. This method consists in making the same pipe, with a flute, and blowing sound successively with all the elastic fluids, supposed at the same temperature, and in determining the

pitch of tone given by each gas. Admitting that the fluid column contained in the instrument experiences the same mode of subdivision in every case—that it corresponds, for example, to what is called the fundamental sound, or the gravest of all those which the theory of Bernouilli indicates for the same pipe, we easily come to know the length of a wave, and its duration in each elastic fluid; and consequently the velocity with which a vibration would be propagated in each of them.

The following table exhibits the results of Dulong's researches on this subject. (*Ann. Ch. Phys.* xli. 113):

Names of the elastic fluids.	Tones given by the same pipe 60 centim. long.	Number of vibrations in a sexagesimal second.	Temperature by the centigrade therm.	Numbers adopted in the calculation for the density of the fluid.	Velocity of the propagation of sound at 0°, deduced from the tone given by each fluid.	Ratio of the specific heats at a constant pressure, to the specific heat at a constant volume, = k .

The slight difference between the value 1.421, obtained by Dulong for the ratio of the two specific heats of air, and the number 1.414 already given is, in part, due to the changes which have taken place, since the date of his experiments, in the adopted value of the constants which enter into the calculation.

Theoretical views of the nature of heat and the constitution of gaseous bodies, which will have to be further considered in a subsequent part of this article, lead to the conclusion that, for all perfect gases, the difference between the two specific heats of a unit of volume is expressed by the equation

$$\gamma' - \gamma = A \frac{p}{a + t} \dots \dots (a)$$

where A is a constant (the thermal equivalent of the unit of work), p and t the pressure and temperature of the gas, and $\frac{1}{a}$ the coefficient of expansion, and therefore $a = 273$ nearly. The right hand member of this equation contains nothing which depends on the particular nature of the gas to which it is applied; and hence, if the temperature and pressure are taken the same for all gases, the difference $\gamma' - \gamma$ will be the same for all. If the values of γ' and γ applicable to atmospheric air be distinguished as γ'_a and γ_a , we have

$$\gamma' - \gamma = \gamma'_a - \gamma_a$$

an equation which remains true whatever unit of volume is adopted, and therefore also, if with Regnault, we take this unit to be the volume occupied by a unit of weight of air at the same temperature and pressure as the gas under consideration. Therefore

$$\gamma' - \gamma = \gamma'_a - \gamma_a = 0.2374 - 0.1680 = 0.0694 \text{ and } \gamma = \gamma' - 0.0694.$$

By means of this equation, the specific heats of the various gases under constant volume may be calculated from their specific heats under constant pressure as given in the table on p. 35. The numbers so obtained will refer to the unit of volume adopted by Regnault; to deduce therefrom the specific heats which correspond to a unit of weight, these numbers require merely to be divided by the densities of the respective gases; and to obtain the specific heats compared with that of an equal volume of air, they must be divided by 0.1680.

According to equation (a) the quotient $\frac{\gamma}{\gamma} = k$ becomes

$$k = 1 + \frac{4}{\gamma} \cdot \frac{p}{a + t}$$

and it therefore exceeds unity by a quantity which is inversely proportional to γ .

Further, the general considerations above referred to make it probable that the true specific heat of equal volumes of all simple gases is the same, and that the specific heat of compound gases is equal to that of the simple gases multiplied by the fraction which represents their molecular condensation (e.g. for hydrochloric acid the multiplier would be $\frac{1+1}{2} = 1$, for water $\frac{2+1}{2} = 1.5$, for ammonia $\frac{3+1}{2} = 2$, &c.).

The following table, which is copied with very slight modifications from tables given by Clausius (*Ann. Ch. Pharm.* cxviii. 118) and Bu ff (*ibid.* cxv. 312; see also pp. 306, 307), and may be considered supplementary to the table on p. 35, gives the results of the application of these formulae to the gases and vapours which were the

subject of Regnault's experiments. Column I. gives the names of the gases; column II. their chemical composition: the formulae in this column represent two volumes of the several gases: hence the molecular condensation of each gas is obtained by dividing the number of atoms in its formula by 2. Column III. gives the densities

adopted by Regnault in his calculations. Column IV. gives the specific heats under constant pressure compared with that of an equal volume of air taken as unity. The numbers in this column are obtained from those in the last column of the table on p. 35 by dividing each by 0.2374 = specific heat of air under constant pressure. Columns V. and VI. contain the specific heats corresponding to a constant volume compared (V.) with that of an equal weight of water, and (VI.) with that of an equal volume of air. Column VII. gives the ratio of the two specific heats for some of the most important gases, obtained by dividing the specific heats of equal weights under constant pressure, as given in the previous table (p. 35), by the corresponding values in column V. of this table. Column VIII. contains the theoretical true specific heats, compared with the true specific heat of an equal volume of air or any simple gas. These numbers are calculated upon the supposition that the true specific heats of the elementary gases are the same in the combined as in the uncombined state.

On comparing the numbers in columns VI. and VIII. it will be seen that there is, on the whole, an unmistakable correspondence between them, but that they exhibit also in many cases decided discrepancies. These are probably due, in part to errors of experiment, and in part to the fact that the method, by which the numbers representing the specific heats at constant volume are calculated from those representing the specific heats at constant pressure, is quite accurate only in the case of perfect gases; and further that, even if the numbers in column VI. represented the specific heats for constant volume with perfect accuracy, these numbers would not necessarily agree with those in column VIII., except for perfect gases.

The true specific heat of a gas, that is, its specific heat under a constant volume, is regarded by Clausius (Phil. Mag. [4] xxiv. 204, 205) as the true specific heat of the substance in all states of aggregation, and in the combined as well as the free state. Rankine, on the other hand (*A Manual of the Steam Engine, &c.*, p. 307), while admitting that the true specific heat of each substance remains constant at all densities, so long as the substance retains the same condition, solid, liquid, or gaseous, supposes that a change of real specific heat, sometimes considerable, often accompanies the change between any two of these conditions. But, as Clausius has pointed out (*loc. cit.*; also Pogg. Ann. cxx. 438), there is no obvious reason why the real specific heat of a body should be supposed to undergo alteration on the passage from one state of aggregation to another, if it remains constant within the same state of aggregation; for the changes of density and elasticity, which accompany changes of temperature within one and the same state, do not differ in kind, but only in degree, from those which constitute the passage from one state to another. Assuming, therefore, that the specific heat under constant volume of a substance in the gaseous state is its real specific heat under all conditions, we have, for water, for instance,

$$\text{Ratio of apparent to real specific heat in the solid state (between } -20^{\circ} \text{ and } 0^{\circ}) \quad = \frac{.504}{.369} = 1.367$$

$$\text{Ratio of apparent to real specific heat in the liquid state (between } 0^{\circ} \text{ and } 100^{\circ}) \quad = \frac{1.008}{.369} = 2.732$$

$$\text{Ratio of apparent to real specific heat in the gaseous state} \quad = \frac{.4805}{.369} = 1.302$$

2. Changes of Volume produced by Heat.

It is an almost universal law that, when heat is imparted to any body, the body expands or augments in bulk, unless prevented from doing so by a corresponding increase of external pressure, and that any body from which heat is withdrawn contracts or diminishes in bulk. The exceptions to this law are extremely few, and occur only within particular limits of temperature: the most important will be specially pointed out hereafter. Admitting the atomic hypothesis of the constitution of matter, it is impossible to conceive of expansion otherwise than as a movement of the molecules of a mass, which has for its effect to increase their mean distance from each other. Hence when heat causes a body to expand, it acts in opposition to the forces which tend to prevent the further separation of the molecules; and the bulk of the body at any given temperature is the result of an equilibrium between these forces and the expansive force of the heat contained in it at that temperature. The forces by which the particles of a mass are held together consist in part of the pressure to which it is subjected from without, and partly of the pressure arising from the mutual attractions of the particles themselves. This latter pressure, which is known as cohesive force, has a much greater effect in determining the bulk of solid and liquid

bodies than any pressure which acts upon them from without, and it varies not only in different bodies, but even in the same body its value is different at different temperatures. Hence it is not surprising that the relations subsisting between the temperature and bulk of solid and liquid substances should be somewhat complex. In perfect gases, however, cohesion does not exist, and hence the only opposing force which heat has to overcome in order to cause them to expand is the external pressure. Consequently it is found that the rate of expansion of gases bears a much more simple relation to the heat by which it is caused, than that observed in solid and liquid bodies. It is, therefore, convenient to consider the laws of the expansion of gaseous substances before examining those which regulate the expansion of matter in the two other states of aggregation.

Expansion of Gases.—In a perfect gas, volume, elasticity, and temperature would be related to each other in the manner expressed by the equation

$$pv = J(a + t), \dots\dots\dots (a)$$

where v is the volume of a given weight of the gas at the temperature t and under the pressure p , and J and a are constants. Hence, if v' were the volume of the same weight of the same gas corresponding to any other pressure, p' , and temperature, t' , we should have

$$\frac{p}{p'} \frac{v}{v'} = \frac{a + t}{a + t'} \dots\dots\dots (b)$$

No absolutely perfect gas, however, is known in nature, so that, according to the best experiments, the values of a which correspond to different values of p , v , and t , are not quite constant, but vary slightly, not only with variations of these factors, but also according to the nature of the gas. The properties of air, however, and the other non-condensable gases accord so nearly with the above formulæ—which are in fact nothing more than a statement of the laws of Boyle and Gay-Lussac (GASES, ii. 819*)—that, except in cases where extreme accuracy is required, the accord may be considered perfect.

If in the above equation (b) we make $p = p'$ we get

$$\frac{1}{a} = \frac{v - v'}{v't - vt'}; \dots\dots\dots (c)$$

that is, $\frac{1}{a}$ is the coefficient of expansion of the gas under constant pressure, or the amount by which that quantity of gas which occupies a unit of volume at 0° C. expands, under constant pressure, when its temperature is raised one degree. Similarly, by making $v = v'$, we have

$$\frac{1}{a} = \frac{p - p'}{p't - p't'}, \dots\dots\dots (d)$$

or $\frac{1}{a}$ is also the coefficient of expansion of the gas under constant volume, or, more correctly (since when $v = v'$ no actual expansion can take place), $\frac{1}{a}$ is the coefficient of increase of elasticity, or the increment of elasticity, under a constant volume, for a rise of temperature of one degree, of a gas whose elasticity at 0° C. is unity. For a perfect gas, it is obvious that these two values of $\frac{1}{a}$ would be equal.

The first tolerably accurate determinations of the coefficients of expansion of gaseous bodies were made by Gay-Lussac. He used in his experiments a vessel shaped much like a thermometer, having a bulb about 1 centimetre in diameter, and a tube about 30 or 40 centimetres long, and 1 or 1.5 millimetres wide. The tube was divided into lengths of equal capacity, and the proportion between the total capacity of the bulb and that of one division of the tube was accurately determined. The apparatus having been filled with air dried by passing through a chloride-of-calcium tube, a drop of mercury, occupying a short length of the divided tube, was employed to cut off the enclosed air from communication with the atmosphere, and at the same time to serve as an index whereby to read off its volume. The bulb was then fixed, with the stem horizontal and projecting through the side, in a vessel filled with water, through the medium of which it could be heated to various temperatures. The volumes occupied by the air at each temperature could be read off upon the divided tube by noting the position of the little column of mercury; but the volumes thus determined required to be corrected (a) for the

* Equation (b) may obviously be put into the form $v = v' \frac{p'}{p} \cdot \frac{a + t}{a + t'}$, and is then identical with that by which these laws are represented at the place quoted.

expansion of the glass, (b) for the lower temperature of the portion of air contained in the part of the tube outside the water-bath, and (c) for the possible alterations of barometric pressure during the experiment. Independently of these latter alterations, which were always very inconsiderable, the pressure upon the gas remained constant during the experiment: it was the volume which changed. Applying the same method to other gases and to vapours, Gay-Lussac concluded that all gases and vapours (at temperatures sufficiently removed from their points of liquefaction) expanded by heat to the same extent; that, namely, when heated from 0° to 100° C. they expanded in the proportion of 1 : 1.375, or for 1° C. by $0.00375 = \frac{1}{267}$ of their volume at 0° .

The confidence which these results naturally excited, in consequence of the high reputation of the author, was still further increased by the confirmation which they received at the hands of Dulong and Petit, and also because it was considered probable, on theoretical grounds, that in substances in which cohesive force no longer existed, the expansive action of heat should be independent of chemical composition. Hence, when the Swedish physicist Rudberg announced, as the result of his own more accurate experiments, that the coefficient of expansion found by Gay-Lussac was considerably too high, the statement was at first received with hesitation.

Rudberg determined the value of the coefficient of expansion of air $\left(\frac{1}{a}\right)$ between 0° and 100° C. by two series of experiments. In the first he determined the contraction undergone by a given quantity of air on cooling from 100° to 0° under a nearly constant pressure; in the second, the difference in the elastic force at 0° and 100° of a quantity of air kept at the same volume at the two temperatures. Making t and t' in equations (c) and (d) respectively = 100 and 0, the results of his experiments may be stated as follows:—The mean of twelve experiments by the first method gave for the coefficient of expansion under constant pressure—

$$\frac{1}{a} = \frac{v - v'}{100v} = 0.003648 = \frac{1}{274};$$

the mean of ten experiments by the second method gave for the coefficient of expansion at constant volume—

$$\frac{1}{a} = \frac{p - p'}{100p'} = 0.003646 = \frac{1}{274}.$$

a result identical with the preceding.

More recently (1841) the expansion of air and other gases has been again made the subject of elaborate experiments by Regnault (*Relation des Expériences . . . pour déterminer les principales lois et les données numériques qui entrent dans le calcul des Machines à Vapeur*, Mém. Acad. Roy. des Sciences, xxi. 16–120 (1847); also Ann. Ch. Phys. [3] iv. 5 and v. 52) and by Magnus (Pogg. Ann. lv. 1, and lvii. 177).

Regnault made five series of experiments by methods more or less distinct. His first method was the same as the first method employed by Rudberg. It consisted in heating a cylindrical glass vessel of known capacity, about 2.5 or 3 centimetres wide, and about 11 centimetres long, filled with dry air, to 100° ; sealing it hermetically at that temperature; then cooling it to 0° , and observing the quantity of mercury which entered on breaking off the point of the instrument under the surface of that metal. The apparatus employed and the method of experimenting were, in fact, exactly the same as in determining a temperature by means of the air-thermometer in the manner already described (pp. 19 and 20): for it is obvious that the same experiment which, the coefficient of expansion of air being known, serves to determine the temperature at which the air-thermometer is sealed, would, if this temperature were known, serve for the determination of the coefficient of expansion.

The second set of determinations were made by a method only slightly different from the first, the only essential difference in the apparatus being that the tube connected with the air-reservoir was about 40 centimetres (16 inches) long, and that a portion of it, about two inches long and separated from the air-reservoir by about four inches, was wide enough to produce only a very slight capillary depression in a column of mercury. The effect of this modification of the apparatus was that when, after being heated to 100° and sealed at that temperature, the instrument was placed with the tube pointing vertically downwards and with the point dipping into mercury, the mercury rose only as far as the wide part of the tube, on breaking off the point, and did not reach the reservoir at all. Hence the space occupied by the air at zero differed from that which it had occupied at 100° , only by the capacity of that portion of the tube which became filled with mercury on opening the point; and since the diameter of the tube was, with the exception of the wider portion already mentioned, very small, this capacity bore a small proportion to the total capacity of the instrument. The experiment consisted therefore essentially in a determination of the difference of the elastic force of the air at the two temperatures.

In the third and fourth sets of experiments, the air-reservoir was made to communicate with a manometer, whereby the pressure upon the enclosed air could be varied at will and accurately measured. The pressures were so regulated that the air was caused to occupy accurately the same volume at 0° and 100° , and the differences of pressure required were determined. The apparatus for the third series of experiments was copied, with some improvements of detail, from that employed by Rudberg in his second series. The apparatus for the fourth series was the same in principle, but its construction was such that the pressure upon the air could be determined with still greater accuracy than was possible with the preceding apparatus.

In the fifth set of experiments, the pressure upon the air remained constant, and the alteration of volume was determined by weighing the quantity of mercury which filled the space into which it expanded.

The mean results of numerous experiments made by each of these processes were as follows:—If p_0 and v_0 represent respectively the pressure and volume of the air at 0° , and p_1 and v_1 its pressure and volume at 100° , the value of $\frac{p_1 v_1}{p_0 v_0}$ was—

By the first series	1.36623
„ second series	1.36633
„ third series	1.36679
„ fourth series	1.36650
„ fifth series	1.36706

In the second, third, and fourth series, the expansion was calculated from the change of elastic force undergone by the same volume of air when its temperature changed between 0° and 100° ; in the experiments made by the first method, both pressure and volume changed considerably, so that they gave a mixed result. From the consideration of all the experiments by the first four methods, Regnault adopts for the coefficient of expansion of air, under *constant volume*, for 1 degree centigrade between 0° and 100° , the number

$$0.003665 = \frac{1}{272.9} = \frac{1}{273} \text{ nearly.}^*$$

This result agrees precisely with that obtained by Magnus.

For the coefficient of expansion of air under *constant pressure*, Regnault adopts the number

$$0.00367$$

given by the experiments of the fifth series.

Similar experiments extended to other gases gave the mean results recorded in the following table, in which are also included the results obtained by Magnus:—

Table of EXPANSION OF GASES between 0° and 100° at Ordinary Pressures.

Name of gas.	Value of $\frac{p_1 v_1}{p_0 v_0} = 1 + \frac{100}{a}$.		
	Constant volume.		Constant pressure.
	Regnault.	Magnus.	Regnault.
Hydrogen	1.3667	1.3657	1.3661
Air	1.3665	1.3665	1.3670
Nitrogen	1.3668		
Carbonic oxide	1.3667		1.3669
Carbonic anhydride	1.3688	1.3691	1.3710
Nitrous oxide	1.3676		1.3719
Sulphurous anhydride	1.3845	1.3856	1.3903
Cyanogen	1.3829		1.3877

The foregoing results are all deduced from experiments in which the gases operated upon were subject to pressures differing but little from the ordinary pressure of the atmosphere. In another investigation (*Op. cit.* pp. 96–120) Regnault determined the coefficients of expansion of air and some other gases at pressures considerably different from that of the atmosphere. The following table gives the mean results:

* If the coefficient of expansion of air be taken = 0.003666 It may be represented by the vulgar fraction $\frac{11}{3000}$, a number which is very convenient for the purposes of calculation.

Table of EXPANSION OF GASES between 0° and 100° at Various Pressures.

2545	1.36616	985	1.3984

The following general conclusions may be drawn from these results:

1°. The coefficients of expansion of air, hydrogen, nitrogen, and carbonic oxide, between 0° and 100°, are sensibly equal.

2°. The coefficients of expansion of the condensable gases, carbonic anhydride, nitrous oxide, sulphurous anhydride, and cyanogen, are slightly greater than the coefficient of expansion of the permanent gases. For the condensable gases also the coefficient of expansion (under constant pressure) slightly exceeds the coefficient of increase of elasticity (the gas being kept at constant volume), a difference which is likewise observed, though in a less degree, in the case of air.

3°. The coefficient for hydrogen is not influenced by a change of pressure from 1 to 3 atmospheres. The coefficients for air, carbonic anhydride, and sulphurous anhydride are greater at high densities and pressures than at low ones.

Notwithstanding the differences in the absolute values of the coefficients of expansion of air at different densities, and of air, hydrogen, and carbonic anhydride, Regnault found by direct experiments (*Op. cit.* pp. 171-190) that the elastic force of air, of any initial pressure at 0° between 400 mm. and 1300 mm., and the elastic force of hydrogen and carbonic anhydride increased according to the same law at all temperatures between 0° and 350° C. Hence gas-thermometers filled with air of any density, or with hydrogen, or carbonic anhydride, would give perfectly similar indications, provided that, in calculating the temperatures, the coefficient proper to each gas were employed. The coefficient of expansion of sulphurous anhydride was found to diminish, relatively to that of air, in proportion as the temperature rose, being 0.0038261 at 98.12° of the air-thermometer, and 0.0037893 at 310.31°.

Hence as a general conclusion: Although no gas appears to follow *absolutely* the law

of expansion expressed by the equations (a) and (b), page 46, the permanent gases follow this law so closely that, in all except the most refined calculations, these formulæ may be taken as strictly applicable to them; the value of a being for all a number sensibly equal to 273.

The following consequences of these equations are of importance in calculating the changes of volume and elastic force of gases corresponding to given changes of temperature: Let v be the volume of a given weight of gas at 0° C., and p its elastic force at the same temperature; let v_1 and p_1 be the volume and elastic force of the same quantity of gas at any other temperature, t_1° ; and let v_2 and p_2 be the volume and elastic force corresponding to any third temperature, t_2° : then, the volume at t_1 , expressed in terms of the volume at 0° , will be—

$$v_1 = v \frac{p}{p_1} \cdot \frac{a + t_1}{a} = v \frac{p}{p_1} \cdot \left(1 + \frac{1}{a} t_1\right),$$

$$\text{or } v_1 = v \frac{p}{p_1} \cdot \frac{273 + t_1}{273} = v \frac{p}{p_1} \cdot \left(1 + \frac{1}{273} t_1\right) = v \frac{p}{p_1} \cdot \left(1 + 0.003665 t_1\right);$$

the volume at 0° , in terms of the volume at t_1° , will be—

$$v = v_1 \frac{p_1}{p} \cdot \frac{a}{a + t_1} = v_1 \frac{p_1}{p} \cdot \frac{1}{1 + \frac{1}{a} t_1},$$

$$\text{or } v = v_1 \frac{p_1}{p} \cdot \frac{273}{273 + t_1} = v_1 \frac{p_1}{p} \cdot \frac{1}{1 + \frac{1}{273} t_1} = v_1 \frac{p_1}{p} \cdot \frac{1}{1 + 0.003665 t_1}$$

and the volume at t_2° , in terms of the volume at t_1° , will be—

$$v_2 = v_1 \frac{p_1}{p_2} \cdot \frac{a + t_2}{a + t_1} = v_1 \frac{p_1}{p_2} \cdot \frac{1 + \frac{1}{a} t_2}{1 + \frac{1}{a} t_1},$$

$$\text{or } v_2 = v_1 \frac{p_1}{p_2} \cdot \frac{273 + t_2}{273 + t_1} = v_1 \frac{p_1}{p_2} \cdot \frac{1 + 0.003665 t_2}{1 + 0.003665 t_1}.$$

The elastic force at t_1° , in terms of the elastic force at 0° , will be—

$$p_1 = p \frac{v}{v_1} \cdot \frac{a + t_1}{a} = p \frac{v}{v_1} \cdot \left(1 + \frac{1}{a} t_1\right),$$

$$\text{or } p_1 = p \frac{v}{v_1} \cdot \frac{273 + t_1}{273} = p \frac{v}{v_1} \cdot \left(1 + \frac{1}{273} t_1\right) = p \frac{v}{v_1} \cdot \left(1 + 0.003665 t_1\right);$$

the elastic force at 0° , in terms of the elastic force at t_1° , will be—

$$p = p_1 \frac{v_1}{v} \cdot \frac{a}{a + t_1} = p_1 \frac{v_1}{v} \cdot \frac{1}{1 + \frac{1}{a} t_1},$$

$$\text{or } p = p_1 \frac{v_1}{v} \cdot \frac{273}{273 + t_1} = p_1 \frac{v_1}{v} \cdot \frac{1}{1 + \frac{1}{273} t_1} = p_1 \frac{v_1}{v} \cdot \frac{1}{1 + 0.003665 t_1};$$

and the elastic force at t_2° , in terms of the elastic force at t_1° , will be—

$$p_2 = p_1 \frac{v_1}{v_2} \cdot \frac{a + t_2}{a + t_1} = p_1 \frac{v_1}{v_2} \cdot \frac{1 + \frac{1}{a} t_2}{1 + \frac{1}{a} t_1},$$

$$\text{or } p_2 = p_1 \frac{v_1}{v_2} \cdot \frac{273 + t_2}{273 + t_1} = p_1 \frac{v_1}{v_2} \cdot \frac{1 + 0.003665 t_2}{1 + 0.003665 t_1}.$$

It is very important to bear in mind, with reference to all calculations of this kind, that when the coefficient of expansion of the permanent gases is said to be uniform at all temperatures, and equal to $\frac{1}{273}$, it is not meant that 1 vol. of a gas at any temperature, t_1° , becomes $1\frac{1}{273}$ vol. at the temperature $(t_1 + 1)^\circ$; but that 1 vol. at 0° becomes $1\frac{1}{273}$ vol. at 1° , and $1 + \frac{t}{273}$ vol. at t° , and that consequently 1 vol. at t° becomes

$$1 + \frac{1}{273 + t} \text{ at } (t + 1)^\circ.$$

The irregularities in the expansion of the more condensable gaseous anhydrides, which are brought to light by Regnault's experiments, are due to a greater or less extent in the case of all liquefiable gases or vapours, and are more marked in proportion as the gases are examined nearer to their points of liquefaction. The law with regard to the expansion of vapours appears to be, that their coefficients of expansion are considerably greater than $\frac{1}{273}$ at temperatures near to the boiling points of the liquids from which they are formed, and that they continue to diminish as the temperature rises, so as to approach more and more closely to a constant value of nearly $\frac{1}{273}$. Hence, at sufficiently high temperatures, all vapours and liquefiable gases acquire the properties of sensibly perfect gases. The rapidity with which the coefficients of expansion of different vapours approach their limiting values, varies greatly. Some vapours, as that of ether, have a nearly uniform rate of expansion within twenty or thirty degrees of the boiling point of the liquid, whereas others show a sensibly diminishing rate of expansion throughout a much wider interval of temperature: for instance, acetic acid through upwards of 120 degrees, and sulphur-vapour through 400 degrees above the boiling point of sulphur. This property of vapours is of great importance in relation to the experimental determination of their densities. (For further details, see SPECIFIC GRAVITY; also ii. 811.) The fact of a vapour having reached a temperature at which its rate of expansion is the same as that of air, is indicated by its density, compared with that of air at the same temperature and pressure, remaining constant for any further rise of temperature: thus the density of acetic acid vapour (boiling point 118°) was found, by Cahours, to be,

at 125° ,	150° ,	180° ,	200° ,	240° ,	270° ,	310° ,	336° C.,
= 3.180,	2.727,	2.438,	2.248,	2.090,	2.088,	2.085,	2.083.

That is to say, it expands more rapidly than air up to about 240° , but above that temperature its expansion is very nearly the same as that of air.

Relation between the Expansion of a perfect Gas and the Quantity of Heat required to produce it.—Equation (a) (page 46) may be written—

$$pv = m(1 + \alpha t), \dots\dots\dots (e)$$

If we put m for Ja , and α for $\frac{1}{a}$ = coefficient of expansion. Let the volume, v , be expressed in cubic metres, the pressure, p , in kilogrammes per square metre, and the temperature, t , in degrees of the centigrade thermometer. Then, since m is a constant, its value is independent of the variations of v , p , and t , and in order to find it, we may make any suppositions we please with regard to these factors. To determine its value, let a be the normal atmospheric pressure of 0.76 metre referred to 1 square metre, = $10,333$ kilogr., let v be one cubic metre, and let t be 0° C. Then we see that m must be the atmospheric pressure on 1 square metre = $10,333$ kilogr. = H , and we have—

$$pv = H(1 + \alpha t) \dots\dots\dots (f)$$

In fig. 533 let distances measured parallel to the axis of abscissae, OV, represent volumes, and distances measured parallel to the axis of ordinates, OP, represent pressures. Then, since the condition of a gas is defined if p and v , two of the three variable quantities upon which it depends, are known, that condition may be represented by the position of a point relatively to the lines OP and OV. Let the point A represent the initial condition ($p \cdot v$) of a gas: we will consider the quantities of heat which must be imparted to, or withdrawn from, the gas, in order to make it pass through the series of conditions represented by the sides of the rectangle ADBC, parallel to OP and OV.

1. When the gas passes from the state A to the state D, its elastic force increases while its volume, v , remains unaltered; to produce this change, its temperature must be raised from t to the temperature t_1 , which is given by the equation $p'v = H(1 + \alpha t_1)$, which, combined with (f), $pv = H(1 + \alpha t)$, gives

$(p' - p)v = H\alpha(t_1 - t)$. Hence, putting D for the weight of a cubic metre of the gas at 0° , and c for its specific heat when kept at a constant volume, we have for the quantity of heat which must be imparted to the gas to produce the change in question, the expression—

$$q = Dc(t_1 - t);$$

Fig. 533.

$$t_1 - t = c' \frac{p' - p}{H\alpha}, \text{ therefore—}$$

$$q_1 = \frac{D}{H\alpha} c' v (p' - p) \dots \dots \dots (g)$$

2. When the gas passes from the condition D to the condition B, it remains under the constant pressure p' , but its volume increases from v to v' : its temperature must therefore be still further raised to t' , which is given by the formula $p'v' = H(1 + \alpha t')$. This combined with $p'v = H(1 + \alpha t_1)$, gives $p'(v' - v) = H\alpha(t' - t_1)$; hence the quantity of heat required will be $q_1 = Dc'(t' - t_1)$, c' denoting the specific heat under constant pressure. Putting for $t' - t_1$ its value deduced from the previous equation, this becomes—

$$q_1 = \frac{D}{H\alpha} c' p' (v' - v) \dots \dots \dots (h)$$

3. In passing from the condition B to the condition C, the gas is cooled without change of volume; the corresponding temperature t_2 is therefore given by the formula $p'v' = H(1 + \alpha t_2)$, which, combined with $p'v' = H(1 + \alpha t')$, gives $(p' - p)v' = H\alpha(t' - t_2)$. The heat that must be withdrawn will therefore be $q' = Dc'(t' - t_2)$, or, by substitution—

$$q' = \frac{D}{H\alpha} c' v' (p' - p) \dots \dots \dots (i)$$

4. Lastly, when the gas passes from the condition C to its original condition A, it cools under the constant pressure p , and its temperature again becomes t , defined by the formula $p'v = H(1 + \alpha t)$, which, combined with $p'v' = H(1 + \alpha t')$, gives $p(v' - v) = H\alpha(t_2 - t)$. The quantity of heat to be withdrawn, to cause the temperature to fall from t_2 to t , will be $q_1 = Dc'(t_2 - t)$, which, by substitution, becomes—

$$q_1 = \frac{D}{H\alpha} c' p (v' - v) \dots \dots \dots (k)$$

The general result is that, during the passage of the gas from the state A to the state B, a quantity of heat is expended which (by g and h) is represented by—

$$Q = q + q_1 = \frac{D}{H\alpha} [c v (p' - p) + c' p' (v' - v)]; \dots \dots \dots (l)$$

and that, during the return of the gas from the condition B to the condition A, a quantity of heat is evolved, which (by i and k) is expressed by—

$$Q' = q' + q_1' = \frac{D}{H\alpha} [c v' (p' - p) + c' p (v' - v)]. \dots \dots \dots (m)$$

Consequently, there is an ultimate expenditure of a quantity of heat equal to—

$$Q - Q' = \frac{D}{H\alpha} (c' - c) (p' - p) (v' - v),$$

a quantity which is necessarily positive, so long as $p' - p$ and $v' - v$ are positive (that is, so long as any actual increase of pressure and volume takes place), being proportional to the product of these two quantities, and represented by the area of the rectangle ADBCA.

By tracing in the same way the heat expended and evolved in the cycle of changes represented by the passage of the point A about the same rectangle, but in the opposite direction, ACBDA, it would be found that, as a final result, a quantity of heat $Q - Q'$ would be evolved by the process instead of expended. Hence we see that the quantity of heat necessary to change the condition of a gas from A (p, v) to B (p', v'), depends not only on the nature of the conditions A and B, but also on the manner in which the passage from one to the other takes place.

If B approaches indefinitely near to A, the quantity of heat, $Q - Q'$, expended or evolved as the point A passes round the rectangular circuit approaches indefinitely to the value 0. That is, in order to cause a gas to pass from the condition A to the condition B, infinitely near to it, the same infinitely small quantity of heat must be expended whether the passage is in the direction ADB, the direction ACB, or that of the diameter of the rectangle, AB. Hence, an element, AB, of any curve may be replaced by its two projections DA and DB parallel to the axes, and changes of condition represented by curve-lines may be considered as made up of rectangular elements parallel to these axes, so that the result derived from the consideration of the rectangular circuit ADBCA may be extended to a closed circuit of any form whatever. (Bourget, Ann. Ch. Phys. [3] lvi. 267; also Daguin's *Traité de Physique*, 2nd ed. ii. 512.—See further the section of this article: Relations of Heat to Mechanical Energy.)

Attention must here be drawn to an important consequence of the relations that we

have found to exist between the pressure, volume, and temperature of a gas. The consequence referred to will be most easily deduced from the above equations (4) and (5), which show that, when a gas expands from the volume v to the volume v' , under the constant pressure p , a quantity of heat is absorbed equal to

$$q = \frac{D}{H\alpha} c' p (v' - v),$$

and that when the gas contracts from the volume v' to the volume v , under the same pressure, an equal quantity of heat is evolved. It is plain, however, from the above equation, that if p , the pressure upon the gas, is nothing, the quantity of heat, q , needed to cause the gas to expand will also be nothing. This condition is actually fulfilled when, instead of having to force up a piston or overcome the pressure of the atmosphere in its expansion, a gas is allowed to expand into a vacuum space; and it has been experimentally proved by Joule that the expansion of a gas, under these circumstances, is not attended with expenditure or absorption of heat. He immersed two copper vessels in water, and removed the air from one and compressed an additional quantity of air into the other, until the pressure amounted to 22 atmospheres: on opening a communication between the two, air rushed from the latter vessel into the exhausted one until the pressure in both was 11 atmospheres. Nevertheless, the water by which they were surrounded indicated no alteration of temperature.

Absolute Zero of Temperature.—It results from the fundamental formula of gaseous expansion,

$$p v = J(a + t),$$

that, if the temperature, t , of a gas were reduced until it became $= -a = -273$, the gas would cease to have any gaseous elasticity—the product of elastic force into volume would be $= 0$. The temperature -273°C . is therefore called the absolute zero of temperature, and temperatures reckoned from it are called absolute temperatures. These are obviously obtained in any case by adding 273 to the number of degrees by which a temperature is expressed on the centigrade scale; and by employing them in the expression of the laws regulating the relations between temperature and other properties, the resulting expressions are often much simpler than those required when temperatures are expressed according to any ordinary thermometric scale. Thus, for instance, by using $\tau (= t + 273)$ to denote the absolute temperature corresponding to the centigrade temperature t , we have for the fundamental formulæ (a) and (b) (page 46) relating to pressure, volume, and temperature, the expressions

$$p v = J \tau \text{ and } \frac{p' v'}{p v} = \frac{\tau'}{\tau},$$

and corresponding simplifications will be found to result in many other cases.

Expansion of Liquids.—The relation between the volume of a given weight of liquid and its temperature follows no simple general law, such as that which, as we have seen, applies, at least approximately, in the case of gases. On the other hand, not only has almost every liquid a coefficient of expansion different from that of any other, but the coefficient of the same liquid varies to an important extent with changes of temperature.

In consequence of the small extent to which the volume of liquid substances is influenced by external pressure (ELASTICITY, ii. 370), it may, in all ordinary cases, be considered as a function of their temperature alone, instead of as a function of temperature and pressure combined, as with gases. It results also from the cohesion of liquids, which causes them always to have a definite limiting surface, that their volumes can be determined by observations of a more direct kind than those which can be made on gaseous bodies. Hence, an obvious method of determining the expansion of a liquid, is to observe how many divisions of a vessel graduated into parts of equal capacity, are filled by the same weight of it at various temperatures. Such a method, however, would only be exact if the capacity of the containing vessel were known, not merely at some one temperature, but at each temperature at which an observation of the liquid was made. Thus, it would be inaccurate to conclude that the expansion of a liquid between 0° and 100° amounted to 1 per cent., because the same quantity which filled 100 divisions at the former temperature occupied 101 divisions at the latter; for it is impossible to raise the temperature of a liquid, without at the same time raising the temperature, and so altering the capacity, of the vessel in which it is contained. It is therefore necessary to distinguish between the *apparent* expansion of liquids, or that which would result from observations made in the manner that has been described, without taking account of the changes of capacity of the containing vessel, and their *real* or *absolute* expansion, which is the apparent expansion corrected for the simultaneous expansion of the vessel. Of course, in measuring the changes of volume of gaseous bodies, the expansion of the containing vessel requires to be similarly taken

into account, but in this case it is of much less relative consequence than it is in the case of liquids: thus, for example, the apparent expansion of air in a glass vessel would only differ from its real expansion about in the proportion of 140:141; whereas, in the case of mercury, the difference would amount to one seventh of the total effect to be observed.

Relation between the Absolute and Apparent Expansion of Liquids.—From what has been already said, it will be evident that the apparent expansion of a liquid is equal to its absolute expansion for the same interval of temperature diminished by the corresponding expansion of the containing vessel. That is, if Δ be the coefficient of absolute expansion of a liquid, and δ its coefficient of apparent expansion, the relation between these two quantities will be the following:—Let V be the volume of the liquid, and consequently of that portion of the vessel which it fills, at 0° ; and let V' be the capacity, estimated at 0° , of so much of the vessel as it fills when its temperature has been raised 1° . Then the real volume of the liquid at the latter temperature will be $V(1 + \Delta)$, and the real volume of the portion of the vessel occupied by it will be $V'(1 + \kappa)$ (putting κ for the coefficient of cubical expansion of the material of the vessel): hence we have—

$$V'(1 + \kappa) = V(1 + \Delta),$$

or

$$\frac{V' - V}{V} = \frac{\Delta - \kappa}{1 + \kappa};$$

but $V' - V$ is the apparent increase of volume of the liquid, for a rise of temperature of one degree; $\frac{V' - V}{V}$ is therefore its coefficient of apparent expansion = δ . Accordingly—

$$\delta = \frac{\Delta - \kappa}{1 + \kappa}, \text{ or } \Delta = \delta + \kappa + \delta \kappa;$$

but as δ and κ are always small fractions, we may disregard their product, $\delta \kappa$, and put $\Delta = \delta + \kappa$: that is, the coefficient of absolute expansion of a liquid is equal to its coefficient of apparent expansion in a vessel of any material, increased by the coefficient of cubical expansion of the material of which the vessel is made.

By far the most accurate method of measuring the capacity of a vessel, and of finding the relative values of divisions which may be marked upon it, is to determine the weight of mercury which fills it up to the zero point of the scale, and also the weight which corresponds to the interval between any two divisions. But since both the capacity of the vessel and the specific gravity of mercury vary with variations of temperature, the different weights of mercury which fill the vessel at different temperatures do not at once enable its relative capacities at these temperatures to be calculated; for this it is necessary that the absolute expansion of mercury should be previously known. Hence the absolute expansion of mercury (which, on account of its inalterability and its property of not wetting glass, is better adapted for measuring purposes than any other liquid) is a necessary preliminary datum for the determination of the absolute expansion of liquids in general.

Determination of the Absolute Expansion of Mercury.—Enough has already been said to make it evident that, in order to obtain a trustworthy determination of this constant, some method must be devised whose results are wholly unaffected by changes in the capacity of the vessel in which the mercury is contained. A satisfactory solution of this apparently very difficult problem was first given by Dulong and Petit (*Ann. Ch. Phys.* [2] vii. 124 (1817); Daguin's *Traité de Physique*, 2nd ed. ii. 187; see also Regnault, *Relation des Expériences*, &c., pp. 277–280. Paris, 1847). Their method consisted in measuring the heights of columns of mercury at different temperatures, which produced equilibrium with another column of the same liquid of constant height, and kept always at 0° .

If h denotes the height of the column at 0° , d the density of mercury at this same temperature, h' the height of the column at t° , which produces equilibrium with the first, and d' the density of mercury at the temperature t , we have—

$$\frac{h'}{h} = \frac{d}{d'}.$$

Representing by v and v' the volumes of the same weight of mercury at 0° and at t° , we get—

$$\frac{d}{d'} = \frac{v'}{v}, \text{ and consequently } \frac{v'}{v} = \frac{h'}{h}.$$

The mean coefficient of expansion between 0° and t° is therefore—

$$\delta_t = \frac{v' - v}{vt} = \frac{h' - h}{ht},$$

and its determination requires only that the difference of height of the two columns, and the absolute height of the column at zero, should be accurately measured.

The apparatus employed by Dulong and Petit for the purpose of putting this method into practice is represented in *fig. 534*. It consisted of a kind of inverted glass syphon, the two vertical branches of which (A and B) were about 0.55 metre long, and communicated below by a horizontal tube of very small diameter. The branch A was surrounded by a cylinder of tinned iron which was kept full of ice; the other branch, B, occupied the middle of a cylindrical copper vessel filled with oil and built into a furnace.

Fig. 534.

(In the figure, the front wall of the furnace, as well as a part of the cylinders surrounding each branch of the syphon, is represented as having been removed.) The quantity of mercury in the apparatus was so adjusted that the meniscus in the tube B was a little above the cover of the oil-bath, and the difference in the height of the two columns was measured by a cathetometer (an instrument devised by Dulong and Petit, and first used in this investigation). The temperature of the oil-bath was indicated by an air-thermometer and a mercurial weight-thermometer (pp. 18, 19), the reservoirs of which were of the same length as the mercury-column in the tube B, and were placed near to and parallel with it.

The following table gives the general results of a great number of determinations made with this apparatus:

Absolute Expansion of Mercury (Dulong and Petit).

Temperatures by the air-thermometer.	Mean coefficient of Expansion counted from 0°		
	Maximum values.	Minimum values.	Mean values.
100° C. . . .	5327	5353	5355 = 0.00018018
200°	5319	5351	5335 = 0.0018433
300°	5325	5355	5355 = 0.0018868

Notwithstanding the great approach to accuracy which was undoubtedly made in these experiments, the results were still affected by sources of error which, in the determination of a physical constant of such primary importance as the one in question, cannot be considered as immaterial. The chief of these are: the uncertainty of the determinations of the temperature of the heated column, arising (1) from the employment of the old (and inaccurate) coefficient for the expansion of air, namely 0.00376,

in reducing the indications of the air-thermometer; (2) the cooling effect of the external air upon the portion of the heated column which rose above the cover of the oil-bath; (3) the want of uniformity in the temperature of the oil-bath at different depths; and the comparative shortness of the two mercury-columns, whereby a very small absolute error in the measurement of h and h' comes to have a considerable effect on the value of the fraction $\frac{h' - h}{h^2} = \delta$.

In order to obtain results which should be, as far as possible, free from the errors thus arising, Regnault (*Relation des Expériences*, &c., pp. 271-328. Paris, 1847) repeated the determination of the absolute expansion of mercury, by a method similar in principle to that of Dulong and Petit, but somewhat different in execution. The arrangement of his apparatus will be intelligible from fig. 535. AB and CD are two iron tubes, 1.5 metre long and 10 mm. in internal diameter (in the figure the diameter is greatly exaggerated in proportion to the length), connected above by the horizontal iron tube AC, of 2.5 mm. (0.1 inch) internal diameter, and respectively communicating below with the horizontal tubes BE and DF, likewise of 2.5 mm. diameter, which in their turn carry the vertical glass tubes EG and FG. The apparatus having been adjusted so that the tubes AB and CD are exactly vertical, and the tubes AC, BE, and DF exactly horizontal, mercury is poured into it through one of the short tubes, open at both ends, by which both AB and CD are surmounted, and in proportion as the liquid rises in the glass tubes EG and FG, air is compressed into a copper receiver communicating with them by the leaden pipe G, so as to keep the level of the mercury near the bottom of the glass tubes. The addition of mercury is continued until it begins to run out at a hole, O, bored in the upper side of the tube AC. The vertical tube AB is placed in the centre of an oil-bath; CD is surrounded by a constant current of cold water.

Fig. 535.

On heating the tube AB, the density of the mercury contained in it was of course diminished, and consequently equilibrium of pressure in the tubes EG and FG could only be maintained by the sinking of the mercury-column in the former. The elastic force of the compressed air in the receiver was therefore balanced—on the one hand, by the pressure of the heated column of mercury of the height AB, $= H$, diminished by that of the column in E, $= h$; on the other hand, by the pressure of the cold column CD, $= H'$, diminished by that of the column in F, $= h'$. The temperature of the column AB was indicated by an air-thermometer, that of CD by three mercurial thermometers in the water-vessel which surrounded it, and that of the mercury in E and F by a thermometer placed between them as shown in the figure. When the necessary corrections for the differences of temperature of the several mercury-columns had been applied, the formula for the absolute expansion became—

$$\frac{(H' - h') - (H - h)}{(H' - h')^2} = \delta.$$

But since the required corrections involved the knowledge of the very coefficient sought, the calculation could only be made by the method of successive approximations: that is, Dulong and Petit's coefficient was first assumed in order to calculate an approximate result; then the number so obtained was substituted for the old coefficient, and so a still more accurate result was arrived at.

In another series of experiments, the tubes AB and CD were connected at the bottom by a continuous horizontal tube, and the tube AC was cut across, vertical glass tubes being inserted into the two halves, wherein the different heights attained by the mercury-columns could be observed. In this state, the apparatus was merely a modified form of that employed by Dulong and Petit.

The results ultimately arrived at are given in the following table, the temperatures in the first column of which are those measured by the air-thermometer.

The numbers in the last column of this table represent the amounts by which a unit volume of mercury expands for a rise of temperature of one degree centigrade at various temperatures between 0° and 350° . Thus, 100,000,000 cubic millimetres of mercury, measured at 0° , occupy 100,017,905 cubic millimetres at 1° ; 100,000,000 cubic milli-

metres, measured at 300° , become 100,019,413 cubic millimetres at 301° . Accordingly, the true coefficient of expansion increases as the temperature rises. The third column contains the quotients obtained by dividing the difference between the volume (V_t) of mercury at t° and the volume of the same weight at 0° ($V_0 = 1$) by the number of degrees of temperature ($= t$), that is to say, the mean coefficient of expansion between 0° and t° , $\frac{V_t - 1}{t}$. Between 0° and 100° , the mean coefficients vary so little

that the real expansion of mercury, and much more therefore its smaller apparent expansion in glass, may be taken as proportional to the temperature measured by the air-thermometer. A careful comparison of an air-thermometer and a mercurial thermometer, upon which the points 0° and 100° had been determined under the same circumstances, and which therefore necessarily agreed at these temperatures, showed the following differences between the indications of the two instruments:

Temperatures by air-thermometer—

–36° 0° +100° 129.9° 148.7° 197.0° 245° 292.7° 340°;

Temperatures by mercurial thermometer—

–36° 0° +100° 130° 150° 200° 250° 300° 350°.

From Regnault's table it results that, if the real expansion of mercury be taken as the measure of temperature, the following readings of the air- and mercurial thermometers will indicate the same temperatures—

* In Regnault's original paper, the true coefficient of expansion at 100° is given, doubtless in consequence of a misprint, as 0.00018305, and the same number is repeated in various other places: e.g. *Handwörterb. der Chemie*, 2nd ed. ii. [1], 567, article *Ausdehnung*; also *DuRoi's Traité de Physique*, p. 193. Paris, 1861.

Air-thermometer—

0° 50° 100° 130° 150° 200° 250° 300° 350°;

Mercurial thermometer—

0° 49·6° 100° 130·5° 151° 202·8° 255·2° 308·3° 362·2°.

By a series of observations of the heights of two mercurial barometers, one of which was kept at a temperature near 0° C., while the other was heated to a higher temperature, Militzer (Pogg. Ann. lxxx. 55) obtained for the mean coefficient of absolute expansion of mercury between 0° and 100°, the number

$$0\cdot00017405 \pm 0\cdot00000082 = \frac{1}{5745\cdot4} \left(1 \pm \frac{1}{212}\right),$$

which differs considerably from Regnault's result, and is probably less accurate.

Apparent Expansion of Mercury, and determination of the Cubical Expansion of Glass vessels.—By help of the foregoing table of the absolute expansion of mercury, the cubical expansion of glass vessels may be determined. For this purpose the neck of the vessel is drawn out to a capillary point; it is filled with mercury, care being taken to exclude all moisture or air; exposed successively to the temperatures 0° and 100°, and weighed with the quantity of mercury which fills it at each of these temperatures. Let

the weight of the empty glass vessel be = w ,

the weight of the vessel filled with mercury at 0° = W ,

the weight of the vessel filled with mercury at 100° = W' ,

let Δ be the absolute expansion of mercury, and κ the cubical expansion of glass between 0° and 100°; then we have

$$\frac{W' - w}{W' - W} = \frac{1 + \Delta}{1 + \kappa}, \text{ and therefore } \kappa = \frac{W' - w}{W - w} (1 + \Delta) - 1.$$

When once the cubical expansion of a glass vessel is known, the absolute expansion of any liquid can be deduced, in the manner already explained (p. 53), from its apparent expansion as observed in this vessel. Hence a problem of frequent occurrence is to determine the expansion of the glass of a vessel shaped like a thermometer, and provided with a divided stem, for which the relative capacities of the bulb and of one division of the stem have been previously determined. In such a case, it is only necessary to fill the apparatus to some particular point of the scale with well-boiled mercury, and to observe the apparent volumes of the mercury, v and v' , at 0° and 100°, expressed in divisions of the scale: the expansion of the glass can then be calculated. For (p. 53) the apparent volume of the mercury at 100° is equal to its volume at 0° increased by the amount of its absolute expansion between 0° and 100°; that is:—

$$v' (1 + \kappa) = v (1 + \Delta), \text{ or } \kappa = \frac{v}{v'} (1 + \Delta) - 1.$$

The apparent expansion of mercury in glass varies with the kind of glass employed, but may be taken on an average = 0·0001545 for each degree centigrade. This value may be used, for instance, without hesitation in calculating the corrected length of the portion of the thread of mercury in a thermometer which is not exposed to the temperature that is to be measured. (See below, *Determination of Boiling Points.*) Between 0° and 100° the apparent volume of mercury in glass increases in the proportion of 1 : 1·01545, while the real volume increases in the proportion of 1 : 1·01815; hence the cubical expansion of glass is

$$\kappa = \frac{1\cdot01815}{1\cdot01545} - 1 = 0\cdot002663.$$

Another case in which the absolute expansion of mercury requires to be taken into account, is in reducing barometric observations to 0° C. (BAROMETER, i. 512, 513.)

Expansion of other Liquids.—The absolute expansion of any liquid can now be ascertained by filling with it a small glass bottle, whose cubical expansion has been previously ascertained in the manner already described, and weighing the bottle with the quantity of liquid which fills it at different temperatures. But a more rapid method, and therefore one more frequently adopted, is to observe the apparent expansion of the liquid in a dilatometer, an instrument shaped just like a common mercurial thermometer, and then to correct these observations for the previously known cubical expansion of the glass. In this way very numerous determinations have been made by Isidore Pierre (Ann. Ch. Phys. [3] xv. 325; xix. 193; xx. 5; xxi. 336; xxxi. 118; xxxiii. 199) and by Hermann Kopp (Pogg. Ann. lxxii. 1 and 223; Ann. Ch. Pharm. xiv. 257; xvi. 207; xcvi. 153 and 303; c. 19). The principal results of these investigations are given below.

Expansion of Water. (Kopp.)

Temperature.	Volume. (Volume at 0° = 1.)	Density. (Density at 0° = 1.)	Volume. (Volume at 4° = 1.)	Density. (Density at 4° = 1.)

The numbers in the second column of the above table, compared with that representing the volume of the same quantity of water at 0°, give the following four interpolation-formulae—

Between 0° and 25° C.

$$V = 1 - 0.000061045 t + 0.0000077183 t^2 - 0.00000003734 t^3.$$

Between 25° and 50°

$$V = 1 - 0.000065415 t + 0.0000077582 t^2 - 0.00000000000 t^3.$$

Between 50° and 75°

$$V = 1 - 0.00005916 t + 0.000003184 t^2 - 0.00000000000 t^3.$$

Between 75° and 100°

$$V = 1 - 0.00008645 t + 0.0000031892 t^2 + 0.00000000000 t^3.$$

It will be seen that, between 0° and a temperature of about + 4°, water presents the exceedingly rare phenomenon of a substance which contracts when heated and expands

EXPANSION OF WATER.

59

when cooled, so that at about 4° it is more dense than at any other temperature. According to the first of the above formulæ, the exact temperature at which water possesses its maximum density would be 4.08° . The results of other experimenters indicate in general very nearly the same temperature for this point. For example, Hållström fixed it at 4.1° , Despretz at 4° , Playfair and Joule at 3.95° , Hagen at 3.67° , Frankenheim at 3.86° , Plücker and Geissler at 3.8° (nearly), C. v. Neumann at 3.68° . Although the melting point of ice (0° C.) is also the point at which water freezes under ordinary circumstances, it may by special precautions be cooled much lower without becoming solid (p. 74). It is then found that the expansion which takes place when water is cooled from 4° to 0° , continues as the temperature sinks below the latter temperature. This is shown in the following table by Despretz (Daguin's *Traité de Physique*, ii. 205. Paris, 1861), which gives the volumes and densities of water for each degree from -9° to $+4^{\circ}$, compared with its volume and density at 4° as unity. The complete table, which extends from -9° to 100° , agrees in general very closely with that already given by Kopp; it is therefore not necessary to reproduce it here entire: the portion given corresponds to the last two columns of Kopp's table.

Expansion of Water between -9° and $+4^{\circ}$. (Despretz.)

Temperatures.	Volumes.	Densities.	Temperatures.	Volumes.	Densities.
-9°	1.0016314	0.998371	-2°	1.0003077	0.999692
-8	1.0013734	0.998628	-1	1.0002138	0.999786
-7	1.0011354	0.998865	0	1.0001269	0.999873
-6	1.0009184	0.999082	$+1$	1.0000730	0.999927
-5	1.0006987	0.999202	2	1.0000331	0.999966
-4	1.0005619	0.999437	3	1.0000083	0.999999
-3	1.0004222	0.999577	4	1.0000000	1.000000

Frankenheim (Jahresber. üb. Chemie, u. s. w., 1852, 51) calculated from Pierre's observations the following empirical formulæ, to express the volume of water at t° , compared with its volume at 0° taken as unity:

Between -13° and 0° .

$$1 - 0.00009417 t + 0.000001449 t^2 - 0.0000005985 t^3.$$

It is not necessary to give the other six similar formulæ which he calculated for other intervals of temperature up to $+98^{\circ}$, nor to reproduce any part of the table which he calculated by means of them, except the following numbers referring to temperatures below 0° :

Temperatures	-15°	-10°	-5°	0°
Volumes	1.0037584	1.0016851	1.0005819	1.0000000.

Tables of the expansion of water between 0° and 100° have also been constructed by Hagen (see Jahresber. üb. Chemie, u. s. w., 1856, 50), Kremers (*ibid.* 1861, 62), and others.

Kopp's table further shows that water expands more and more rapidly as the temperature rises. This property likewise is found to remain the same when, by increasing the pressure upon it, water is kept liquid at temperatures above 100° . Thus, for example, by observing under the microscope the apparent expansion of water in thermometer-tubes, Sorby (Phil. Mag. [4] xviii. 81) obtained results from which he calculated the following formula for its expansion between 0° and 200° :

$$V = 0.9977 + 0.000123 t + 0.00000330 t^2,$$

which accords closely with the formula which he calculated for the same interval of temperature from Kopp's experiments, namely,

$$V = 0.997686 + 0.0001101 t + 0.00000343 t^2.$$

Mendelajeff (Zentralbl. Chem. Pharm. 1861, 33; Ann. Ch. Pharm. cxix. 1) investigated the expansion of water above 100° with the following results:—

Temperatures.	Volumes of water at $0^{\circ} = 1.$	Volumes calculated by Kopp's formula.
99.9°	0.99903	1.0429
131.0	0.9979	1.0716
156.8	0.9970	1.1014

The presence of saline substances in solution in water renders its rate of expansion more uniform, both below and above 100° . [For determinations of the rate of expansion of aqueous solutions, see Kremers (Pogg. Ann. c. 394; Jahresber. ü. Chemie, u. s. w., 1857 [1] 44: chlorides of potassium, sodium, lithium, and barium.—Further, Pogg. Ann. cv. 360; Jahresber. 1858, 41: chlorides of calcium, cadmium, strontium, zinc, magnesium; bromides of potassium, sodium, lithium, barium, strontium.—Further, Pogg. Ann. cviii. 115; Jahresber. 1859, 48: bromides of strontium, calcium, magnesium, zinc, cadmium; iodides of potassium and sodium; hydrochloric acid.—Further, Pogg. Ann. cxi. 60; Jahresber. 1860, 45: iodides of lithium, barium, strontium, calcium, magnesium, zinc, cadmium.—Further, Pogg. Ann. cxiv. 41; Jahresber. 1861, 60: nitrates and sulphates of potassium, sodium, lithium; aqueous nitric and sulphuric acids), Gerlach (Jahresber. 1859, 42-43: chlorides of potassium, sodium, lithium, ammonium, magnesium, calcium, barium, aluminium; sulphates of potassium and sodium; carbonates of potassium and sodium; tartaric acid, citric acid, cane-sugar), and Sorby (*loc. cit.*: chlorides of potassium and sodium, sulphate of sodium).]

The temperature of maximum density of aqueous solutions is lower than that of pure water. In fact, with solutions of many substances, this temperature lies lower than the ordinary freezing-point of the solution, and is in general (as well as the freezing-point) lower the larger the proportion of saline matter contained in the solution.

Points of Maximum Density and Congelation of Aqueous Solutions. (Despretz.)

In the tables which follow, Kopp has collected together the results of his own and Pierre's determinations of the expansion of nearly ninety other liquids, chiefly organic. In each table, the several substances are arranged in the order of their boiling-points, beginning with the lowest. Except where the contrary is stated, the volume of each liquid at 0° C. is taken as the unit, with which its volume at higher temperatures is compared.

Table A (Ann. Ch. Pharm. c. 21) gives the expansion of seven nitrogenous compounds from the determinations of Kopp and Pierre.

EXPANSION OF LIQUIDS.

57

Table B (*ibid.* xvi, 188) gives the expansion of forty-two liquids, containing no other elements than carbon, hydrogen, and oxygen, according to the experiments of H. Kopp:—Table C (*ibid.* xvi, 804) gives the expansion of thirty-eight compounds containing sulphur, iodine, bromine, and chlorine, according to the experiments of Kopp and Pierre.

From the inspection of these tables it will be seen that, as a general, though not universal, rule, those substances expand most rapidly at ordinary temperatures whose boiling-points are lowest; that isomeric compounds having the same boiling-point, expand at the same or very nearly the same rate (e. g. formate of ethyl and acetate of methyl, $C^2H^5O^2$; propionate of ethyl and butyrate of methyl, $C^3H^7O^2$; butyrate of ethyl and valerate of methyl, $C^4H^9O^2$); that the rate of expansion of each liquid increases as the temperature rises. This last fact becomes still more apparent on comparing the coefficients of expansion at different temperatures (for a table of the true and mean coefficients of expansion of the liquids examined by Pierre, see Gmelin's *Handbook*, i. 226), and a consequence of it is that, when the volumes of different liquids are compared at the same number of degrees below their several boiling-points, the volume of each liquid at its boiling-point being taken as unity, the alterations corresponding to equal intervals of temperature are found to be often much more uniform than when the comparison is made (as in the tables which follow) for the same absolute temperatures. (Tables of Pierre's results, calculated for equal distances from the boiling-points, are given in Gmelin's *Handbook*, i. 227–230.)

Observations of the expansion of liquids by the methods already described are limited to temperatures below the ordinary boiling-points, but by special methods such observations can be extended to higher temperatures, and it is then found that the increasing rate of expansion continues up to the highest points at which determinations can be made, so that, under such circumstances, liquids may expand as rapidly as

HEAT.

* The volumes given by Drilon are the *apparent* volumes, uncorrected for the expansion of the glass: the corrected, or true, volumes would be a little greater.

gases, or even more rapidly, for equal increments of temperature. Determinations of the expansion of water above 100° , by Mendeleeff, have already been given (p. 59); the preceding table (p. 66) contains the results of the observations of Drion (Ann. Ch. Phys. [3] lvi. 5), Andr  eff (*ibid.* lvi. 317), and Mendeleeff (*loc. cit.*) on some other liquids at temperatures above their usual boiling points. To serve as a standard of comparison, the expansion of air is given in the last column of the table.

Expansion of Solids.—In speaking of the expansion of solid bodies, it is needful to distinguish between *linear* expansion, or the increase in length of a linear unit; *superficial* expansion, or the increase in the area of a unit of surface; and *cubical* expansion, or the increase in bulk of a unit of volume. If a solid body, whose length is A linear units, expands, when heated from 0° C. to 1° , so as to measure $A + a$ at the higher temperature, a portion of its surface containing A^2 superficial units at the lower temperature will become $(A + a)^2$ when expanded, and, at the same time, the volume A^3 will become $(A + a)^3$. We have therefore for the increase in length, or

$$\begin{aligned} \text{linear expansion,} & A + a - A = a; \text{ for the} \\ \text{superficial expansion,} & (A + a)^2 - A^2 = 2Aa + a^2; \text{ for the} \\ \text{cubical expansion,} & (A + a)^3 - A^3 = 3A^2a + 3Aa^2 + a^3. \end{aligned}$$

But since a is always a very small fraction of A , a^2 is also a very small fraction of a ; hence the second and third terms of these expressions may be omitted. Accordingly, the expansion of A linear units may be taken as a , the expansion of A^2 superficial units as $2Aa$, and the expansion of A^3 cubical units as $3A^2a$. The coefficients of linear, superficial, and cubical expansion, or the expansion of one unit of each kind, will therefore be respectively

$$\frac{a}{A}, \frac{2Aa}{A^2} = 2 \frac{a}{A}, \text{ and } \frac{3A^2a}{A^3} = 3 \frac{a}{A};$$

that is to say, the coefficient of superficial expansion is *twice* as great, and the coefficient of cubical expansion *three times* as great as the coefficient of linear expansion.

When a hollow vessel is heated, its capacity increases to exactly the same extent as it would do if filled with the substance of which its sides are composed; that is, its expansion is the same as the cubical expansion of a solid mass of the same material and dimensions. If κ be the coefficient of cubical expansion of any kind of glass for a rise of temperature of 1° C., a vessel made of this glass and having the capacity V_0 at 0° , would have at t° the capacity $V_t = V_0(1 + \kappa t)$. Similar considerations are applicable in the case of a glass vessel which is divided into parts of equal capacity by a scale etched upon the side, when the space comprised between two consecutive divisions at 0° is taken as the unit of capacity. The apparent volume V_t , read off at t° , would then correspond to the real volume $V_0(1 + \kappa t)$ referred to the unit adopted.

Determinations of Linear Expansion.—The linear expansion has been measured for the greater number of such substances as can be obtained in the form of rods or bars of considerable length. For the purpose of such measurements, one end of the bar is fixed immovably, and its length is measured, by means of micrometric apparatus attached to the other end, at two known temperatures, such as 0° and 100° C., which can be maintained constant sufficiently long to make it certain that they have been attained by the bar throughout its whole mass. The following table of linear expansions between 0° and 100° C. is from Ure's *Dictionary of Chemistry*, ed. 1836, pp. 271, 272.

The last two measurements by an air-thermometer.

Messrs. Calvert, Johnson, and Iowe have determined the linear expansion of a considerable number of metals and alloys by a modification of the method above described, for the details of which we must refer to the original paper published in the *Mechanics Magazine*.

The following are the linear expansions of simple metals between 0° and 100° C. thus determined:—

Cadmium (pure)	0·00332
Lead (pure)	0·00301
Tin (pure)	0·00273
Aluminium (commercial)	0·00222
Zinc, forged (pure)	0·00220
Silver (pure)	0·00199
Gold (pure)	0·00138
Bismuth (pure)	0·00133
Wrought iron	0·00119
Cast iron	0·00112
Steel (soft)	0·00103
Antimony (pure)	0·00098
Platinum (commercial)	0·00068

From the preceding table it will be seen that the coefficients of expansion of the metals vary with their physical condition, being different for the same metal according as it has been cast, hammered and rolled, hardened, or annealed. As a general rule, those operations which increase the density, appear also to increase the rate of expansion by heat. But even for substances in apparently the same condition, different observers have found very unequal amounts of expansion; this may arise, in the case of compound substances, such as glass, brass, or steel, from a want of uniformity in chemical composition, and in simple bodies from slight differences of physical state. Hence, in all cases where great accuracy is required in the determination of the linear expansion, as in rods employed for pendulum observations, or for the measurement of the base-lines of surveys, it is impossible to rely upon the results of previous determinations of the expansion of the material in question; but the linear expansion of each individual rod must be determined by a special experiment: this was done, for instance, by De Borda, with each of the four platinum measuring rods (each two toises, or twelve French feet long), which were employed in the measurement of the arc of meridian, from which the length of the metre was deduced.

Copper rods were laid upon the platinum rods, and both were firmly fixed together at one end; the copper rods carried a divided scale at the other end, which indicated directly the twenty-thousandth part of their length, while by means of a vernier attached to the corresponding end of the platinum rods, tenths of these divisions, or about the one-hundredth part of a French line, could be read off. In this way, the difference in the expansion of two rods of the same length but different materials can be determined with great accuracy, and if the coefficient of expansion for the material of one rod is known, the coefficient of that of the other can be calculated.

If both rods have the same length, L , at 0°, and at t° one has the length $L' = L(1 + \alpha t)$, the other the length $L'' = L(1 + \alpha' t)$, we have $L' - L'' = L t (\alpha - \alpha')$. But $L' - L''$ is the observed difference of length at the temperature t° ; and hence if α is known, α' is easily calculated. In this way, Dulong and Petit deduced the linear expansion of copper from that of platinum.

If, on the other hand, the expansion of the material of two rods thus united is known, and can be taken as proportional, within certain limits of temperature, to the indications of the mercurial thermometer, the combination of the two rods may be employed as a metallic thermometer. The measurement of temperatures in this way is specially valuable in the case of standard measures of length, which can thus be made to indicate their own temperature. If, for instance, the two rods have the same length at 0°, and differ at 100° by the amount D , and at t° by the amount d , the tem-

perature is given by the equation $t = \frac{d}{D} 100$.

The unequal expansion of different metals has been taken advantage of for the construction of thermometers of another kind. If two straight strips of different metals are fastened together throughout their whole length, any variation of temperature must cause the compound strip to bend, so that the least expanded metal will be on the concave side, and the most expanded metal on the convex side of the curve. Breguet's thermometer, constructed upon this principle, is made from a compound plate of platinum, gold, and silver, soldered together, the gold in the middle. This is rolled out very thin, and cut into very narrow strips, which are coiled round into spirals. The thermometer consists of such a spiral suspended by one end from a support, and carrying a needle which swings round a divided circle at the other.

Supposing the silver to be inside of the spiral, any rise of temperature will be indicated by the untwisting of the spiral, and a fall of temperature by its twisting more tightly. The small mass of this instrument, and the low specific heat of the materials composing it, cause it to indicate changes of temperature very rapidly, and to be affected by very small quantities of heat.

Determinations of Cubical Expansion.—When the coefficient of linear expansion of a substance is known, its coefficient of cubical expansion is obtained by multiplying the linear coefficient by 3, as already explained (p. 67). The cubical expansion can also be ascertained by direct measurement. The following method was employed by Dulong and Petit for this purpose: Into a glass tube, 18 millimetres wide, 6 decimetres long, and closed at one end, they introduced a rod, previously weighed, of a metal not attacked by mercury. Let W' be its weight. The tube was then drawn out at the open end and bent as in *fig. 536*, after which it was filled with pure mer-

Fig. 536.

cury, and boiled out to remove every trace of air, exactly as in filling a mercurial thermometer. In this state the apparatus was placed horizontally, and surrounded with

melting ice, the point dipping below the surface of mercury contained in a small capsule. It was thus filled with mercury at 0° . The capsule was next emptied, replaced under the point, and the apparatus allowed again to assume the temperature of the atmosphere. Then, by weighing together the tube and capsule, and deducting from the gross weight their weight before the introduction of the mercury, they obtained the weight, W , of the mercury which exactly filled at 0° so much of the capacity of the tube as was not occupied by the metal rod. The experiment was completed by heating the instrument in an oil-bath to a high temperature, t , and weighing the quantity of mercury which escaped from the point, as in the determination of a temperature by means of the weight-thermometer (p. 18).

If D_0 and D_0' represent the densities at 0° of mercury and of the metal; Δ , α , and κ , the coefficients of cubical expansion of mercury, of the metal, and of glass respectively, their volumes at 0° will be represented by

$$\frac{W}{D_0}, \quad \frac{W'}{D_0'}, \quad \text{and} \quad \left(\frac{W}{D_0} + \frac{W'}{D_0'} \right);$$

and if w is the weight of mercury which escapes from the tube between 0° and t° , the weight of mercury remaining in the tube at the latter temperature will be $W - w$. Then putting the volume of this weight of mercury at the temperature t , together with that of the metal rod at the same temperature, equal to the capacity of the tube which contains them, we have

$$\frac{W - w}{D_0} (1 + \Delta t) + \frac{W'}{D_0'} (1 + \alpha t) = \left(\frac{W}{D_0} + \frac{W'}{D_0'} \right) (1 + \kappa t);$$

whence

$$\alpha = \frac{w D_0'}{W' D_0 t} + \frac{D_0'}{W'} \left\{ \left(\frac{W}{D_0} + \frac{W'}{D_0'} \right) \kappa - \left(\frac{W - w}{D_0} \right) \Delta \right\}$$

It is of course necessary that the values of Δ and κ should have been determined by previous experiments in the way already described.

Another, to some extent similar, method of measuring the cubical expansion of solid bodies, consists in determining their specific gravities at various temperatures, the bulk of a given weight of a substance being inversely as its density.

In applying this method, the weight of water free from air which fills a specific-gravity bottle at various temperatures is first ascertained; then, the weight of the bottle is determined at the same temperatures after a known weight of the substance

under examination has been put into it, and the interstices filled with water. Let W be the weight of water which fills the bottle at the temperature t , W' the weight of the solid substance, and S the weight of water and solid substance which together fill the bottle at t° ; then the density of the substance at t° , compared with that of water at the same temperature, is $D_t = \frac{W}{W - (S - W')}$; and if V_t represents the bulk which a unit-volume of water measured at 0° assumes at t° , the density of the substance at t° , compared with that of water at 0° , is $\frac{D_t}{V_t} = D_0$. Lastly, if the density D_0 of the substance at some other temperature t° , has been determined in the same way, its mean coefficient of cubical expansion for one degree between t° and t'° is $\frac{D_0 - D_0'}{(t' - t)D_0}$.

The cubical expansion of a considerable number of crystallised compounds has also been determined by Joule and Playfair (*Chem. Soc. Qu. J. i. 121*; for a table of the results, see also *Gmelin's Handbook*, i. 234).

From the determinations given at the beginning of this table, it will be seen that the coefficients of expansion of solid bodies become greater as the temperature rises; but that the coefficient of expansion of platinum, which at the temperatures of the experiments is very far from the point at which fusion or softening occurs, increases much less than the coefficients of expansion of the more fusible metals, copper and iron. The rule thus indicated has been found to be verified in other cases also, so that with solids, as well as with liquids, the coefficients of expansion remain sensibly constant at temperatures far removed from those at which change of state occurs, and vary more and more rapidly as these latter temperatures are approached.

The expansion of amorphous solids, and of those which crystallise in the regular system (*CRYSTALLOGRAPHY*, ii. 121), is the same for all dimensions, unless when they are subject to a mechanical strain in some particular direction. A fragment of such a substance varies in bulk with variations of temperature, but retains always the same shape.

Crystals not belonging to the regular system exhibit when heated an unequal expansion in the direction of their axes, in consequence of which the magnitude of their angles becomes altered (*Mitscherlich*, *Pogg. Ann.* i. 125; *x. 137*). In crystals belonging to the trimetric system, the expansion is different in the direction of all three axes; in arragonite, on raising the temperature from 0° to 100° , the inclination of the lateral faces increases by $2' 46''$, and that of the terminal faces diminishes by $5' 29''$; gypsum is, according to *Fresnel* (*Bull. des Sc. Mathem.* 1824, 100; also *Pogg. Ann.* ii. 109), more expanded by heat in the direction of the principal axis than in that of the lateral axes. In crystals belonging to the hexagonal system, the expansion is the same in the directions of the three secondary axes; but different from that according to the principal axis. The obtuse angles of the primitive rhombohedron of calc spar diminish by $8\frac{1}{2}'$ when the crystal is heated 100° , and the acute angles increase by the same quantity. Hence it may be calculated that the relative expansion of the principal axis (compared with that of the secondary axes) amounts to 0.00342; moreover since, according to *Mitscherlich* and *Dulong*, the cubical expansion of calc spar between 0° and 100° is only 0.001961, it may likewise be determined that calc spar, when thus heated, does not expand in the direction of the secondary axes, but contracts by 0.00056, and that the absolute expansion of the principal axis may be estimated at 0.00286. In bitter-spar, the obtuse angle of the primitive rhombohedron diminishes when the temperature is raised from 0° to 100° by $4' 6''$, in ferruginous bitter-spar by $3' 29''$; in iron-spar containing a considerable quantity of manganese, by $3' 31''$, and in pure iron-spar by $2' 22''$. Since now, among all these minerals, calc spar forms the least, and ferruginous bitter-spar the most obtuse rhombohedron, it follows that the expansion in the direction of the principal axis does not increase in the same proportion as the relative length of the axis itself diminishes (*Mitscherlich*).

The following direct determinations of the linear expansion of several crystallised substances, between 0° and 100° , made by *Pfaff* (*Jahresber.* 1858, 7), show very distinctly the inequality in the amounts of expansion in the direction of the different axes.

NOTE.—A minus sign (-) in the last column denotes contraction, instead of expansion.

This alteration of shape caused by change of temperature is most easily rendered evident in gypsum, of which substance twin-crystals often occur, having pretty nearly

the form shown in *fig. 537*. From such a crystal, a portion *ab, cd* is cut, so that the new surfaces are perpendicular to the surface of combination, *mn*, of the two halves of the crystal, and the face *ab* is ground and polished. At the temperature of the atmo-

Fig. 537.

Fig. 538.

sphere, this surface then constitutes a single, unbroken plane; but when it is heated to about 60° or 80° C., the shape of the crystal alters in the manner shown in *fig. 538*, and now parallel rays of light falling on the two halves from a distant object are reflected in different directions, so that two distinct images of the object may be seen simultaneously by reflection from the surface *ab*.

One or two solid bodies are known which, at least within certain limits of temperature, form exceptions to the general rule of expansion by heat, and contract as their temperature is raised. For example, the alloy of 2 pts. bismuth, 1 pt. tin, and 1 pt. lead, expands when heated from 0° to 44° C.; when still further heated, it contracts, so that at 56° its density is the same as it was at 0° , and at 69° still greater; beyond this temperature, expansion again takes place; at 87.5° the alloy has once more the same density as at 0° , and at 94° , at which it fuses, the same as at 44° . (Erman, *Pogg. Ann.* ix. 557. For the not quite concordant results of H. Kopp, see below, p. 78.)

Again, a piece of vulcanised caoutchouc, which is stretched by a weight to double its length, is shortened by a tenth when its temperature is raised 50° C., and the shortening effect increases rapidly with the stretching weight employed. (Joule, *Proc. Roy. Soc.* viii. 356.)

Relation between the Specific Heats of Liquid and Solid Bodies, and their Coefficients of Expansion at different temperatures.—It has been pointed out above (p. 40), that the specific heat of any substance includes, not only the portion of heat required to cause in it a given alteration of temperature, but also the quantity of heat which is expended in modifying its condition of molecular equilibrium, and whose most obvious external effect is an alteration of the volume of the substance. We have also seen (p. 44), that although no certain data exist for calculating the ratio of these two parts of the total specific heat, except in the case of gases, it is nevertheless probable that the former part, or the *real specific heat* of a substance, remains the same for all conditions. Hence variations in the total or *apparent specific heat* must be supposed to result from variations in the amount of heat expended in overcoming the molecular forces. In sensibly perfect gases, the consumption of heat in this manner is the same at all temperatures, and so small as to be negligible; accordingly, both the real and apparent specific heats of gases are constant at all temperatures (pp. 34 and 42). On the other hand, the molecular changes which accompany alterations of temperature in liquid and solid bodies are such as require the expenditure of very considerable quantities of heat to produce them. These changes doubtless consist in alterations of the relative position or arrangement of the molecules, but of what precise kind we have no means of ascertaining, since the only measurable portion of the total effect is the externally visible change of volume.

This change of volume cannot be taken as in every case a measure of the amount of molecular work performed by the heat independently of causing alteration of temperature; for, as we have seen (p. 59), the communication of heat to water below 4° C. causes a change of bulk of the opposite kind to that which it occasions above that temperature; but we may nevertheless probably admit without great error that, as a general rule, the proportion of the total quantity of heat required to raise the temperature of a given substance 1° , which is consumed in producing molecular changes, is greatest at those points of the thermometric scale at which the greatest amount of expansion accompanies a rise of temperature of 1° , and is least at those points at which the corresponding expansion is least. If this supposition be admitted, it accounts satisfactorily for the fact that both the specific heats of solid and liquid bodies and their coefficients of expansion increase, as a rule, with rise of temperature; and that both

these properties vary most rapidly in the neighbourhood of those temperatures at which changes of the state of aggregation occur (Comp. Verdet, *Exposé de la Théorie Mécanique de la Chaleur*, Paris, 1863, note G, pp. 133 *et seq.*; also Regnault, *Mem. Acad. Sciences*, xxvi. 285 *et seq.*) On the relations between changes of volume produced by external forces and the corresponding evolution or disappearance of heat, see below: Relations of Heat to Mechanical Energy.

3. Changes of State of Aggregation produced by Heat.

Fusion and Solidification.—When the temperature of a solid body is raised continuously, a point is reached sooner or later at which it melts, or exchanges the solid for the liquid form; and when a liquid is cooled, a point is in like manner attained at which it solidifies. With most homogeneous substances, the passage from the one state to the other takes place suddenly at some particular temperature; thus ice, when heated from a lower temperature to 0° C., becomes only very slightly softer or less solid, while if more heat still is imparted to it, it changes at once into perfectly liquid water. This temperature forms a definite limit below which we have solid ice, and above which we have liquid water, and it is therefore called the *melting point* of ice. Some substances, however, pass when heated from the solid to the liquid state without showing any definite melting point; for example, glass and iron become gradually softer and softer when heated, and pass by imperceptible stages from the solid to the liquid condition. Such substances may be said to begin to melt at the lowest temperature at which perceptible softening occurs, and to be fully melted when further elevation of temperature does not make them sensibly more fluid; but no precise temperatures can be given as their melting points.

Subject to the qualifications hereafter stated, the following general laws may be taken as applicable to the phenomena of fusion and solidification:—

1°. The state of aggregation of every substance is always the same at the same temperature: when its temperature is raised, it melts at a certain fixed point, or passes from the solid to the liquid state, and when its temperature is lowered, it solidifies, or passes from the liquid to the solid state, at a point which is also fixed, and is the same as its melting-point. (For substances which melt gradually, a certain fixed interval must be substituted for a fixed point of temperature in the enunciation of this rule.)

2°. The communication of heat to a solid body at its melting point causes it to melt, but does not raise its temperature; so also the withdrawal of heat from a liquid at its freezing point causes it to solidify, but does not lower its temperature.

3°. As a general rule, a sudden change of volume (usually an increase) accompanies the passage from the solid to the liquid state.

We will proceed to consider each of these laws and the exceptions and modifications to which they are subject.

Melting and Freezing Points.—Though the temperature at which the passage from the solid to the liquid state takes place, and *vice versa*, is constant (under the same circumstances) for each substance, the melting and freezing points of different substances vary within very wide limits. Thus sulphurous anhydride melts at -80° (Mitchell, *Berzel. Jahresber.* xxii. 59), mercury at -40° , bromine at -7.3° , ice at 0° , phosphorus at $+44^{\circ}$, tin at 235° , silver at 1000° , platinum at 2000° (Deville and Debray). (For the melting points of particular substances, see the articles in this Dictionary where they are respectively described.)

These differences are sufficient to justify the conclusion that even those substances which have never been seen to melt, would do so at a sufficiently high temperature, and conversely that all liquids, even such as have never yet been frozen, would solidify if exposed to a still more intense degree of cold. Indeed, in proportion as new methods of producing extreme temperatures have been discovered, the number of fusible solids and non-solidifiable liquids has gone on diminishing continually. The only substances which can be considered really infusible are those which, when heated, undergo chemical alteration before their melting point is reached. The most infusible of all substances which are chemically inalterable by heat is, probably, carbon in the form of graphite, and even this body was found by Despretz to soften when exposed to the heat produced by the electric current generated by 600 Bunsen's cells arranged in six series of 100. On the other hand, absolute alcohol, sulphide of carbon, and some other liquids have never been solidified, but at the temperature produced by a mixture of liquid nitrous oxide, solid carbonic anhydride, and ether, Despretz found that absolute alcohol became so viscous that it did not run out on inverting the vessel that contained it.

In very many cases, it happens that a mixture of two or more substances melts at a lower temperature than either of its components taken separately: thus, a mixture of 1 part chloride of sodium with $2\frac{1}{2}$ or $2\frac{3}{4}$ parts ice, melts at about -20° ; mixtures of fatty acids melt at lower temperatures than the pure acids; the carbonates of potassium

FUSION AND SOLIDIFICATION.

and sodium melt more easily when mixed than either salt does alone; Rose's fusible alloy of 2 parts bismuth, 1 part tin, and 1 part lead, melts between 95° and 98° ; an alloy of 1 or 2 parts cadmium with 2 parts tin, 4 parts lead, and 7 or 8 parts bismuth, melts between 66° and 71° (B. Wood); &c.

In homologous series of analogous organic compounds, the melting point of each term usually rises with its atomic weight.

Under particular circumstances liquids may be cooled below the melting point of the corresponding solid body, without solidifying. This occurs especially when they are cooled very slowly, and are at the same time protected from all mechanical disturbance. For instance water at perfect rest, and under a pressure somewhat greater than that of the atmosphere, may be cooled to -16° without freezing, but contact with a solid body or the slightest agitation is then usually sufficient to cause solidification to commence. The smaller the quantity of liquid operated upon, the lower is the temperature to which it can be cooled, and the greater the mechanical disturbance which it will support without freezing. Thus, Fournet (Ann. Ch. Phys. [3] xlii. 203) has remarked the frequent occurrence of mists formed by particles of liquid water suspended in an atmosphere of which the temperature was 10, 12, or even 15 degrees below zero; and Sorby found that in glass tubes of 0.1 millimetre in diameter, water could be maintained in the liquid state as low as -17° .

Some remarkable phenomena of this kind have been also observed by Dufour (Ann. Ch. Phys. [3] lxxviii. 370) in the case of liquids cooled without contact with any solid body. His method of experimenting was to suspend globules of the liquid under examination in some other liquid of the same specific gravity, but of lower freezing point, and in which it was insoluble. Water was examined while suspended in a mixture of chloroform and sweet oil of almonds; sulphur and phosphorus, in an aqueous solution of chloride of zinc; and naphthalene, in water. In the experiments with water, the spheres of this liquid which floated in the mixture of chloroform and oil were very rarely seen to freeze at 0° ; in general, solidification occurred between -4° and -12° , the smallest globules, as a rule, remaining liquid to a lower temperature than the larger ones, some of them having been repeatedly seen still liquid at -18° or -20° . Agitation and the contact of solid bodies appears to have much less effect in causing the solidification of liquids cooled in this way than when they are cooled to the same extent in glass vessels. For instance, Dufour found that the globules of water in his experiments often did not solidify when displaced or violently deformed by a glass rod, and even that crystals of chloride of sodium, sulphate or nitrate of potassium, sugar, &c., would sometimes fall through a globule of water 5 millimetres in diameter, and cooled to at least -8° , without producing any effect. Contact with a fragment of ice, however, invariably caused immediate congelation.

By operating as above described, Dufour obtained globules of sulphur (melting point 115°) of 6 millimetres diameter still liquid at 40° , and globules of 0.5 millimetre diameter remained liquid for several days at 5° or 10° . Globules of phosphorus of considerable size were cooled to 20° , and globules of 1 or 2 millimetres diameter to 0° without solidifying. Globules of naphthalene (melting point 79°) were obtained still liquid at 40° .

When a liquid solidifies after having been thus cooled below its normal freezing point, the solidification takes place very rapidly, and is accompanied by a disengagement of heat often sufficient to raise its temperature from the point at which solidification begins up to its ordinary freezing point. This is well seen with crystallised hyposulphite of sodium ($\text{S}^2\text{Na}^2\text{O}^3, 6\text{H}^2\text{O}$), which melts in its water of crystallisation at 45° , but when carefully cooled will remain liquid for a long time at the temperature of the atmosphere. If it be then caused to solidify, by agitation, or by throwing in a small fragment of the solid salt, the resulting rise of temperature is such as to be distinctly felt by the hand.

This phenomenon of continued liquidity, though seldom observed in so marked a degree as in the cases above mentioned, occurs so frequently to a less extent, that, when the temperature of transition from the solid to the liquid state or *vice versa* is to be used as a mark of the chemical identity of a substance, it is much safer to determine the melting point than the freezing point, for the former temperature is not subject to variations of the same kind.

The following method is convenient for taking the melting points of substances in chemical investigations. Three or four glass tubes are drawn out till their sides become very thin and their bore nearly capillary, and into each is introduced a small quantity of the substance to be examined. They are then sealed at the bottom and placed in a beaker-glass containing water (or, if the substance melts above 100° , paraffin or sulphuric acid), and standing upon a small sand-bath by means of which its temperature can be slowly raised. The liquid is heated until the substance melts; then allowed to cool slowly to the point of solidification; it is then again warmed, and

these operations are repeated, the temperatures of liquefaction and solidification being noted each time, until several closely concordant observations of each have been obtained, the means of which are the melting and solidifying points required.

Influence of Pressure upon Melting Points.—The variations which occur in the pressure of the atmosphere are without perceptible effect in altering the melting points of solids or freezing points of liquids, but greater differences of pressure are found to produce a very sensible effect. This was first observed by Prof. W. Thomson, who found that pressures of 8.1 and 16.8 atmospheres caused a lowering of the melting point of ice to the extent of 0.059° and 0.129° respectively. These results, therefore, verified the previous theoretical conclusions of Prof. J. Thomson, according to which an increase of pressure amounting to n atmospheres must lower the melting-point of ice by $t^{\circ} = n \cdot 0.0075^{\circ}$,—a formula which gives 0.061° and 0.126° as the differences of melting point corresponding to 8.1 and 16.8 atmospheres pressure. By a still greater pressure, Mousson (Ann. Ch. Phys. [3] lvi. 252) succeeded in maintaining water in the liquid state at 5 degrees below zero, and by a pressure estimated at 13,000 atmospheres he caused ice to melt at -18° . Analogous effects have been observed with other substances by Bunson (Jahresber. über Chemie, u. s. w., 1850, 48) and Hopkins (*ibid.* 1854, 48). Their results are given in the following table. Bunson considers that the observations of temperature in his experiments were correct within 0.1° , but that there may be an error of one or two atmospheres in the estimation of the pressures.

Latent Heat of Fluidity.—It has been pointed out already (p. 73) that the specific heats of solid bodies increase as they approach their melting points, and this fact has been connected with the increase of the coefficient of expansion which generally occurs simultaneously. In order to raise the temperature of a solid body 1 degree in the neighbourhood of its melting point, more heat is needed than would suffice to cause an equal rise of temperature at a lower part of the thermometric scale; in other words, of a given quantity of heat imparted to a body near its melting point, a larger proportion goes to produce molecular modifications (expansion, softening, &c.), and a smaller proportion to produce rise of temperature, than is the case at a lower part of the scale. From this point of view, it becomes quite conceivable that, at some particular temperature, depending on the nature of the substance under consideration, the whole quantity of heat communicated to a body might be expended in causing molecular changes (change of the state of aggregation, with or without change of volume, &c.), so that its effect in producing a rise of temperature would be imperceptible. This is exactly what takes place during the melting of solid bodies.

From these considerations we see that the phenomenon indicated in the second law of the passage from the solid to the liquid state of aggregation (p. 74) is one which attains its maximum degree of development at the point of actual liquefaction, but is the same in kind as what occurs at lower temperatures. We see also that the fusion of glass and other bodies which have no definite melting point, but in which liquefaction occurs gradually and extends over a greater or less interval of temperature, does not differ in any essential respect from the sudden melting of ice at the fixed temperature of 0° C. In the case of glass, a certain small proportion of the total quantity of heat imparted to it during its liquefaction, is expended in causing elevation of temperature; in the case of ice, this proportion is so small as to be imperceptible in comparison with that which goes to cause liquefaction.

It was formerly supposed that the temperature of a body was always proportional to the heat contained in it, and therefore that heat could not be communicated to a body without raising its temperature. The cessation of the rise of temperature during the fusion of solids was first observed by Black, while Professor of Chemistry in the University of Glasgow. He ascertained that, during this process, a considerable quan-

tity of heat, different for different substances, disappears so far as the production of thermometric effects is concerned—or, as he expressed it, becomes *latent*—and that an equal quantity of heat appears during solidification. According to modern views, the expression *latent* (or hidden) *heat* is not strictly correct, for the effect of heat imparted to ice at the melting point is just as visible, though not the same, as that which it produces at other temperatures. Nevertheless, the expression is convenient from the fact of its being universally recognised and employed. The latent heat of fluidity is, then, the quantity of heat which must be imparted to one gramme of a solid at its melting point in order to melt it without raising its temperature, or which must be withdrawn from a liquid at its freezing point, in order to render it solid without lowering its temperature.

The following table gives the melting points and latent heats of fluidity, expressed in ordinary heat-units (gramme-degrees), of various substances, according to the determinations of Person (Ann. Ch. Phys. [3] xxvii. 250):—

Latent Heats of Fluidity.

Substance.	Melting Point.	Latent Heat.	Substance.	Melting Point.	Latent H. at.
Mercury . . .	—39°	2·82	Tin . . .	235°	14·25
Phosphorus . .	44	5·0	Silver . . .	1000	21·1
Lead . . .	332	5·4	Zinc . . .	433	28·1
Sulphur . . .	115	9·4	Chloride of calcium } (CaCl. 3H ² O) }	28·5	40·7
Iodine . . .	107	11·7	Nitrate of potassium .	339	47·4
Bismuth . . .	270	12·6	Nitrate of sodium .	310·5	63·0
Cadmium . . .	320	13·6			

The latent heat of water was found by Regnault and by Provostaye and Desains to be 79° C. According to Person, this number denotes the quantity of heat required to convert ice at 0° C. into water, but not the total quantity of the latent heat in the water, inasmuch as a certain additional portion of heat is rendered latent as the temperature of the ice rises from —2° to 0° (Ann. Ch. Phys. [3] xxx. 73). In six experiments on the fusion of ice previously cooled to between —2° and —21° C., the latent heat was found to vary between 79·9° and 80·1°, the mean quantity being 80°. Regnault also found greater values for the latent heat of water, as the ice had been cooled to a lower temperature. According to Hess, the true latent heat of water is 80·34° C. It has been proved by E. Desains (Ann. Ch. Phys. [3] lxi. 419) that when water is cooled below 0° without freezing, the quantity of heat needed, in order to raise the temperature of a given weight from w° below zero to t° above zero, is the same whether the water remains liquid all the time, or whether it first freezes and afterwards melts again.

It is interesting to compare these values of the latent heat of water with those found by Black in 1762 (*Lectures on the Elements of Chemistry*, 2 vols. 4to. Edinburgh, 1803; vol. i. pp. 120–127). In one experiment, this philosopher measured the time required for the conversion of a known quantity of ice at 32° F. into water at 40° F. in a room of which the temperature remained constantly at 47° F., and compared it with the time during which the temperature of an equal weight of water rose under similar circumstances, from 33° F. to 40° F. He thus obtained for the latent heat of water the number 139° F., equal to 77·2° C. In another experiment, he melted 119 parts of ice at 32° F. by immersing it in 135 parts of water at 190° F., and so obtained 254 parts of water at 53° F. Hence, taking into account the different specific heats of the water and of the glass in which it was contained, he deduced the number 143° F., equal to 79·44° C.

The method adopted by Black in the second of these experiments is essentially the same as that still employed for the determination of latent heats of fluidity. A known weight of the substance to be examined is heated to a known temperature, and then immersed in the water (or other liquid) of a calorimeter, the temperature of which is such as to cause the substance to melt if solid, or, if liquid, to solidify; and when uniformity of temperature is established in the calorimeter, this temperature is determined. The experiment is therefore quite similar to the determination of the specific heat of a substance by the method of mixtures; the same apparatus may be used and the same precautions require to be taken in the two cases (see pp. 25–29).

In such an experiment let

A be the weight of water in the calorimeter, the water-equivalents of the calorimeter and thermometer supposed included;

W , the weight of substance operated upon;

- t , the initial temperature of the calorimeter;
 θ , the final temperature of the calorimeter;
 T , the initial temperature of the substance;
 \mathfrak{C} , its melting (or freezing) point;
 C , the specific heat of the substance in the solid state between the temperatures \mathfrak{C} and θ ;
 c , its specific heat in the liquid state between the temperatures T and \mathfrak{C} ; and
 L its latent heat of fluidity.

Suppose that the experiment is made upon a melted substance which gives out heat to the calorimeter and solidifies in it: then it is plain that the quantity of heat $A(\theta - t)$ absorbed by the calorimeter is made up of three parts—first, the heat lost by the substance in cooling from its original temperature to its freezing point; secondly, the heat given out by it during solidification; thirdly, the heat which it loses while cooling from its freezing point to the final temperature of the calorimeter. That is, $A(\theta - t) = W[c(T - \mathfrak{C}) + L + C(\mathfrak{C} - \theta)]$;

whence
$$L = \frac{A}{W}(\theta - t) - c(T - \mathfrak{C}) - C(\mathfrak{C} - \theta).$$

The manner in which this formula will require to be modified, in order that it may apply to the case of a solid substance which is melted in the calorimeter by absorbing heat from it, need not be specially pointed out.

Changes of Volume accompanying Fusion and Solidification.—The accelerated rate of expansion exhibited by most solids as they approach their melting points, is in most cases followed by a further expansion during the actual process of liquefaction, so that the melted substance occupies a greater bulk than the solid of the same temperature from which it is formed. This phenomenon has been particularly studied by Kopp (Ann. Ch. Pharm. xciii. 129), whose principal results are as follows:

Phosphorus (the yellow modification of specific gravity 1·826 at 10°), expands uniformly up to its melting point (44°), at which temperature its volume is 1·017 of what it was at 0°; when melted, its volume at the same temperature is 1·052 of the volume at 0°. Hence 100 vols. solid phosphorus at 44° become 103·4 vols. liquid phosphorus at the same temperature.

Sulphur (native crystals, specific gravity 2·069) expands irregularly near its melting point (115°). Its volume being 1 at 0°, is 1·010 at 50°; 1·037 at 100°; 1·096 at 115°; at the moment of fusion, the expansion amounts to 5 per cent., the volume then increasing to 1·150.

Wax (bleached bees'-wax, specific gravity 0·976 at 10°) expands very rapidly as it approaches its melting point (64°), but only 0·4 per cent. more at the moment of fusion. If the volume at 0° is 1, the volume at 50° is 1·068; at 60°, is 1·128; at 64°, is 1·161, and increases by fusion to 1·166.

Stearic acid (pure, specific gravity nearly 1·0 at 10°) expands less than wax before melting, but then expands as much as 11·0 per cent. The volume at 0° being 1, it is 1·038 at 50°; 1·054 at 60°; and 1·079 at 70°, at which temperature the acid melts, its volume increasing to 1·198.

Rose's fusible metal (2 pts. bismuth, 1 pt. tin, and 1 pt. lead; specific gravity 8·906 at 10°) expands, when heated from 0° to 59°, in the ratio of 1 to 1·0027; but contracts when further heated, its volume at 82° being equal to that at 0°, and at 95° equal to 0·9947; in melting, between 95° and 98°, it expands by 1·55 per cent., so that at 98° its volume is equal to 1·0101. This alloy, therefore, contracts from 59° up to its melting point.

Water presents a remarkable exception to the general rule, and expands at the moment of fusion, or contracts on melting by about 10 per cent. One volume of ice at 0° gives 0·918 volume of water at the same temperature, or 1 volume of water at 0° gives 1·102 volume of ice. Dufour found, as the mean of 24 experiments, the density of ice at 0° equal 0·9175, that of water at the same temperature being 1. Brunner found for the density of ice the number 0·918.

Solid hydrated salts, on the contrary, expand at the moment of fusion, e.g. chloride of calcium ($\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$), by 9·6 per cent.; ordinary phosphate of sodium ($\text{PNa}_2\text{HO} \cdot 12\text{H}_2\text{O}$) and hyposulphite of sodium ($\text{S}^2\text{Na}_2\text{O} \cdot 6\text{H}_2\text{O}$) each by 5·1 per cent.

The expansion which takes place in water at the moment of solidification affords an explanation of several important phenomena. In the first place, it enables us to understand why increase of pressure should retard the freezing of water, instead of facilitating it, as it does that of most other liquids. Since the tendency of both heat and pressure is to diminish the bulk of water at 0°, and therefore to oppose the change of volume that occurs on freezing, it is easily conceivable that the one influence may (at least within certain limits) replace the other, and that a strong pressure applied to water at or below 0° may as effectually prevent its solidification, as the communication

of heat which would raise its temperature above the freezing point. In the case of substances whose volume in the solid state is less than their volume in the liquid state, pressure acts in the opposite sense to heat, and therefore retards liquefaction and promotes solidification.

This same phenomenon is the cause of the powerful mechanical effects which occur when water freezes in a confined space. The bursting of water-pipes, and the breaking of jugs containing water, during frosty weather, are among the most familiar of these effects; and to these may be added the splitting of rocks by the freezing of water in their fissures and the swelling up of moist ground during frost.

The force with which water expands when cooled, and at the moment of becoming ice, is strikingly illustrated in the experiments made by Major Williams, at Quebec. Having filled a 13-inch iron bomb-shell with water, he closed the hole left for introducing the fusee by driving firmly in an iron plug weighing nearly 3lbs., and exposed it in this state to the frost. After some time, the iron plug was forced out with a loud explosion and thrown to a distance of 415 feet, and a cylinder of ice, 8 inches long, issued from the opening. In another experiment, the shell burst before the plug was driven out, and in this case a sheet of ice spread out all round by the crack. If we take into consideration the experiments of W. Thomson and Mouton already recorded (p. 75), it seems probable that some of the water must have remained liquid in these experiments, up to the moment when the resistance was overcome; that it then issued from the shell in the liquid state, but at a temperature below 0° , and therefore instantly began to solidify when the pressure was removed, and so retained the shape of the orifice whence it issued.

Bismuth, cast iron and antimony expand like water on becoming solid.

Solution of Solid Bodies in Water.—Very many solid substances are capable of dissolving in water, and thus forming with it a uniform mixed liquid. As a general rule, the solvent power of water increases with its temperature, but this is not universally the case; for example, chloride of sodium has very nearly the same solubility in cold water that it has in boiling water; lime-water saturated at 0° , contains nearly twice as much lime as can be dissolved by the same quantity of water at 100° . Several other calcium-compounds exhibit similar properties; thus the sulphate is more soluble in cold than in boiling water, and becomes quite insoluble in water between 140° and 150° (Cousté, Ann. des Mines, [5] v. 143). Sulphate of sodium is more soluble in water at 33° than at other temperatures, higher or lower, and has about the same solubility at 0° that it has at 100° . From the experiments of Sullivan (Rep. Brit. Association, 1859, p. 292) it appears that the solubility of very many salts attains a maximum at some particular temperature, above which it diminishes. Hence, perhaps, the reason why the solubility of most solids is commonly supposed to increase continuously as the temperature rises, is that it has been determined only at temperatures below 100° , and that the points of maximum solubility for most substances lie higher. If this be so, the solubility of sulphate of sodium,—and of the few other salts (selenate of sodium, sulphate of iron) in which similar properties have been observed,—is only in so far anomalous, that its temperature of maximum solubility is lower than that of most other substances. Water which is saturated at a given temperature with one substance can usually dissolve an additional quantity of another.

The liquefaction of solid bodies by solution in liquids, obeys essentially the same laws as their liquefaction by the direct application of heat. It is facilitated or retarded in the same way by great variations of pressure, and is attended by the absorption of a certain quantity of heat, which is evolved again when the dissolved substance separates from solution in the solid form; usually also the volume of the solution differs from the combined volumes of solid substance and water at the same temperature; and, lastly, solutions present the phenomenon of supersaturation, analogous to that of the deferred solidification of liquids.

As might be expected from the analogy with the liquefaction of solid bodies in general, increased pressure favours solution in cases where, as is usual, the volume of the water and dissolved substance is less after solution than the volume of the water and substance when separate; and diminishes the solubility of substances whose volume when dissolved is greater than their volume in the solid state, together with that of the water. (Comp. Sorby, Proc. Roy. Soc. xii. 538, also, Möller, Jahresber. 1862, pp. 11-13.)

The absorption of heat which occurs during solution is taken advantage of by the chemist for the artificial production of low temperatures. The table on the next page gives a few of the most frequently useful freezing mixtures, with the reduction of temperature which can be produced by means of each. In order to obtain the greatest possible effect by the use of any of these mixtures, it is necessary to use a considerable quantity of the materials (2 or 3 pounds at least); otherwise the whole heat required for the liquefaction is furnished by the containing vessel, and the whole of the mixture

becomes liquid before its temperature has been much reduced. It is also of importance that the materials should be mixed as intimately as possible. Other more powerful freezing mixtures, depending on the employment of condensed gases, will be described hereafter.

Table of Freezing Mixtures.

Ingredients of the Mixture.	Parts by Weight.	Temperature produced, starting from 10°.	Diminution of Temperature.
Water	1	-16°	26°
Nitrate of ammonium	1		
Water	16	-12°	22°
Nitrate of potassium	5		
Chloride of ammonium	5	-19°	29°
Water	1		
Nitrate of ammonium	1		
Carbonate of sodium	1		
Snow, or pounded ice	5	20°	20°
Chloride of sodium	2		
Snow, or pounded ice	1	45°	45°
Crystallised chloride of calcium	2		
Crystallised sulphate of sodium	8	-20°	30°
Hydrochloric acid	5		

From a table already given (p. 60), it will be seen that water containing saline substances in solution freezes at a lower temperature than pure water, and that the depression of the freezing point increases with the quantity of substance in solution. This latter point is proved still more distinctly by the more recent experiments of Rudorff (Phil. Mag. [4] xxii. 552), from which it appears that the depression is very nearly in exact proportion to the quantity of salt dissolved. The ice which forms from a dilute solution of a salt yields nearly pure water when melted.

When a saturated solution is cooled, the excess of dissolved substance, beyond that which saturates the liquid at the lower temperature, generally separates out in the crystalline form; sometimes, however, especially if the solution is cooled slowly and is kept at perfect rest, a condition of unstable equilibrium may arise, like that of liquids cooled below their ordinary freezing points without solidifying, in which a greater quantity of substance is retained in solution than the liquid would be capable of dissolving if it were put in contact with it in the solid form. In this state, solutions are said to be supersaturated; and the same causes are in general sufficient to cause the separation of the excess of dissolved substance, as cause the solidification of over-cooled liquids.

If an aqueous solution of a salt is boiled in a flask of which the neck is drawn out to a fine point, and if the point is then hermetically sealed when all the air has been expelled, the solution very frequently remains supersaturated when cold; but on breaking the point, so as to readmit the air, even if this is done without shaking the solution in the least, or allowing the smallest fragment of glass to fall into it, crystallisation in most cases begins. If, however, the air that enters the flask has been previously passed through a red-hot tube, or even if it has been merely filtered through a column of cotton wool, crystallisation does not take place (comp. *Loebel, Jahrbes. 1852, p. 369; Schröder, Ann. Ch. Pharm. cix. 45; also particularly Mellin's Handbuch, p. 9-11*). The most probable explanation of this difference is that the solid particles of soluble matter contained in the unheated or unfiltered air, disturb the molecular equilibrium of the solution by dissolving in it, and so cause crystallisation to begin. This explanation is confirmed by the fact that a supersaturated solution frequently does not crystallise if stirred with a glass rod or platinum wire which has been recently heated to redness, but crystallises instantly if touched with a rod that has lain long exposed to the air.

By cooling supersaturated solutions below 0°, they may be brought into such a condition, that either ice or the dissolved salt will crystallise out according to circumstances. Thus Rudorff found (*loc. cit.* and Pogg. Ann. cxvi. 55) that a small fragment of ice, thrown into a strongly cooled solution of platinoeyanide of magnesium or sulphate of sodium, caused a crystallisation of ice, the whole of the salt remaining dissolved, until a very large proportion of the water had been transformed into ice; while a fragment of the solid salt thrown in caused the salt to crystallise, but no ice. The crystals of ice and of the salts used in these experiments were easily distinguishable by their

different colours and specific gravities. These results are quite analogous to the simultaneous separate crystallisation of two or more salts contained in the same solution.

Vaporisation and Condensation.—When a quantity of water or alcohol is left exposed to the air, it gradually disappears, owing to its transformation into a transparent, invisible vapour, which diffuses into the atmosphere. This formation of vapour at the free surface of a liquid constitutes *evaporation*. It takes place more or less rapidly with all liquids, except some of those which are easily decomposed by heat when their temperature is sufficiently high. Some liquids, such as water, evaporate at all temperatures, but this is not the case with all: for instance, mercury gives off no sensible quantity of vapour at -10° , and two basins may be placed near each other, under an exhausted receiver, at the ordinary temperature, one containing oil of vitriol and the other a solution of chloride of barium, without the smallest precipitate being formed in the latter. Some solid bodies, *e.g.* ice, iodine, camphor, give off vapour without previously passing into the liquid state; and it is proved by Regnault's experiments (upon benzene, bromide of ethylene, glacial acetic acid, chloride of cyanogen, and chloride of carbon), that substances which are capable of existing at the same temperature either as solids or liquids, produce, in both states of aggregation, vapours of equal tension (see next paragraph).

Fig. 540.

Fig. 539.

Tension of Vapours.—The quantity of any given liquid which can evaporate in an enclosed space, either previously vacuum or already containing a gas or vapour, is limited, and depends on the nature of the liquid, on the temperature, and on the extent of the enclosed space. When the liquid is in excess, that is, when some of it remains after the formation of the largest quantity of vapour that is possible under

the circumstances, evaporation ceases when the vapour exerts a certain pressure upon the sides of the containing vessel. The laws of evaporation are, therefore, most easily arrived at by studying, in the first instance, the phenomena of the formation of vapour in a vacuum, in which case the pressure exerted by the vapour itself is the only one to which the sides of the vessel are exposed.

If a glass tube, closed at one end, about a yard long and three-quarters of an inch wide, is filled with mercury and inverted in a basin of that liquid, as shown in *fig. 539*, a vacuous space, about six inches in length, is formed at the top of the tube. On now passing up a drop or two of ether or alcohol into this space, the liquid will immediately evaporate, so that the surface of the mercury and of the tube will remain dry, but the mercury column will be depressed by the elastic force of the vapour which has been formed. The amount of this elastic force, or of the pressure which the vapour exerts upon the sides of the tube and upon the top of the column of mercury, is evidently measured by the difference between the height of this column and that of the barometer at the time of the experiment. On transferring the tube in this condition to a mercury-trough provided with a deep cylindrical well (*fig. 540*), and depressing it slightly, the space occupied by the vapour above the mercury will be diminished; the tension of the vapour will therefore increase, and the mercury column AC will be still further depressed. But on continuing to diminish in this way the volume of the vapour, a point will soon be reached at which part of it returns to the liquid state and condenses as a dew upon the inside of the tube and on the mercury; and if the height of the column AC be measured, as soon as the first trace of condensed liquid becomes visible, it will be found to remain the same until the tube has been depressed so far

Fig. 541.

that the whole of the vapour has been converted into liquid, and the tube becomes filled with mercury, surmounted by a drop of liquid ether or alcohol. The progress of the experiment in this stage will be easily understood from *fig. 541*, where CD represents the tube when the liquid first begins to appear in the space above the mercury, and AB the level of the mercury in the tube above that in the trough. As the tube is depressed successively to the positions $C_1 D_1$, and $C_2 D_2$, more and more of the vapour is liquefied, but the remaining portion exerts neither more nor less pressure than the quantity which existed in the tube at the instant when liquefaction first began to take place; and hence the surface of the mercury remains immovably at the level AB. Again, if the tube is raised up out of the mercury, the top of the mercury column will still remain at the level AB, until the whole of the liquid has again evaporated into the space above it, but from this point it will begin to rise higher and higher as the tube is still further raised; if, however, when the tube has attained its highest position (so that the open end is only just covered by the mercury in the trough), an additional quantity of ether or alcohol is passed up into it, the column of mercury will sink; and if the quantity of liquid passed up is more than can evaporate in the portion of the tube unoccupied by the mercury, the surface of the latter will sink again to the level AB (*fig. 541*).

These experiments prove that when a vapour is compressed, its temperature remaining always the same, its elastic force increases up to a certain limit which it cannot exceed, the effect of any further compression being to change it to a liquid; and that when a vapour is in contact with any portion of the corresponding liquid, in a space otherwise vacuous, its elastic force always attains this limit, whatever may be the relative volumes of vapour and liquid. In this condition, a vapour is said to be saturated, or to exert its maximum tension.

Maximum Tension.—The maximum tension which the vapour of any liquid can exert depends upon the nature of the liquid, and upon its temperature.

If we pass up into the first of three barometric tubes, like that represented in *fig. 539*, a small quantity of ether, into the second some alcohol, and into the third some water, taking a larger quantity of each liquid than can evaporate completely within the tube, the mercury column will be depressed to a different level in each, supposing all three to have the same temperature. If, for instance, the temperature is 10°C , the mercury will be depressed about $11\frac{1}{2}$ inches in the first tube, nearly 1 inch in the second tube, and a little more than $\frac{1}{2}$ inch in the third.

If the three tubes are now gradually heated, by surrounding them with warm water or otherwise, more vapour will be formed from the liquid contained in each of them; the elastic force or tension of each vapour will accordingly increase, and the mercury will descend lower and lower in the tubes as the temperature rises. At about 35° , the tension of the ether-vapour will have become equal to that of the atmosphere, and hence at this

temperature, the mercury in the tube containing it will have been driven down so as to be at the same level as that in the reservoir; at about 78.5° the same will be the case with the mercury in the alcohol-tube; and at about 100° with that contained in the water-tube.

When a saturated vapour is cooled, the pressure upon it remaining unaltered, complete liquefaction takes place, just as it does when the pressure is increased and the temperature remains the same. The condition of saturation, or maximum tension, is therefore a limiting condition, beyond which a vapour can neither be compressed nor cooled without returning to the state of liquid.

On the other hand, when a saturated vapour not in contact with an excess of liquid is heated, it ceases to be saturated (unless the pressure upon it is increased at the same time to a corresponding extent). Hence, when a further quantity of liquid is brought in contact with a vapour which has been thus heated, more vapour is formed in the same space, until saturation is again produced, and the tension increases at the same time till it reaches the maximum tension corresponding to the higher temperature.

Distinction between Vapours and Gases.—It has been already stated, that when the space into which a liquid can evaporate is increased until the whole quantity of liquid has become vapour, the tension of the vapour diminishes with any further increase of volume; and that when a vapour, not in contact with the liquid from which it is formed, is compressed, its tension augments until liquefaction begins. In proportion as a vapour under these conditions is expanded, its tension becomes more and more nearly inversely proportional to the volume which it occupies; that is, its properties approach more and more nearly to those of a perfect gas. Similarly, when a saturated vapour, not in contact with an excess of liquid, is heated, its elastic force increases, and it expands if the pressure upon it is not proportionably augmented; and as the temperature rises, the relation between the tension or elastic force, p , of the vapour, its volume, v , and its temperature, t , comes to be more and more nearly expressed by the equation

$$pv = J(a + t);$$

which, as we have already seen (p. 45), expresses the relation between these three quantities in the case of a perfect gas (see also p. 50).

Hence the physical properties of vapours, when sufficiently expanded, and at sufficiently high temperatures, are identical with those of the permanent gases.

From this it is natural to conclude, conversely, that the so-called permanent gases themselves are only vapours which, at ordinary pressures and temperatures, are very far removed from their points of saturation, and that by exposing them to lower temperatures and increasing the pressure, a point might be reached for each of them, at which the pressure would be equal to the maximum tension which it was capable of exerting at the temperature of the experiment, and therefore, that any further diminution of temperature or increase of pressure would cause it to become liquid. This conclusion has been actually verified in the case of many gases formerly regarded as permanent, the only gases which have hitherto resisted all attempts to liquefy them being hydrogen, oxygen, nitrogen, nitric oxide, carbonic oxide and marsh-gas. (The methods employed for the liquefaction of gases will be further considered in connection with the processes adopted for obtaining great reductions of temperature.)

Tension of Vapours in presence of Permanent Gases.—The familiar fact of the evaporation of water in the open air affords sufficient proof that the presence of a permanent gas in any given space does not prevent volatile liquids giving off vapour into the same space. By measuring the volume and elastic force of a given quantity of dry air, or other gas, then introducing a little more of any liquid than can completely evaporate in it, and when equilibrium has been re-established, again measuring the volume and elastic force of the mixture of gas and vapour, the tension of the latter can be ascertained. In this way it has been found that, when the liquid exerts no solvent or chemical action upon the gas, the combined tension of gas and vapour is nearly equal to the separate tension of the gas, increased by the maximum tension which the vapour is capable of exerting in an otherwise vacuum space at the temperature of the experiment. In other words, the vapour given off by a liquid at any temperature has nearly the same maximum tension, whether it is formed in a space previously vacuum or filled with a permanent gas. The only essential difference between the evaporation of a liquid in a vacuum, and its evaporation in a gas, is that, in the former case, the vapour attains the condition of saturation in an inappreciably short time, while in the latter, this condition is arrived at more slowly. Regnault's experiments (*Mém. Acad. Sciences*, xxvi.) prove, however, that liquids do not give off vapour of quite so great a tension in a space occupied by a permanent gas, as they do in a vacuum, and that the difference increases as the temperature rises.

Boiling Points.—Ebullition.—From the facts stated in the last paragraph, it follows

that the temperature at which the vapour of a liquid introduced into the barometric vacuum would exert sufficient elastic force to drive the mercury down to the bottom of the tube, so as to make it stand at the same level inside and outside, is also the temperature at which the vapour formed on heating the liquid in the air would exert an elastic force equal to the atmospheric pressure. As already stated, the first of these effects is produced by ether-vapour at 35° , by alcohol at 78.5° , and by water at 100° ; these temperatures, however, are those at which the liquids respectively boil when heated in the open air, the barometer being at its average height. The boiling point of a liquid is, therefore, the temperature at which the tension of its vapour becomes equal to the atmospheric pressure. This temperature is evidently not absolutely constant for each liquid, but varies more or less with alterations of the pressure of the atmosphere. A liquid at its boiling point is in a limiting condition, comparable to that of a saturated vapour; any diminution of pressure or increase of temperature equally causes it to pass from the liquid to the vaporous state. The two conditions are in fact continuous; and the temperature at which a liquid produces vapour of any given maximum tension, is also the temperature at which the liquid would boil under an atmospheric pressure equal to that tension. Hence the observation of the pressures under which a liquid boils at various temperatures constitutes a method of determining the maximum tension of its vapour at those temperatures.

The phenomenon of ebullition, which presents itself when heat is applied to the lower part of a mass of liquid, already at such a temperature that the tension of its vapour is equal to the pressure of the atmosphere, results from the transformation of the liquid into vapour at the points where the heat is applied, and the escape of this vapour in the form of bubbles through the superincumbent liquid.

The temperatures at which different liquids boil, under the ordinary atmospheric pressure, vary very greatly. They will be found given for each liquid in the article of this dictionary wherein it is specially described; in the following table a few boiling points are given in order to illustrate the range of temperature through which they occur.

Table of Boiling Points.

Liquid.	Boiling Point.	Pressure in millimetres of mercury.	Authority.
Nitrous oxide . . .	-87.9°	759	Regnault
Carbonic anhydride . .	-78.2	767.3	"
Ammonia . . .	-33.7	749.3	Bunsen

Determination of Boiling Points.—The boiling points of different liquids being among their most characteristic properties, the determination of them becomes a very frequent and important operation in chemical research. The method recommended by Kopp, in order to ensure as much accuracy as possible in these observations, is as follows:—

The liquid to be examined is placed in a cylindrical glass vessel, containing a few scraps of freshly ignited platinum foil, the diameter of which, when the quantity of liquid is small, need not much exceed that of the bulb of the thermometer. This vessel is closed by a cork, through the centre of which the thermometer is inserted, in such a way that it can be raised or lowered, so that the bulb may dip either into the liquid or

merely into the vapour. It is generally advisable to give the thermometer the latter position, since, as will be seen by what follows, the temperature of the liquid may, under circumstances which not unfrequently occur, rise somewhat above the true boiling point; but even when this is the case, a thermometer in the vapour will show the real boiling point of the liquid: under nearly all circumstances, the thermometer will stand lower in the vapour than it does in the liquid, if this is a mixture of two or more liquids of different boiling points instead of a pure, homogeneous substance. Through a second hole in the cork is inserted a glass tube, open at both ends, and bent at a right angle, as shown in *fig. 542*; by connecting this tube with a condenser, the loss of the liquid used for the experiment can be prevented. The liquid is heated either by applying a small flame to the outside of the vessel, or by means of a water-bath or sand-bath, care being taken that the sides of the vessel above the liquid do not get over-heated. The indications of the thermometer are observed during the whole time that the liquid is being slowly boiled away, until only a small quantity remains. The temperature thus observed is not, however, in most cases, the true boiling point of the liquid: usually, part of the mercury column in the thermometer rises above the cork, and is therefore exposed to a lower temperature than that of the boiling liquid; consequently, the upper extremity of the column stands at a lower point than it would do if the thermometer were completely immersed in the liquid. In order to find the correction which it thus becomes necessary to apply, a second thermometer is placed so that its bulb is in contact with the stem of the thermometer inserted into the cork of the boiling vessel, and is half way between the top of the mercury column of the latter thermometer and the middle of the cork. The temperature indicated by this second thermometer may be taken as the mean temperature of that portion of the mercury column of the principal thermometer which is not heated by the vapour of the boiling liquid. Let this temperature be t° ; let the uncorrected boiling point, directly indicated by the principal thermometer, be T° ; let N be the difference between T and the point of the scale situated at the middle of the cork, that is to say, the length, expressed in degrees of the scale, of that portion of the mercury column of the principal thermometer of which the mean temperature is t° ; lastly, let δ be the coefficient of apparent expansion of mercury in the glass of which the thermometer is constructed. The correction to be applied to the directly observed temperature T° is then

$$= N(T - t)\delta.$$

As already stated (p. 57), δ may always be taken, in calculating the value of this expression, as = 0.0001545.

The table which follows on p. 86 gives the amounts of the correction in question for various values of N and of $T - t$. The amounts corresponding to other values of these factors can be easily deduced by interpolation from the numbers given in the table.

This table sufficiently shows that the correction in question can never be neglected in accurate experiments, and that in the case of liquids of high boiling points, its value may become very considerable.*

Since the boiling point of a liquid depends on the pressure to which the liquid is subjected, another correction becomes necessary in order to reduce determinations made under the varying pressure of the atmosphere, to the values which would be found if the atmosphere exerted always its normal pressure, equal to that of 760 millimetres of mercury at 0° . Strictly speaking, the correction to be applied to the boiling point of a liquid observed under an atmospheric pressure differing by a given amount from the above standard pressure, varies with the nature of the liquid; since equal alterations of pressure do not cause precisely equal changes in the boiling points of different liquids. Nevertheless, the greatest variations which ever occur in the pressure of the atmosphere are relatively so small, that they may, without any appreciable error, be regarded as affecting the boiling points of all liquids equally: to the extent, namely, of 0.1° for a variation of pressure of 2.7 millimetres of mercury, this number being deduced from direct determinations of the boiling point of water under different pressures.

In what follows, whenever the boiling point of a liquid is spoken of without further explanation, it is to be understood to mean the boiling point under a pressure equal to that of 760 millimetres of mercury at 0° .

* It is obvious that a precisely similar correction ought to be applied to all thermometric observations in which any portion of the mercury in the stem of the thermometer is at a different temperature from that in the bulb.

Fig. 542.

Circumstances which modify the Boiling Point.—Although, when a liquid is heated in such a manner that vapour can escape freely from some part of its surface, the vapour so formed has a tension equal to the pressure upon the free surface of the liquid as soon as the temperature of the latter reaches the boiling point, this temperature may nevertheless be attained, and even considerably exceeded, without the formation of a trace of vapour, if no portion of the surface of the liquid is freely exposed. These conditions can be realised by suspending the liquid to be examined in a second liquid of equal specific gravity, but higher boiling point.

The phenomena which take place under these circumstances have been particularly studied by Dufour (Ann. Ch. Phys. [3] lxxiii. 378). In order to examine them in the case of water, he employed a mixture in the requisite proportions of oil of cloves (previously heated alone to about 200°) and linseed oil. The water, already heated to 80° or 90°, was dropped gently into the mixture of oils, so as not to disturb the film which coated the bottom of the vessel, and the temperature of the bath was gradually raised. Under these circumstances the ordinary boiling point of water, 100°, was passed without the occurrence of any perceptible change, and traces of ebullition scarcely began to show themselves below 110° or 115°. Even at these temperatures, ebullition seldom began except when the globules of water came in contact with the sides of the vessel or with the thermometer. A burst of vapour then occurred, and the globule, more or less diminished in size, was driven rapidly away, like a pith ball after touching an electrified conductor. These contacts were of course more difficult to avoid in the case of large than of small globules; hence the latter remained liquid, as a rule, to higher temperatures than the former.

In these experiments, it was a rare exception when ebullition occurred between 100° and 110°; very commonly globules of 10 mm. in diameter reached 120° or 130°, and in one experiment the last temperature was attained by a globule of 18 mm. diameter, and therefore containing more than 3 c.c. of water. Spheres of 10 or 12 mm. diameter often reached 140°; those of 5 or 6 mm. reached 165°; and others of from 1 to 3 mm. attained 176° or even 178°, temperatures at which the elastic force of the vapour which forms at the freely exposed surface of water is between 8 and 9 atmospheres.

At these high temperatures, the contact of a solid body very generally occasioned the sudden partial or complete vaporisation of the globules, accompanied by a hissing sound like that produced on immersing red-hot iron in water. This invariably occurred when the globules were touched with pieces of wood or chalk, shreds of cotton, paper, &c., but not always on contact with a glass rod or metallic wire, the difference appearing to depend on the porous structure of the former substances. A platinum wire appeared to lose, to some extent, by frequent usage, the power of causing sudden vaporisation.

Sudden ebullition, amounting even to an explosion, if the temperature was above 120°, invariably occurred on passing the discharge of a Leyden jar or induction coil through a globule. A similar, but less violent, effect was produced by the passage of a weak galvanic current. These results are attributed by Dufour less to the contact of the globules with the conducting wires, than to the disengagement of gas at the extremities of the latter.

Saturated aqueous solutions of various salts—for example, chloride of sodium, sulphate of copper, nitrate of potassium, &c.—also remained liquid at temperatures much above their boiling points, when immersed in melted stearic acid resting on a layer of melted sulphur. In like manner, globules of chloroform (boiling point 61°), suspended in a solution of chloride of zinc, often remained liquid up to 97° or 98°; and globules of liquid sulphurous anhydride (boiling point -10.5°) could be heated in diluted sulphuric acid as high as +8°. In all these cases, the same causes that operated in the case of water, sufficed to occasion the sudden complete or partial conversion of the overheated globules into vapour.

These results throw important light upon the nature of ebullition, and seem to indicate that it is to some extent an accidental phenomenon. In order to understand them, we must remember that the globules being surrounded on all sides by liquid, evaporation cannot go on at their surface in the ordinary way. They are, however, in a state of tension, or unstable equilibrium, such that a very slight cause may occasion the sudden formation of vapour of more than the atmospheric tension. The most effectual of such causes would obviously be the contact of a minute globule of air or other gas: this globule, however small, would be a space into which vapour could be given off, and this vapour, having an elastic force greater than the pressure (that of the atmosphere and the upper layers of the liquid) whereby the globule was prevented from expanding, would force back the liquid walls of the bubble of gas, suddenly converting it into a large bubble of steam. Hence the unfailing efficacy, in causing the ebullition of the overheated globules of liquid, of the passage of an electric current or the contact

of porous substances, such as chalk, wood, paper, &c., which either allow air to escape from their pores when immersed in the heated liquid, or carry down into it small globules of air adhering to them. These globules afford space for the commencement of the formation of vapour, and this process being once begun, the space is increased by the force of the vapour already formed within it. In the absence of any such space, the liquid globule is in a condition somewhat analogous to that of a drop of melted glass which has been suddenly cooled in water (Rupert's drops), and which falls to powder on receiving the smallest scratch: there is no reason why the formation of vapour should begin at one point of the mass rather than at another, and thus the whole remains in a state of molecular tension until something occurs at some particular point to weaken the effect of the forces which oppose the formation of vapour, or until the tension increases (in consequence of rise of temperature) to such a degree that these forces are overcome simultaneously throughout the whole mass. It will be seen further on that these considerations exactly agree with the explanation which the mechanical theory of heat affords of the passage from the liquid to the gaseous state.

Even when liquids are heated in open vessels, the occurrence of ebullition, or the formation of vapour in the interior of the mass, appears to depend on like accidental causes. Thus the influence of the nature of the vessel wherein a liquid is contained has been long recognised. It has been observed, for instance, that water, which will boil steadily at 100° in a metallic vessel, may often be heated to 105° or 106° without boiling, in a glass vessel previously washed with strong sulphuric acid. Under these circumstances, ebullition generally takes place very irregularly: at a certain temperature a sudden burst of vapour occurs, and the temperature of the liquid falls at the same time to nearly the normal boiling point; the liquid then remains tranquil for a time, until the temperature having again risen considerably, another burst of vapour takes place, and so on. The "bumping" of heated liquids which results from this intermittent formation of vapour, is familiar to every chemist. It may be prevented to some extent by putting into the liquid a few scraps of platinum, or a globule of mercury; a small piece of charcoal is, however, much more effectual than either of these, though not always admissible. This irregular ebullition occurs much more frequently in some liquids than others, and to a greater extent in certain glass vessels than in others. For instance, methylic alcohol (boiling point 61°) may show a difference in its temperature of ebullition amounting, according to Kopp, to 5 or 6 degrees, depending on the vessel in which it is examined. When a liquid is boiling steadily in a glass flask or retort, it may almost always be noticed that the bubbles of vapour start from one or two particular points of the surface of the glass, indicating the existence of some irregularity of the glass at those points favourable to the formation of vapour. Another illustration of the necessity of some other cause than mere temperature in order to bring about the ebullition of liquids, is afforded by the remarkable observation of Professor Donny, of Ghent, that water thoroughly deprived of air and sealed up in a rather long glass tube quite free from air, may be heated to 138° at one end of the tube without boiling, and is then suddenly and violently thrown to the other end by a burst of vapour. An additional fact of the same kind may sometimes be observed during the distillation of liquids under the ordinary pressure. The writer has occasionally seen a liquid distil very rapidly, thus showing that vapour was being formed rapidly at the surface, although ebullition could not be maintained by the use of a more powerful flame than that which had sufficed, at an earlier stage of the experiment, to boil a larger quantity of the same liquid.

The whole of these phenomena cease to be unintelligible if, with Dufour, we distinguish between the boiling point of a liquid, and the temperature at which the elastic force of its vapour becomes equal to the pressure of the atmosphere, and define the boiling point as the lowest temperature at which ebullition can occur, instead of as the temperature at which, under normal conditions, it must occur.

Spheroidal State.—When a drop of water is allowed to fall upon a piece of iron, the temperature of which considerably exceeds 100° , it retains its globular form, moves about rapidly on the surface of the iron without wetting it, and evaporates with comparative slowness. As the iron cools, a point is reached at which the globule of water wets it, spreads over its surface, boils and quickly disappears. The condition of the globule first described has been distinguished as the spheroidal state. This condition can be assumed by all volatile liquids when they come in contact with the surface of either a solid or a liquid body heated considerably above their boiling points. The temperature of a liquid in the spheroidal state is always below its ordinary boiling point, notwithstanding the higher temperature of the surface on which it rests. The absence of ebullition is therefore due in this case to some other cause than that which produces the phenomena of deferred ebullition which were considered in the last paragraph. It is the result of a want of perfect contact between the liquid and the heated surface. Many experiments prove that the liquid globule rests upon a sort of cushion of its own

vapour, produced by the heat radiated from the hot surface against its under side. As fast as this vapour escapes from under the globule, its place is supplied by a fresh quantity produced in the same way, so that the globule is constantly buoyed up by it, and never comes into actual contact with the heated surface. If, however, the temperature of the latter is allowed to fall, the formation of vapour becomes less and less rapid, until at last it is not supplied fast enough to prevent the globule touching the hot metal or liquid on which it rests: as soon as contact occurs, heat is rapidly imparted to the globule, it enters into ebullition, and quickly boils away.

According to Boutigny's experiments, the lowest temperature at which a metallic vessel will cause the spheroidal state to be assumed by water is 142° ; for alcohol the lowest temperature is 134° , and for ether 61° .

Solid bodies which evaporate without becoming liquid also assume a condition analogous to the spheroidal state of liquids, when they are placed upon a surface whose temperature is sufficiently high to vaporise them very rapidly. This is very distinctly seen on throwing a piece of solid carbonate of ammonium into a red-hot platinum crucible, and when a fragment of solid carbonic anhydride is placed upon any good conducting surface at the ordinary temperature.

Effect of Substances in Solution on the Boiling Point of Liquids.—Liquids holding solid bodies in solution boil generally at higher temperatures than they do in the pure state. On the other hand, the boiling point of water is lowered by mixing it with alcohol, and that of alcohol by mixing it with ether; the boiling point of a mixture being always intermediate between the boiling points of its components. The effect of salts in raising the boiling point of water may be considered as also coming under this rule. The following table gives the boiling points of saturated solutions of several salts, according to Legrand.

Table of Boiling Points of Saturated Saline Solutions.

Salt.	Weight of salt dissolved in 100 parts of water.	Boiling Point.	Salt.	Weight of salt dissolved in 100 parts of water.	Boiling Point.
Acetate of potassium .	798.2	169.0	Tartrate of potassium .	296.2	114.7.0
Nitrate of calcium .	362.2	151	Chlorate of potassium .	61.5	104.2
Carbonate of potassium	205.0	135	Chloride of sodium .	41.2	108.4
Acetate of sodium .	209.0	124.4	Phosphate of sodium } (dried) }	112.6	106.6
Nitrate of sodium .	224.8	121	Carbonate of sodium .	48.5	104.6
Chloride of strontium .	117.5	117.8	Chloride of barium .	60.1	104.4
Nitrate of potassium .	335.1	115.9			
Chloride of ammonium	88.9	114.2			

(For Legrand's determinations of the boiling points of weaker solutions of these and some other salts, and for the similar experiments of Griffiths and Faraday, see Gmelin's *Handbook*, i. 269, 270.)

Very contradictory opinions have been maintained by different observers with regard to the temperature of the vapour which issues from boiling saline solutions. It has been said, on the one hand, to be the same as that of pure water boiling under the same pressure; and, on the other hand, to be equal to that of the highest stratum of the solution. According to the recent experiments of Magnus (Pogg. Ann. cxii. 408), the latter statement appears to be nearest the truth. These experiments prove decisively that the vapour of boiling solutions is hotter than that of pure water, and that its temperature rises as the solutions become more concentrated, and therefore boil at higher temperatures; nevertheless, the vapour was always found a little colder than the mass of the boiling solution, and the difference was greater at high temperatures than it was at low ones.

Relations between the Boiling Point of substances and their Chemical Composition.—Many attempts have been made to trace some connection between the boiling points of different liquids and their chemical composition. The most extensive and important series of observations that have been made upon this point are due to Kopp (Ann. Ch. Pharm. xvi. 2, 330; xxviii. 267, 367; Phil. Trans. 1860, 257). The principal conclusions deducible from these investigations are as follows:—

1. Analogous compounds, presenting the same difference of composition, very frequently differ by the same amount in their boiling points, or the interval between their boiling points is proportional to their difference of composition. A compound containing x C more or less than another of analogous function, generally boils at a

temperature $x \times 29$ degrees higher or lower than the latter, and if it contains xH more or less it commonly boils at $x \times 5$ degrees lower or higher. A particular instance of the application of this rule is to homologous compounds: in the homologous acids $C^xH^{2x}O^2$ (Acids, i. 50), and in the corresponding alcohols and compound ethers, the addition of CH^2 to the formula of a compound raises its boiling point on an average by 19° , agreeing with the above rule.

2. An acid, $C^xH^{2x}O^2$, boils at a temperature 40° higher than the alcohol, $C^xH^{2x+2}O$ (Alcohols, i. 97), the oxidation of which may give rise to the acid.

3. A compound ether (Ethers, ii. 512), $C^xH^{2x}O^2$, boils at a temperature 82° lower than the acid, $C^xH^{2x}O^2$, isomeric with it.

If we start from the boiling point of ethyl-alcohol, $= 78^\circ$, these three propositions enable us to calculate the boiling points of a large number of organic substances, alcohols, acids, and compound ethers, represented by the above general formulae. The following tables serve to show how far the boiling points thus calculated correspond with those actually observed.

Boiling Points of Alcohols, $C^xH^{2x+2}O$.

Name.	Formula.	Calculated Boiling Point.	Observed Boiling Point.
Methylic alcohol .	CH^4O	59°	{ Kane, 60° ; Delffs, 60.5° ; Kopp, 65° ; Pierre, 66° ; Dumas and Péligot, 66.6° .
Ethylic alcohol .	C^2H^6O	78	{ Dumas and Boullay, 76° ; Gay-Lussac, Pierre, Kopp, Delffs, Andrews, 78° .
Tritylic alcohol .	C^3H^8O	97	Chancel, 96° .
Tetrylic alcohol .	$C^4H^{10}O$	116	Wurtz, 109° .
Amylic alcohol .	$C^5H^{12}O$	135	{ Pasteur, 127° — 129° ; Cahours, Pierre, Kopp, Delffs, 132° ; Rieckher, 135° .
Hexylic alcohol .	$C^6H^{14}O$	154	Faget, 148° — 154° .
Heptylic alcohol .	$C^7H^{16}O$	173	Städeler, 177° — 177.5° .
Cetylic alcohol .	$C^{16}H^{34}O$	344	Favre and Silbermann, 366° ?

Boiling Points of Acids, $C^xH^{2x}O^2$.

Name.	Formula	Calculated Boiling Point.	Observed Boiling Point.
Formic acid .	CH^2O^2	99°	{ Liebig, 99° ; Bineau, Favre and Silbermann, 100° ; Kopp, 105° .
Acetic acid .	$C^2H^4O^2$	118	{ Delffs, 116° ; Kopp, 117° ; Sébille-Auger, 119° ; Dumas, 120° .
Propionic acid .	$C^3H^6O^2$	137	{ Dumas, Malaguti, and Leblanc, about 140° ; Limpricht, Kopp, 142° .
Butyric acid .	$C^4H^8O^2$	156	{ Kopp, Delffs, 156° ; Pierre, 163° ; Pelouze and Gélis, about 164° .
Valeric acid .	$C^5H^{10}O^2$	175	Dumas and Stas, Delffs, 175° ; Kopp, 176° .
Caproic acid .	$C^6H^{12}O^2$	194	{ Brazier and Gossleth, Wurtz, 198° ; Fehling, 202° — 209° .
Enanthylic acid .	$C^7H^{14}O^2$	213	Städeler, 218° .
Caprylic acid .	$C^8H^{16}O^2$	232	Fehling, 236° ; Perrot, 238° .
Pelargonic acid .	$C^9H^{18}O^2$	251	Perrot, 225° ; Cahours, 260° .

In other groups of compounds, a difference of CH^2 in the composition of analogous substances corresponds frequently to a nearly constant difference of boiling point: but this difference sometimes amounts to more than 19 degrees, and sometimes to less. For instance, in the series of hydrocarbons C^xH^{2x+2} , homologous with benzene, C^6H^6 , a difference of CH^2 in composition corresponds to an average difference of about 24° in boiling point; in the series of alcohol-radicles (or hydrides) C^xH^{2x+2} , homologous with ethyl, C^2H^6 , (or marsh-gas, CH^4) the difference of boiling point corresponding to the same difference of composition, is also nearly 24° ; in the series of acetones $C^xH^{2x}O$, it is about 22° . On the other hand, the difference of boiling point, corresponding to a difference of CH^2 in composition, is less than 19° in the anhydrides

Boiling Points of Compound Ethers, CⁿH²ⁿ⁺²O².

Name.	Formula.	Calculated Boiling Point.	Observed Boiling Point.
Formate of methyl .	C ² H ⁴ O ²	36°	Kopp, Andrews, 33°; Liebig, 36°—38°.
Acetate of methyl .	C ³ H ⁶ O ²	55	{ Andrews, 55°; Kopp, 56°; Dumas and Péligot, 58°.
Formate of ethyl .			
Acetate of ethyl .	C ⁴ H ⁸ O ²	74	{ Liebig, Delffs, 53°; Kopp, 55°; Löwig, 56°.
Butyrate of methyl	C ⁵ H ¹⁰ O ²	93	{ Dumas and Boullay, Pierre, Kopp, Delffs, 74°.
Acetate of trityl .			
Formate of tetryl .			
Propionate of ethyl			
Valerate of methyl.			
Butyrate of ethyl .	C ⁶ H ¹² O ²	112	{ Favre and Silbermann, Delffs, 93°; Kopp, 96°; Pierre, 102°.
Acetate of tetryl .			
Formate of amyl .			
Valerate of ethyl .			
Butyrate of trityl .	C ⁷ H ¹⁴ O ²	131	{ Berthelot, about 90°.
Acetate of amyl .			
Caproate of ethyl .			
Propionate of amyl	C ⁸ H ¹⁶ O ²	150	{ Wurtz, about 100°.
Butyrate of amyl .			
Valerate of amyl .	C ⁹ H ¹⁸ O ²	169	{ Kopp, 96°—98°; Limpricht and Usler, 101°.
Acetate of capryl .			
Pelargonate of ethyl	C ¹⁰ H ²⁰ O ²	188	{ Kopp, 114°—115°.
Caproate of amyl .			
Laurostearate of ethyl	C ¹¹ H ²² O ²	264	{ Pelouze, 110°; Delffs, 113°; Kopp, 115°; Pierre, 119°.

C²H⁴—2O², homologous with acetic anhydride, C²H⁴O³ (namely, about 12·5°); in the ethers of the acids CⁿH²ⁿ⁺²O⁴, homologous with oxalic acid, C²H²O⁴ (namely, about 14°); also in the carbonates, sulphocyanates and borates of the alcohol-radicles CⁿH²ⁿ⁺¹.

These results seem to show that, as a rule, the greater the quantity of oxygen contained in any series of compounds, the smaller is the effect on the boiling point of a difference of composition amounting to CH².

In the chlorides, bromides and iodides of the alcohol-radicles CⁿH²ⁿ⁺¹, a difference in composition of CH² causes a difference in boiling point of from 24 to 31 degrees; in the corresponding sulphides and sulphydrates (mercaptans) the difference also considerably exceeds 19°.

Measurement of the Tension of Vapours.—The various methods that have been employed for measuring the maximum tension of vapours at different temperatures, depend upon principles already explained. We have here to describe briefly the manner in which these principles were put in practice, and to state the most important results obtained.

The tension of vapours at temperatures below the ordinary boiling points of the corresponding liquids, and therefore at pressures less than that of the atmosphere, have been measured by determining the depression of the mercury column of a barometer produced by the saturated vapours at known temperatures. *Fig. 543* represents the apparatus employed by Regnault (*Relation des Expériences*, &c. p. 489) in his principal series of experiments made by this method. The liquid whose vapour is to be examined is contained in a small bulb almost completely filled by it, and hermetically sealed without any trace of air. This bulb is introduced into a glass globe, the neck of which is then drawn out, bent at a right angle, and cemented into a narrow T-tube of copper, the other branches of which communicate, one of them through a drying tube containing pumice-stone and sulphuric acid, with an air-pump, the other, by a capillary tube, with the top of a wide glass tube open below and dipping into mercury. This last tube forms the barometer, the depressions of which are observed; its upper part

is inside a metal water-bath, one face of which is formed by a sheet of plate glass, and in which are also contained the upper part of an ordinary barometer, to serve as a standard of comparison, and the glass globe spoken of above; this, as shown in the figure, rests on a metal ring carried by a support rising from the bottom of the bath. Previous to beginning the experiments, the inside of the glass globe and of the tubes communicating with it is rendered absolutely dry by repeatedly pumping out the air, and each time allowing it to be filled again by air dried by passing through the sulphuric acid drying tube. Then, by bringing a piece of hot charcoal near the outside of the globe, the bulb containing the liquid is burst, and the experiments are proceeded with by observing simultaneously the temperature of the bath in which the globe is immersed, and the difference in height of the two barometers.

Fig. 543.

The same apparatus, slightly modified, served for the determination of the tension of vapours in presence of air or other gases.

For the determination of the tension of the vapour of water at higher temperatures, Regnault (*ibid.* p. 515) employed the apparatus represented in *fig. 544*, an apparatus which enabled him to measure the pressure under which water boiled at various temperatures (see p. 83). The apparatus consists of a copper retort, containing the water to be experimented upon, and communicating, through a tube surrounded by cold water, with a manometer which indicates the pressure inside the whole apparatus, and

Fig. 544.

also with a branch tube by means of which air can be withdrawn from or forced into the apparatus, so as to bring the pressure to the required amount. The temperature of the boiling water in the retort is indicated by four thermometers, two of which dip into the water, and two into the steam. In order to prevent any alteration in the capacities of the bulbs of the thermometers, resulting from the pressure of the vapour upon them, they are enclosed in iron tubes, closed at the bottom and containing mercury.

The following table gives the results obtained at intervals of five degrees between

-- 32° and $+230^{\circ}$. (For tables of the tensions of water-vapour at each degree centigrade between these limits, and at each tenth of a degree between -10° and $+35^{\circ}$ and between 85° and 101° , see Regnault, *loc. cit.* pp. 624-633.)

Maximum Tension of Water-vapour between -32° and $+230^{\circ}$. (Regnault.)

Temperature.	Tension, millimetres.	Temperature.	Tension, millimetres.	Temperature.	Tension, millimetres.

Determinations of the tension of water-vapour up to 111° degrees have also been made by Magnus (Pogg. Ann. lxi. 225) by a method essentially similar to the first of those above described. His results agree closely with those of Regnault. (For the older determinations of the pressure of steam at high temperatures by Arago and Dulong, see Gmelin's *Handbook*, i. 262.)

The following table, by Fairbairn and Tate (Phil. Trans. 1860, p. 220), gives the temperatures at which water is completely converted into saturated steam under various pressures, together with the volume of steam formed under these circumstances compared with that of the water from which it is produced.

Pressure, Temperature, and Volume of Saturated Steam.

Pressure.		Temperature.		Volume.
Inches.	Millimetres.	Fahrenheit.	Centigrade.	
6.35	135.9	136.77°	58.20°	8275.3
8.62	219.9	155.33	68.51	5333.5

It was supposed by Dalton that the tension of the vapours of all liquids is the same at temperatures equally distant from their respective boiling points. The observations from which the above tables are constructed show that this rule is not strictly true, but is nearly so in most cases for small intervals of temperature above or below the boiling points: hence, in order to correct boiling point observations for the variations of atmospheric pressure, it may be assumed without sensible error that a difference of pressure equal to 2.7 millimetres of mercury causes a difference in the boiling points of all liquids, equal to that which it produces in the case of water, —namely, 0.1° C. (see pp. 85 and 92.)

Tension of the Vapours of Mixed Liquids and of Saline Solutions.—Regnault's experiments on the tension of the vapour of mixed liquids prove that: (1) when two liquids exert no solvent action upon each other, as *water* and *sulphide of carbon*, *water* and *bichloride of carbon* (CCl₄), or *water* and *benzene*, the tension of the vapour which rises from a mixture of them is very nearly equal to the sum of the tensions of the two separate liquids at the same temperature; (2) with *water* and *ether*, which dissolve each other to some extent, but not in all proportions, the tension of the vapour of the mixture is much less than the sum of tensions of the separate liquids, being scarcely equal to that of ether only; (3) when the two liquids dissolve each other in all proportions, as *ether* and *sulphide of carbon*, *benzene* and *alcohol*, *water* and *alcohol*, the tension of the vapour of the mixed liquid is intermediate between the tensions of the separate liquids.

The tension of the vapour of saline solutions has been examined by Regnault and by Wüllner (Jahresber. 1858, 42-47; 1860, 47-49). Regnault's experiments were

made by means of the apparatus represented in *fig. 513*, p. 92; Wüllner employed a differently arranged apparatus, but one which depended on essentially the same principles. It results from these investigations that the tension of the vapour of a solution is less than that of the vapour of pure water at the same temperature, and that in the case of efflorescent salts and of salts that are permanent in the air, the diminution of the tension of the vapour emitted by the solution is exactly proportional to the quantity of salt dissolved in a constant weight of water, but in the case of deliquescent salts it is proportional to the quantity of hydrated salt dissolved: *e. g.*, for a solution of potash, to the quantity of $\text{KHO} \cdot 2\text{H}_2\text{O}$; for a solution of soda, to the quantity of $\text{NaHO} \cdot \frac{1}{2}\text{H}_2\text{O}$; for a solution of chloride of calcium, to the quantity of $\text{CaCl}^2 \cdot 6\text{H}_2\text{O}$. The absolute amount of diminution of tension depends on the temperature, and becomes greater as the temperature rises.

Tension of Vapours in an unevenly heated space.—In an enclosed space, the temperature of which is different at different parts, the vapour of a liquid can assume a state of statical equilibrium only when its tension is equal to the maximum tension corresponding to the temperature of the coldest part of the space. If the vapour has, to begin with, a greater tension than this, liquefaction will take place in the coldest part, since the pressure is greater than that which the vapour can support at the temperature of this part, and this process will continue until the tension throughout the whole space is reduced to the point already stated. It is upon this principle that the process of distillation, and the action of the condenser of the steam engine, depend.

Complete Vaporisation of Liquids under great pressures.—When the temperature of a liquid is raised sufficiently high, vaporisation occurs under the highest pressure to which the substance can be subjected. Alcohol, ether, or rock-oil, enclosed in a tube of strong glass or iron, is completely converted into vapour only when the space not occupied by the liquid is somewhat greater than the volume of the liquid itself. With rock-oil the empty space may be somewhat smaller than with alcohol, and with ether still less. Alcohol when thus heated acquires increased mobility, expands to twice its original volume, and is then suddenly converted into vapour. This change takes place at 207°C . (404.6°Fah.), when the alcohol occupies just half the volume of the tube; if the tube is more than half filled with alcohol, it bursts when heated. A glass tube one-third filled with water becomes opaque when heated, and bursts after a few seconds. If this chemical action of the water on the glass be diminished by the addition of a little carbonate of soda, the transparency of the glass will be much less impaired; and if the space occupied by the water be $\frac{1}{4}$ of the whole tube, the liquid will be converted into vapour at about the temperature of melting zinc (Cagniard de la Tour).—If liquid carbonic anhydride sealed in a glass tube occupies $\frac{2}{3}$ of the volume of the tube at 0° , it neither increases nor diminishes in bulk when heated, because the increase of volume produced by heating is just compensated by the diminution caused by vaporisation. If it occupies $\frac{1}{2}$ of the space at 0° , its volume diminishes when it is heated, and increases when it is cooled, because the loss by evaporation preponderates over the expansion. If it takes up $\frac{2}{3}$ of the space, its volume increases by heat and contracts by cold, as in a thermometer; but at $+30^\circ$ (86°Fah.) the whole is converted into vapour. The gas, which at 0° occupies the space above the liquid carbonic anhydride would, if condensed, yield $\frac{1}{12}$ of its volume of liquid acid; and that which is produced at $+30^\circ$ would give $\frac{1}{3}$ ($\frac{2}{3}$ Gmelin) of its volume of liquid carbonic anhydride at 0° . (Thilorier.)

When chloride of ethyl was heated in a very thick sealed tube, the upper surface ceased to be distinctly marked at about 170° , and was replaced by an ill defined nebulous zone possessing no reflecting power; as the temperature rose, this zone increased in width in both directions, becoming at the same time more and more transparent. After a time, the liquid was entirely converted into vapour, and the tube became quite transparent and apparently empty. As the temperature fell, the same phenomena were reproduced in the opposite order (Drion, *Ann. Ch. Phys.* [3] lvi. 33). Similar appearances were observed on heating ether in a sealed tube to about 190° . According to Drion, the temperature at which ether is completely vaporised, in a space nearly three times its original volume, is 19.5° . The precise temperatures observed in these experiments are, however, of no real significance, unless they are accompanied by accurate determinations of the corresponding real volumes of the liquid and vapour.

It has been similarly observed by Andrews that when liquid carbonic anhydride was gradually heated to 31° , the surface of demarcation between the liquid and gas became fainter, lost its curvature, and at last disappeared. The space was then occupied by a homogeneous fluid, which exhibited, when the pressure was suddenly diminished, or the temperature slightly lowered, a peculiar appearance of moving or flickering stræ throughout its entire mass. At temperatures above 31° no apparent liquefaction of carbonic anhydride or separation into two distinct forms of matter could be effected,

even when a pressure of 300 or 400 atmospheres was applied. Nitrous oxide gave similar results. (Andrews, in *Miller's Chemical Physics*, ed. 1863, pp. 328, 329.)

Latent Heat of Vaporisation.—When heat is imparted to a volatile liquid, its effect is, at most temperatures, twofold. Part of it goes to increase the temperature of the liquid, and part to cause vaporisation. But when a liquid is boiling under constant pressure, however much heat is communicated to it, the whole of it is absorbed in producing the second of these effects only. Conversely, when heat is withdrawn from a saturated vapour, under a pressure which is maintained constant, the vapour is changed into a liquid, without alteration of temperature. The consumption of heat in vaporisation, without the production of a corresponding elevation of temperature, and its evolution during condensation, unaccompanied by a corresponding fall of temperature, were first observed by Black. These phenomena were described by him by saying that during the former process, a certain quantity of sensible heat became latent, and that this latent heat became sensible again during condensation. The quantity of heat that must be given to a liquid to convert it into vapour, or which must be withdrawn from a vapour to convert it into liquid, without causing change of temperature, is still spoken of as the latent heat of vaporisation.

The determination of this quantity is made by determining the specific heat of the substance for an interval of temperature within which it passes from the liquid to the vaporous state, or *vice versa*, and is therefore in principle similar to the determination of the latent heat of fluidity (p. 77). The following table gives the number of units of heat which must be imparted to a unit of weight of various liquids at their respective boiling points, in order to convert them into vapours at the same temperatures. The letters FS in the third and sixth columns denote that the determinations were made by Favre and Silbermann (*Ann. Chim. Phys.* [3] xxxvii. 464-470); the letter A denotes determinations by Andrews (*Chem. Soc. Qu. J. i.* 27); and Rg, by Regnault.

The latent heat of vaporisation varies with the temperature at which the vapour is formed; more heat is for instance required to convert a given quantity of water at 50° into vapour of the same temperature than to produce the same change in water at 100°. It was supposed by Watt that the latent heat of vaporisation diminished exactly at the same rate as the sensible heat increased, so that the sum of the two remained constant at all temperatures. But Regnault (*Relation des Expériences*, &c., pp. 635-728; also *Works of the Cavendish Society*, vol. i. p. 294) has shown that this is not the case. He finds that the total quantity of heat λ (expressed in heat-units) which a unit of weight of saturated aqueous vapour contains at the temperature t° C., exceeds the amount contained in the same weight of water at 0° by the quantity

$$\lambda = 606.5 + 0.305 t.$$

If from this we subtract the quantity of heat which a unit of weight of water at t° contains, beyond that which is contained in the same weight of water at 0° (see Regnault's determinations of the specific heat of water at different temperatures, p. 34),

we shall obtain the latent heat L of the vapour of water at the temperature t° . The values of λ and L for various temperatures are given in the next table, together with the tensions expressed in millimetres and atmospheres.

Latent Heat of Water-Vapour.

Temperature.	Tension.		λ	L
	mm.	atm.		
0° C.	4.60	0.006	606.5	606.5
50	91.98	1.121	621.7	571.3
100	760.00	1.000	637.0	536.5
150	3581.23	4.712	652.2	500.7
200	11688.96	15.380	667.5	461.3
230	20926.40	27.535	676.6	441.9

The following formulæ represent in like manner the results of Regnault's determinations (Mém. Acad. Sciences, xxvi. 881) of the total heats of vaporisation of several other substances at various temperatures:

Sulphide of carbon:	$\lambda = 90.0 + 0.14601 t - 0.0004123 t^2$.
Ether:	$\lambda = 94.0 + 0.4500 t - 0.0005555 t^2$.
Benzene:	$\lambda = 109.0 + 0.2443 t - 0.0001315 t^2$.
Chloroform:	$\lambda = 67.0 + 0.1375 t$.
Perchloride of carbon (CCl_4):	$\lambda = 52.0 + 0.1463 t - 0.000172 t^2$.
Acetone:	$\lambda = 140.5 + 0.3664 t - 0.000516 t^2$.

The following table gives the total heats of vaporisation of some additional liquids at the temperatures at which they boil under the ordinary atmospheric pressure (*ibid.* 913):

Substance.	Boiling Point.	Total Heat of Vaporisation.	Substance.	Boiling Point.	Total Heat of Vaporisation.
Alcohol	78.26°	265.52	Bromine	60°	50.95
Amylic alcohol	132	211.78	Chloride of tin	114	46.84
Oil of lemons	174.80	160.49	Chloride of arsenic	133	69.74
Oil of turpentine	144.15	139.15	Trichloride of phosphorus	73.80	67.24
Petroleum		194.87	Acetate of ethyl	74	154.49
Chloride of ethyl	12.50	97.70			
Iodide of ethyl	71	58.95			

Regnault finds, as the result of direct experiments (*ibid.* 903), "that the total heat of vaporisation of a liquid in a current of gas is equal to that which the same liquid absorbs when it boils in an atmosphere formed by its own vapour, and exerting an elastic force equal to that actually acquired by the vapour of the liquid in the current of gas."

Cold produced by Vaporisation. Liquefaction of Gases.—When the evaporation of a liquid is hastened by reducing the pressure upon it and continually removing the vapour which forms, or by exposing a large surface and rapidly renewing the atmosphere in contact with it, the consequent absorption of heat is such, in the case of the more volatile liquids, as to produce a very considerable fall of temperature. Water, for instance, may be frozen by placing it under the exhausted receiver of an air-pump near a vessel of strong sulphuric acid (Leslie). The rapid volatilisation of more volatile liquids produces still more striking results, and in fact constitutes the most effectual means known of producing extremely low temperatures.

By causing a rapid stream of dry air from the bellows of a glass-blowers' lamp to bubble by several tubes at once through about 200 grammes of ether, Iodine and Chlorine (Bull. Soc. Chim. Paris, i. 184; Séance du 22 Juin, 1860) succeeded in reducing the temperature of the liquid to -34° in 4 or 5 minutes, and maintaining this temperature very nearly constant for at least 15 or 20 minutes. At this temperature considerable quantities of cyanogen can be condensed at the atmospheric pressure. The condensation of this gas begins under these circumstances at about -22° ; by blowing gently on the surface of the condensed liquid with a common pair of bellows it is immediately caused to solidify. By similar means, sulphurous anhydride is easily liquefied. Chlorine does not condense under the common pressure at -34° , but by using liquid

sulphurous anhydride in place of ether, a temperature of -50° can be produced, and this is amply sufficient for the liquefaction of both chlorine and ammonia. Lastly, by evaporating liquid ammonia (which boils in the air at -35.7°) in an exhausted receiver over sulphuric acid, they attained the temperature of about -87° , at which point the ammonia solidified, and carbonic anhydride condensed to a liquid at the common atmospheric pressure.

An apparatus for the liquefaction of ammonia, to be used for refrigeration, has been described by Regnault (*Mém. Acad. Sciences*, xxvi. 609), and a very simple contrivance for the same purpose was exhibited by Carré at the International Exhibition in London in 1862. (For a description and figure of the last apparatus, see Miller's *Chemical Physics*, ed. 1863, p. 298, footnote.)

Several gases can be liquefied by increased pressure alone, without reducing their temperature below that of the atmosphere. The necessary pressure can often be attained by evolving the gas in an enclosed space (as in a sealed glass tube); under these circumstances, the elastic force continues to increase until the point of maximum tension is reached, and then liquefaction occurs. In this way, carbonic anhydride may be liquefied by its own pressure when it is evolved from acid carbonate of sodium and diluted sulphuric acid in a strong wrought iron bottle connected with a wrought iron receiver. When the liquid carbonic anhydride thus produced is allowed to escape in a fine stream into the air, part of it is immediately vaporised, and the consequent absorption of heat is sufficient to cause the remainder to condense to a white, crystalline solid, like snow. The principle of this method was first put in practice by Faraday in experiments on the small scale; an apparatus in which considerable quantities of liquid carbonic anhydride could be thus prepared was first devised and constructed by Thilorier.

The pressure necessary for the liquefaction of gases may also be produced by compressing them by means of a force-pump, as in Natterer's apparatus for the liquefaction of nitrous oxide.

By the evaporation of gases, condensed by any of the processes above indicated, the lowest temperatures yet attained can be produced, the greatest degree of cold hitherto recorded being -140° , the temperature, according to Natterer, of a mixture of liquid nitrous oxide and bisulphide of carbon evaporating *in vacuo*.

Still more powerful means of liquefaction than those already mentioned, were employed by Faraday in his later experiments on this subject (*Phil. Trans.* 1845, p. 170), and he thereby succeeded in reducing to the liquid state all known gases, with the exception of oxygen, hydrogen, nitrogen, nitric oxide, carbonic oxide, and marsh-gas, —and in solidifying the greater number of them. The method adopted was to subject the gases to the joint action of powerful mechanical pressure and extreme cold. The first object was attained by the successive action of two air-pumps, the first having a piston one inch in diameter, the second only half an inch. The first produced a pressure of about 20 atmospheres, the second increased it to upwards of 50. The tubes into which the gas thus condensed was made to pass were of green bottle-glass, from $\frac{1}{16}$ to $\frac{1}{4}$ of an inch in external diameter, and had a curvature in one portion of their length adapted for immersion in a freezing mixture. The mixture employed consisted of solid carbonic anhydride and ether. The cold produced by it amounted to -76.6° in the open air and to -110° under the exhausted receiver of the air-pump.

Many gases, when subjected to this extreme degree of cold, were liquefied without the use of the condensing apparatus: this was the case with chlorine, cyanogen, ammonia, sulphuretted hydrogen, arseniuretted hydrogen, hydriodic acid, hydrobromic acid, carbonic anhydride, ethylene, nitrous oxide, and oxide of chlorine. Fluoride of silicon liquefied at a pressure of 9 atmospheres. The following were solidified when subjected to the action of the carbonic anhydride bath *in vacuo*: hydriodic acid, hydrobromic acid, sulphurous anhydride, sulphuretted hydrogen, carbonic anhydride, oxide of chlorine, cyanogen, ammonia, and nitrous oxide. The following gases did not solidify, even at the lowest temperature that could be obtained: ethylene, fluoride of silicon, fluoride of boron, phosphoretted hydrogen, hydrochloric acid, and arseniuretted hydrogen. The six gases mentioned at the commencement of the preceding paragraph showed no signs of liquefaction when cooled by the carbonic anhydride bath *in vacuo*: hydrogen and oxygen at 27 atmospheres, nitrogen and nitric oxide at 50, carbonic oxide at 40, and marsh-gas at 32 atmospheres.

Andrews has since succeeded in exposing these gases to still greater pressures, but without producing liquefaction, although a bath of ether and solid carbonic anhydride was used; air was reduced to $\frac{1}{275}$ of its bulk, oxygen to $\frac{1}{512}$, hydrogen to $\frac{1}{100}$, carbonic oxide to $\frac{1}{278}$, and nitric oxide to $\frac{1}{281}$ of its original volume. Hydrogen and carbonic oxide departed less from Boyle's law than oxygen and nitric oxide.

Distillation. — One of the processes most frequently resorted to by the chemist for the purpose of separating different substances is to expose the mixture containing

them to a temperature at which the constituent it is wished to isolate rises in vapour, while the others remain still solid or liquid. The ordinary methods of performing this operation of distillation, and the apparatus commonly employed are too familiar to every chemist for it to be necessary to describe them here in detail. (For a full description of the process and the modifications that become desirable in particular cases, the reader is referred to *A Handbook of Chemical Manipulation*, by C. Greville Williams, London, 1857, pp. 202-244.)

When the liquid submitted to distillation is a mixture of two or more substances of unequal volatility, the vapour formed when ebullition begins generally contains a larger percentage of the most volatile constituent than the liquid remaining in the retort. Hence, the composition of the liquid alters as the distillation continues, and its boiling point rises accordingly. On the other hand, if the boiling point of a liquid remains constant during distillation, it is usually an indication that its composition is unaltered by the process, and therefore that the composition of the distillate also continues the same throughout. The boiling point of a liquid becomes therefore a very useful indication of the uniform or varying nature of the products of its distillation, and by collecting apart the portions which pass over at different temperatures, a mixture of different liquids may often be to a great extent resolved into its constituents. It seldom happens, however, except with a mixture of two liquids whose boiling points are very distant from each other, that a single operation of this kind gives either constituent in a state of purity. This is especially the case when the distillation is performed in a retort or other vessel which allows the vapour to pass to the condenser almost immediately after its formation. Under these circumstances, the distillate obtained at any period of the operation is almost identical in composition with the vapour that is rising from the liquid, and therefore contains a certain quantity of every constituent of the liquid that produces vapour of sensible tension at the temperature at which ebullition is going on. Hence, in order to effect any great amount of separation in this manner, the distillate must be collected in separate fractions, each of them corresponding to a definite interval of temperature; each fraction must then be fractionally distilled by itself, in the same way as the original liquid, the products which pass over between the same temperatures on the second distillation of the first fractions being collected together; and this process must be repeated as long as any further separation into

Fig. 545.

distinct constituents can be effected. These numerous re-distillations may often be considerably curtailed by using, instead of a retort, a flask fitted with a rather wide branched tube, of the form shown in *fig. 545*. The thermometer is inserted into the upright limb of the branched tube, and is so adjusted in the cork or piece of india-rubber tube which holds it in its place, that the top of the bulb is just below the opening of

the side branch by which the vapour passes to the condenser. In an apparatus thus arranged, the vapour rising from the liquid comes in contact with a considerable surface of glass cooled by contact with the air, before it is able to leave the distilling vessel; the consequence is that, in proportion as it rises above the surface of the boiling liquid, it becomes more and more completely freed from its less volatile constituents; and the vapour which ultimately reaches the condenser, at any stage of the operation, is identical with the most volatile portions that would be obtained by the repeated fractional distillation of the liquid resulting from the complete condensation of the vapour existing in the flask at the time. In fact, one distillation made in this way is equivalent to several made in a retort; nevertheless, this method is not always applicable, since the temperature of the boiling liquid requires to be always considerably higher than that of the liquid which is actually distilling, otherwise the whole of the vapour would be condensed before reaching the exit tube—and this would sometimes cause chemical alteration of the substance.

The composition of the distillate which a liquid yields at any period of its distillation does not depend solely upon the tension of the vapours of its several constituents at the temperature of ebullition; it is greatly influenced also by their relative proportions, and by the densities of their vapours. In distilling a volatile liquid containing a small quantity of a less volatile one (for instance, benzene containing a little water), it may very often be noticed that the whole of the less volatile constituent is contained in the first few drops of the distillate. This is because the latter substance produces vapour of whatever tension corresponds to the temperature of ebullition of the mass of the liquid, just as a larger quantity of it would do; this vapour diffuses itself through that of the more volatile constituent and is carried forward with it into the condenser; a further quantity of the less volatile vapour is then formed, and the process continues thus until the whole of the less volatile liquid has been volatilised, although the temperature may not have approached within many degrees of its boiling point.

The influence of the vapour-densities of the several constituents of a mixed liquid, upon the rapidity with which they respectively distil, has been specially pointed out by Wanklyn (*Proc. Roy. Soc.* xii. 534) and by Berthelot (*Compt. rend.* lvii. 430). Leaving out of consideration the influence of the adhesion of the ingredients for each other, the quantity of each ingredient which distils may be found by multiplying its tension at the boiling point of the mixture by its vapour-density. Hence, the liquid whose vapour has the highest tension will not necessarily distil the quickest: what the other liquids want in tension, they may make up by the greater density of the vapours which they give off. Wanklyn gives the following experiment in illustration of this effect: 18 grms. of methylic alcohol—boiling point 66° , vapour-density 1.107—was mixed with 17 grms. of iodide of ethyl—boiling point 72° , vapour-density 5.397—and the mixture was distilled until rather more than one-third had passed over. The distillate (14.7 grms.) consisted of 6.0 grms. of methylic alcohol and 8.7 grms. of iodide of ethyl, showing that the less volatile constituent, owing to its greater density of vapour, had distilled most quickly. When the vapour-densities and tensions are inversely proportional, the mixture must distil over unchanged. This influence of vapour-density goes a great way to explain why homologous bodies are so difficult to separate by fractional distillation. The more complex the formula the higher the boiling point, but also the higher the vapour-density, and therefore the greater the value of the vapour. It also explains why oils, &c. distil so readily in steam; for aqueous vapour is one of the lightest, while oily vapours are generally heavy. (Wanklyn, *loc. cit.*)

The action of the sun upon the water at the surface of the earth causes a natural process of distillation upon an enormous scale to be always going on. The water evaporated from the earth's surface rises in the atmosphere as vapour, and being afterwards deprived of its heat of vaporisation—partly by radiation into space, and partly by contact with mountain summits, or with the cold air existing at high elevations—returns to the earth in the various forms of dew, mist, rain, snow, hail, &c. In this way an immense quantity of water is being continually lifted from the sea-level, a large proportion of which does not fall again directly into the sea, but, being deposited on elevated portions of the land, becomes the inexhaustible source whence streams and rivers are supplied. The watery vapour which reaches the higher and colder regions of the atmosphere, is there condensed into snow. This, as it falls again towards the earth, returns to the condition of water, if the air through which it passes is sufficiently warm to liquefy it; but part of it reaches the earth unmelted, and that which falls upon regions whose mean temperature is below zero, accumulates to form the enormous masses of ice known as glaciers. Now it is universally admitted by geologists that, at an epoch by no means (geologically) remote, extensive glaciers existed where none have been known within historic times, and that glaciers which still exist had then a very much greater extent. In order to account for the former existence of so much larger a quantity of ice at the surface of the earth than that which is now to be found, it has often been supposed that, at the period when this occurred, the mean tempera-

ture of the earth was considerably lower than at present. But, as Tyndall has pointed out (*Heat considered as a Mode of Motion*, pp. 192, 193), even admitting such to have been the case, the observed result would not have followed. If cold is necessary to condense the vapour of water into ice, heat is no less needed for the first production of the vapour. Hence the condition of the earth which is in reality indicated by the vast development of glaciers in former ages, is one in which the process of distillation went on more rapidly. These considerations have been recently carried further by Frankland. He has shown, by the comparison of well-established data, that the height of the line of perpetual snow above the sea-level at different parts of the earth, depends, not only upon the temperature, but also upon the amount of atmospheric precipitation which takes place; and he concludes, from Tyndall's experiments on the absorption and radiation of heat by aqueous vapour (see RADIATION OF HEAT), that the condensation of the vapour contained in the atmosphere takes place chiefly by the direct radiation of its heat of vaporisation into space. If this conclusion is correct, condensation must have occurred with nearly equal readiness at all stages of the earth's history, and all that was therefore necessary to cause a greater atmospheric precipitation in past times, was a more rapid supply of aqueous vapour. Hence, according to Frankland, the glacial epoch of the geologists is an indication of a higher mean temperature of the earth's surface in former ages, and not of a lower temperature. The climatological conditions of this epoch he considers to have been a necessary consequence of the continuous cooling of the earth's crust from the high temperature which it is admitted to have had at a still earlier era to that which it has at present. In the earlier ages alluded to, the temperature of the earth is supposed to have been such that a great part of the waters of our present ocean must have existed as vapour; and notwithstanding that rapid condensation of this vapour must have occurred, the surface of the earth was too hot to allow the precipitated water to accumulate as ice. But as the cooling progressed, the temperature of the land would fall more quickly than that of the ocean; hence a period would arrive when the former would be so far cooled that ice could accumulate upon it, while the temperature of the water still remained such that evaporation, and consequently condensation, went on much more rapidly than at present. It is during this period that, according to Frankland, the glacial epoch occurred. Its cessation he attributes to the further action of the same cause as that which produced it; namely, to the progressive cooling of the earth, which has now arrived at such a point that evaporation no longer takes place with sufficient rapidity to supply the materials required for the formation of the enormous glaciers of former ages. It is impossible to discuss here the cause of the former high temperature of the earth's surface, indicated by the tropical fauna and flora which preceded the glacial epoch, and, according to Frankland, by the glacial epoch itself; but it has been proved by Thomson that, for ages long anterior to either of the periods referred to, the internal heat of the earth can have produced no sensible effect upon the climate of the surface.

Just as in the process of distillation, as carried on in the laboratory, there is a transference of heat from the retort to the condenser, and consequently a constant tendency to the approximation of their temperatures: so one of the effects of the great natural process of distillation is the partial equalisation of the temperature of different parts of the earth's surface, and of the different strata of the atmosphere.

Various instruments and processes, mostly depending on principles already explained in this article, have been proposed for measuring the quantity of aqueous vapour existing in the air at any given time. A full description of all the most important of them will be found in the article **HYGROMETER**.

SUBLIMATION.—When, during the distillation of a volatile substance, the temperature of the receiver is kept so low that the vapour which enters it passes at once into the solid state, without previous liquefaction, the process is called sublimation, and the product a sublimate. This process is often resorted to for the purification of substances which volatilise rapidly at temperatures below their melting points.

Changes of Physical Structure.—Some solid substances are capable of existing under two or more forms distinguished from each other by differences of specific gravity, hardness, crystalline form, fusibility, optical and electrical properties, &c. Carbon, for instance, exists as diamond, graphite, and charcoal, as well as in other secondary modifications; phosphorus occurs either as an easily fusible, translucent, yellowish, crystalline substance, or as a much less fusible, opaque, amorphous body of a brick-red colour; and so for many other substances, simple and compound. It thus often happens that the different modifications of the same substance differ more in their physical properties, than other substances do which are chemically distinct; and the passage from one modification to another, though not amounting to a change of state of aggregation, may be considered as a phenomenon of the same class as such changes. Accordingly, it has been found, in all cases in which this point has been investigated, that the passage of a solid body from one modification to another, is attended either

with development or with absorption of heat. The experiments which have been made on this subject are not numerous enough to enable any general conclusions to be drawn from them with great certainty, but they appear to indicate that development of heat usually attends the passage from a vitreous or amorphous condition to a crystalline condition, and consequently that the opposite change is accompanied by absorption of heat.

The following are examples of transformations of the kind under consideration:—

1. If melted sugar be allowed to cool to about 38° , and then, while it is still soft and viscid, be rapidly and frequently extended and doubled up, till at last it consists of threads, as in drawn sugar, the temperature of the mass quickly rises so as to become insupportable to the hand. After this liberation of heat, the sugar on again cooling, is no longer a glass, but consists of minute crystalline grains and has a pearly lustre. The same change may occur in a gradual manner, as when a clear stick of barley-sugar becomes white and opaque in the atmosphere (Graham, *Elements of Chemistry*, 2nd ed. i. 46).—2. When the soft vitreous sulphur, obtained by pouring sulphur melted at 180° or 200° into cold water, is gradually heated in an air-bath of which the temperature is about 98° , the temperature of the sulphur, as soon as it reaches 93° , rises suddenly to 110° , and it then passes immediately into the hard crystalline state which it would have assumed gradually at the ordinary temperature (Regnault, *Ann. Ch. Phys.* [3] i. 206). The prismatic crystals of sulphur obtained by fusion have been long known to pass gradually into octahedral crystals. The same change takes place much more quickly when the crystals are agitated, or when they are put in contact with sulphide of carbon, even if this liquid is already saturated with sulphur. Mitscherlich found that the rapid transformation of prismatic into octahedral sulphur which occurs under these circumstances was attended by the evolution of a quantity of heat sufficient to raise the temperature of the sulphur employed by 12° , or which, taking into account the specific heat of sulphur, amounted to 2.27 units of heat per gramme of sulphur (*ibid.* xlv. 124). Favre, who has estimated by an indirect process (*Jahresber.* 1853, p. 29) the heat evolved in the transformation of one variety of sulphur into another, finds that the quantity of heat liberated, when one equivalent (16 parts) of ordinary sulphur is converted into the modification insoluble in sulphide of carbon, amounts to 3102 units, and that the conversion into the same modification of one equivalent of soft vitreous sulphur, evolves 3804 units of heat.—3. Selenium, when completely melted and then rapidly cooled, constitutes a black mass with a brilliant surface and a fracture exactly resembling that of obsidian or of black glass. When this is heated very gradually, a sudden rise of temperature to 200° or 230° takes place as soon as the thermometer arrives at 96° or 97° . The selenium is afterwards of a bluish grey colour, and has a distinctly metallic lustre. Its fracture, instead of being vitreous, now shows a fine granular structure like that of grey cast iron. The heat evolved in the transformation is estimated by Regnault as sufficient to raise the temperature of the selenium operated upon by more than 200 degrees (*Ann. Ch. Phys.* [3] xlv. 290).—4. According to Favre (*loc. cit.*), 28,246 units of heat are evolved when one equivalent (31 parts) of common phosphorus is converted into red phosphorus.—5. The transformation of 1 grm. of arragonite into calc-spar corresponds to the evolution of 12.9 units of heat (Favre and Silbermann, *Ann. Ch. Phys.* [3] xxxvii. 435).—6. Many amorphous minerals and artificially prepared metallic oxides become temporarily incandescent when gently heated, and are then found to have become crystalline without having undergone any alteration in weight. Gadolinite (silicate of yttrium) exhibits this behaviour in a remarkable degree. (For further examples of analogous changes, see Gmelin's *Handbook*, i. 104–107.)

The existence of ozone seems to prove that the same chemical substance may exist even in the gaseous state, in more than one modification, and analogy renders it probable that, when such is the case, the transformation of one modification into the other is attended by calorimetric phenomena. Sulphur-vapour at temperatures only slightly above the boiling point of sulphur, and at 800° and upwards, is an instance of another kind of difference in the properties of one and the same gaseous substance, which undoubtedly depends on the quantity of heat present in it, although the heat needed to change the one modification into the other has not been measured.

4.—Relations of Heat to Chemical Affinity.

Whatever may be the real nature of that property of matter called chemical affinity, by virtue of which mutual alterations of composition occur when chemically dissimilar bodies are brought together under appropriate conditions, one most important fact is clearly established with regard to it; namely, that its manifestations are always accompanied by the production or annihilation of heat. Change of composition, or chemical action, and heat are mutually convertible: a given amount of chemical action will give rise to a certain definite amount of heat, which quantity of heat must be directly or indirectly expended, in order to reverse or undo the chemical

action that has produced it. The production of heat by chemical action, and the definite quantitative relation between the amount of heat evolved and the quantity of chemical action which takes place, are roughly indicated by the facts of our most familiar experience; thus, for instance, the only practically important method of producing heat artificially consists in changing the elements of wood and coal, together with atmospheric oxygen, into carbonic anhydride and water, and every one knows that the heat which can be thus obtained from a given quantity of coal is limited and is at least approximately always the same.

The accurate measurement of the quantity of heat produced by a given amount of chemical action is a problem of very great difficulty; chiefly because chemical changes very seldom take place alone, but are almost always accompanied by physical changes involving further calorimetric effects, each of which requires to be accurately measured and allowed for, before the effect due to the chemical action can be rightly estimated. Thus the ultimate result comes, in most cases, to be deduced from a great number of independent measurements, each of which is liable to a certain amount of error. It is therefore not surprising that the results of various experiments should differ to a comparatively great extent, and that some uncertainty should still exist as to the exact quantity of heat corresponding to even the simplest cases of chemical action.

Heat evolved in rapid combustions.—The reactions in which the evolution of heat is most strikingly evident, are of course those which are accompanied by visible incandescence or combustion; and, accordingly, the earliest experiments on the heat of chemical action had reference solely to the heat disengaged in rapid combustions. Lavoisier and Laplace were the first investigators of this subject. Their experiments, made about 1780, consisted in ascertaining the quantity of ice which could be melted by burning in a current of air known weights of the substances examined. In 1814, Count Rumford made experiments of a similar kind by means of a water-calorimeter. His chief object was to ascertain the relative calorific values of the principal combustible substances in actual use as fuel, and from this point of view his results still possess considerable value, although they cannot lay claim to scientific accuracy. In order to counteract the influence of the air and other external objects upon the temperature of his calorimeter, or at least to reduce that influence to a minimum, Rumford began each experiment when the water of the calorimeter was as much colder than the surrounding air, as (he had found by preliminary trials) it would be hotter at the end of the experiment. In this way, the calorimeter gained heat from the air during the first half of each operation, and lost an almost exactly equal quantity during the second half, so that the total effect was almost nothing. This artifice, employed for the first time by Rumford, has been adopted in nearly every subsequent investigation relating to calorimetry. The experiments of Rumford were followed by those of Crawford, Dalton, and Clement Desormes, and more recently by the investigations of Despretz and Dulong. The researches of the last named physicist were left unfinished at his death, but the results obtained appear to have been much more accurate than those of his predecessors. The most exact and comprehensive researches hitherto made into this subject are, however, those of Favre and Silbermann (*Ann. Ch. Phys.* [3] xxxiv. 357; xxxvi. 5; xxxvii. 406), and Andrews (*Phil. Mag.* [3] xxxii. 321 and 426).

The calorimeter employed by Favre and Silbermann in their experiments on combustion in oxygen gas, and in other actions whereby large quantities of heat were generated, is represented in section in *fig. 546*, the scale of which is one-fifth of that of the actual apparatus. The calorimeter, properly so called, is the cylindrical vessel *CCC*, made of copper plated externally with silver and brightly polished, and closed by a cover of the same material. This is surrounded by a second vessel, *bb*, also of silvered copper, but having the polished surface inside, the space between *C* and *b* being filled with swan's down; outside this again is a third

Fig. 546.

vessel, *c c c*, to the bottom of which *b* is firmly connected by screw-bolts. The annular space which separates this vessel from *b* contains water, the temperature of which is indicated by the thermometer *t*, and which serves to neutralise the effect of accidental variations of the temperature of the atmosphere. The chamber in which the combustions take place is made of gilt copper-plate, and is represented by *A*. When the combustions are to be made in oxygen, the gas, previously purified, enters this chamber by the tube *d*; the products of combustion escape, if gaseous, by the vertical tube *s*, and pass from thence into the serpentine *S*, where they give up their heat to the water of the calorimeter, and then finally leave the apparatus by the upper part of the tube *s*: when no gaseous products are formed, the extremity of this tube is closed. If the substance to be burned is a gas, it enters the combustion-chamber by a jet connected with the tube *o*; solid bodies are attached to fine platinum-wires, suspended from the cover *B*, which closes the combustion-chamber; liquids are burned in small capsules, or in lamps with asbestos wicks; charcoal is placed in a sort of sieve, through the openings of which the oxygen has access to it. The progress of the combustion can be watched in the mirror *m* through a window in the tube below composed of a triple disc of glass, alum, and quartz. The temperature of the water in the calorimeter is kept uniform throughout by means of the agitator *a a a*, which is moved by special mechanism. In all cases where it was practicable to do so, Favre and Silbermann deduced the quantity of substance burned from the weight of the products of combustion.

The apparatus employed by Andrews was of much simpler construction. When the substances to be combined were in the gaseous state, and the products of combustion were also gaseous, the two gases were mixed in the proper proportions, as in a eudiometric experiment, and introduced into a vessel of thin sheet copper, of about 24 cubic inches capacity. This vessel was closed by a screw, through which passed a silver wire, insulated from it by a cork, and connected by a thin platinum wire within the vessel to a second silver wire soldered to the screw itself. By passing a voltaic current through the platinum wire for an instant, it could be heated to redness and the gaseous mixture exploded. The copper vessel was introduced into a larger vessel, which was filled up with water: this was suspended in a cylinder provided with a movable cover, and the whole was enclosed in an outer cylindrical vessel, arranged so as to admit of its being made to rotate upon its shorter axis. The apparatus having been mounted, was caused to rotate, so as to bring every part to a uniform initial temperature, which was carefully read off by a very sensitive thermometer. The thermometer was then withdrawn; the gases exploded; the outer vessel of water closed by a cork; and the apparatus caused to rotate for thirty-five seconds. The thermometer was then again introduced and the rise of temperature ascertained; after which the apparatus was made to rotate a third time for thirty-five seconds, and the temperature again observed, in order to ascertain the cooling effect of the atmosphere upon the apparatus during the time that the experiment lasted: it was found that this effect seldom exceeded $\frac{1}{100}$ of the total quantity to be measured.

When solid bodies were burned in oxygen, the combustion was effected in a copper vessel, of about 250 cubic inches in capacity, which was filled with oxygen; a known weight of the combustible was placed in a small platinum dish, and when all was ready, it was fired by means of a voltaic current sent through a very fine platinum wire. The vessel in which the combustions took place was immersed in a large cylinder containing a known quantity of water, and surrounded by an outer vessel of tin-plate, to prevent radiation. The copper vessel could be moved up and down in the water by means of a lever. Particular expedients were sometimes required to insure ignition: thus, in burning zinc-filings and other metals in oxygen, a small fragment of phosphorus (from 1 to 8 milligrammes) was employed to kindle the metal; the weight of the phosphorus being known, the heat evolved by it could be calculated and deducted from the total amount produced. Some of these experiments lasted a quarter of an hour and upwards, so that the correction for the cooling effect of the air became of considerable importance.

When the combustions were made in chlorine, the substance to be burned was enclosed in a thin glass bulb, which was broken by agitation after being immersed in the gas; in these experiments it was not necessary to apply heat to cause the combustion to begin. The chlorine itself was usually contained in a glass vessel, filled with it by displacement; in the experiments on potassium, a brass vessel was used, perfectly dry chlorine having no action on brass. An excess of the metal was always used, so as to insure the complete absorption of the chlorine, and the quantity of the latter substance consumed was, in most cases, ascertained by weighing the quantity of water which rushed into the vessel after the experiment on opening it under water.

The following table gives the quantities of heat, expressed in heat-units (gramme-degrees), evolved in the combustion of various elementary substances in oxygen, referred (1) to 1 gm. of each element burned, (2) to 1 gm. of oxygen consumed, (3) to 1 atom (expressed in grms.) of the several elements.

NOTE.—Andrews' determinations have been recalculated from the original experimental numbers, using the atomic weights and specific gravities of gases adopted in this Dictionary, and therefore the numbers in the above table do not always agree precisely with those contained in the general table of results which he has himself given (Phil. Mag. [3] xxxii. 432).

The following results have been obtained by the complete combustion of partially oxidised substances :

Substance.	Product.	Units of heat evolved		Observer.
		by 1 grm. of substance.	in formation of 1 molecule of the ultimate product.	
Carbonic oxide .	CO ²	{ 2403 2431	67284 68064	Favre & Silbermann. Andrews.
Stannous oxide .	SnO ²	519	69581	"
Cuprous oxide .	CuO	256	18304	"

The substances enumerated in this table contain exactly half as much oxygen as the completely oxidised products, and on comparing the amount of heat evolved in the formation of one molecule of stannic or cupric oxide from the corresponding lower oxide, with the quantity produced when a molecule of the same product is formed by the complete oxidation of the metal in one operation (see previous table), we find that the combination of the second half of the oxygen contained in these bodies evolves sensibly half as much as the combination of the whole quantity. In the formation of carbonic anhydride, however, the second half of the oxygen appears to develop more than two-thirds of the total amount of heat; but this result is probably due, in part at least, to the fact that when carbon is burned into carbonic anhydride, a considerable but unknown quantity of heat is expended in converting the solid carbon into gas, and thus escapes measurement; while, in carbonic oxide, the carbon already exists in the gaseous form, and therefore no portion of the heat evolved in the combustion of this substance, is similarly expended in producing a change of state.

It seems probable also, that a similar explanation may be given of the inequalities in the quantities of heat produced by the combustion of different varieties of pure carbon and of sulphur,—that is to say, that a portion of the heat generated by the combustion of diamond and graphite goes to assimilate their molecular condition to that of wood-charcoal, and that there is an analogous expenditure of heat in the combustion of native sulphur: indeed, with regard to the latter case, it is proved by direct experiments (see p. 102), that the opposite change to that supposed to take place here of recently melted sulphur into the same molecular condition as native sulphur is accompanied by disengagement of heat.

In like manner, the heat evolved in combustions may in some cases be in excess of that due to the strictly chemical action which takes place: thus, when the product of combustion is solid, part of the heat must be ascribed to the solidification of the oxygen absorbed. Again, the heat of combustion of hydrogen, as given above, includes the latent heat of vaporisation of the water formed. In Andrews' experiments the temperature of the calorimeter was about 20°C .: at this temperature the latent heat of vaporisation of 9 grms. of water (the quantity formed from 1 grm. or atom of hydrogen) may be taken as = 5500; and deducting this quantity from 33,881, we have 28,381 as the number of units of heat evolved by the chemical combination of 1 grm. hydrogen and 8 grms. oxygen, according to these experiments. Favre and Silbermann do not give the temperature of their calorimeter, but probably the same correction may be applied to their experiments without much error: they then give $34,462 - 5500 = 28,962$ as the true heat of combustion of 1 grm. of hydrogen.

The experiments which have been made on the heat of combustion of definite compounds, other than the three already mentioned, relate almost exclusively to bodies composed of carbon and hydrogen, or of carbon, hydrogen, and oxygen. The results obtained by Favre and Silbermann and Andrews are contained in the following table. The numbers here given represent the total heat produced, and therefore include that due to the condensation of the vapour of water formed in the experiments.

Many of these numbers must be regarded as approximations only (and sometimes as not very close approximations) to the truth. The chief causes of uncertainty with regard to them, besides the difficulties inherent in the experimental determinations themselves, are the different calorimetric properties of the substances examined—differences, that is, in regard to specific and latent heats—and, in some cases, their admittedly doubtful purity. Hence it is impossible to trace any exact correspondence between the composition of the bodies experimented upon, and the amount of heat which they evolve upon combustion. A few general conclusions are, however, indicated with sufficient clearness to make it worth while to dwell upon them briefly.

In the first place it appears that the heat of combustion of a compound is in general less than the heat of combustion of its elements. This rule is verified in the case of all the hydrocarbons given in the table, with the exception of olefiant gas, whose heat of combustion is almost exactly the same as that of its constituents, according to Favre and Silbermann's determinations, and somewhat greater, according to Andrews. When a hydrocarbon is burned into carbonic anhydride and water, the chemical change which takes place consists, not merely in the union of carbon and hydrogen with oxygen, but also in their separation from their previous state of combination with each other. Now, it is an almost self-evident proposition, and one which has moreover received direct experimental confirmation, that whatever may be the calorimetric effect of any given chemical change, the calorimetric effect of its reversal is equal and opposite. Hence, if we suppose the combination of carbon and hydrogen—to form marsh-gas, for example—to be accompanied by evolution of heat, we must suppose that their separation is attended by the disappearance of an equal quantity of heat. The heat produced by the combustion of one molecule of marsh-gas, CH_4 , is therefore less than the quantity due to the combustion of one atom of (gaseous) carbon and four atoms of hydrogen, by the quantity of heat absorbed when these atoms separate from combination with each other. Assuming (for want of more certain data) that the heat of combustion of an atom of gaseous carbon is twice that of a molecule of carbonic oxide, we have, for the heat of combustion of $\text{C} + \text{H}^4$ (in round numbers), $134,600 + (4 \times 34,460) = 272,440$; but the heat of combustion of CH_4 is 209,000, which gives $272,440 - 209,000 = 63,440$ as the number of units of heat produced by the combination of 1 atom of carbon with 4 atoms of hydrogen, or absorbed when these atoms separate. In like manner, we have, for the heat of combustion of $\text{C}^2 + \text{H}^4$, $(2 \times 134,600) + (4 \times 34,460) = 407,040$ units; and deducting from this the heat of combustion of olefiant gas, we have $407,000 - 332,000 = 75,000$ for the calorimetric effect due to the separation of the atoms of a molecule of olefiant gas from each other. The difference between 63,440 (the heat of formation of CH_4) and 75,000 (the heat of formation of C^2H^4), namely 11,600, may perhaps be taken as representing the calorimetric effect of the combination or separation of the two atoms of carbon contained in olefiant gas. The fact that the heat of combustion of olefiant gas, as found by direct experiment, is very nearly equal to the sum of the heats of its constituents, when the heat of an atom of carbon is taken at 96,960 units, the quantity deduced from the combustion of wood-charcoal, probably indicates that the heat of vaporisation required to change the physical condition of two atoms of carbon from that of wood-charcoal to that which it has in the form of olefiant gas, is nearly the same as the heat required to separate the atoms of a molecule of olefiant gas from each other. That the heat of vaporisation of carbon is very considerable is further indicated by the great difference, already alluded to, between the calorific effect of the first and second atoms of oxygen contained in carbonic anhydride,

as well as by the fact that the heat of combustion of a molecule of sulphide of carbon exceeds the sum of the heats of its constituents.

It will be understood that the foregoing calculations are given, rather for the sake of drawing attention to the necessity of taking account of *all* the changes, whether

chemical or physical, which accompany a given chemical reaction, when we are discussing the quantity of heat produced by it, than because the results arrived at are supposed to be numerically accurate. Indeed it is by no means probable that these results are, at best, anything more than roughly approximative; for, to mention no other source of uncertainty, the assumption that we have made, that the heat produced by the complete combustion of carbon is twice as great as that evolved by the combustion of the same quantity of carbon in the form of carbonic oxide, is most likely not strictly true. For it has been pointed out by Butlerow that the four units of combining capacity (CLASSIFICATION, i. 1010 *et seq.*) possessed by one atom of carbon are not exactly equivalent to each other in chemical function, and Erlenmeyer has suggested, with great probability, that the difference between them is due to differences in the strength of the chemical affinity with which each unit enters into combination (see references in the article FORMULÆ, ii. 704). If this be so, the combination of an atom of carbon with one atom of oxygen must evolve more heat than the combination of the product so formed (carbonic oxide) with a second atom of oxygen.

The numbers in the above table show that the heat evolved by the combustion of equal weights of the hydrocarbons (CH^2)*, homologous with olefiant gas, diminishes as their molecular weights increase. But it is not easy to say how far this result may be due to accidental causes (the numbers given are deduced from a single experiment, except in the case of olefiant gas, for which Favre and Silbermann obtained very concordant results in two experiments), or to the influence of the physical properties of the substances. It may be remarked that the isomeric substances, oil of lemons, oil of turpentine, and terebene, also gave different quantities of heat, although their molecular weights are the same.*

The acids homologous with acetic acid may be regarded, empirically, as formed by the combination of the hydrocarbons (CH^2)* with oxygen; that is, they may be considered as products of the partial combustion of the hydrocarbons. Hence, we should expect each acid to give out, when burned, less heat than the hydrocarbon containing the same quantity of carbon and hydrogen, and this is shown by the numbers in the above table, to be really the case, the difference between the heat of combustion of an acid and that of a given hydrocarbon being greater in proportion as the acid is more oxidised. Thus, starting from amylene, C^3H^{10} , and comparing with it quantities of valeric, butyric, and acetic acids which contain the same quantity of carbon and hydrogen, we have the following numbers:

1	molecule amylene,	C^3H^{10}	= 70	produces 804400 units of heat.
1	"	valeric acid, $\text{C}^3\text{H}^{10}\text{O}^2 = \text{C}^3\text{H}^{10} + \text{O}^2$	= 102,	656800
1½	"	butyric acid, $1½\text{C}^3\text{H}^{10}\text{O}^2 = \text{C}^3\text{H}^{10} + \text{O}^{2½}$	= 110,	621200
2½	"	acetic acid, $2½\text{C}^3\text{H}^{10}\text{O}^2 = \text{C}^3\text{H}^{10} + \text{O}^3$	= 150,	525750

Compared in this way, the difference in composition between amylene and valeric acid, namely O^2 , is four times as great as that between valeric acid and butyric acid, and the corresponding differences in the heats of combustion of these substances are exactly almost in the same proportion: but this close agreement is, probably, in great part accidental: for the heat of combustion of acetic acid is decidedly greater than what might be calculated in the same way.

The table further shows that isomeric substances by no means always give out equal quantities of heat when burned. For instance, acetic acid, $\text{C}^2\text{H}^4\text{O}^2$, produces considerably less heat than its isomer, formate of methyl; butyric acid, $\text{C}^4\text{H}^{10}\text{O}^2$, less than its isomer, acetate of ethyl; valeric acid, $\text{C}^5\text{H}^{12}\text{O}^2$, less than its isomer, butyrate of methyl. That differences of this kind would be found to exist, might have been deduced, with considerable probability, from the differences in the chemical constitution of the acids and of the isomeric ethers: for, of the four equivalents of oxygen contained in these compounds, one must be regarded as combined with hydrogen, and the other three with carbon in the acids; whereas, in the ethers, all four equivalents of oxygen are combined with carbon. Hence, the differences between the heats of combustion of the acids $\text{C}^n\text{H}^{2n}\text{O}^2$ and those of the isomeric ethers may be ascribed, at least in part, to the difference between the heat of combustion of an equivalent of carbon and that of an equivalent of hydrogen; but considerations, such as have been already alluded to, make it impossible to assign any exact numerical value to this difference.

But, according to the experiments hitherto made, not only do the acids differ from the isomeric ethers, in the quantity of heat which they produce when burned, but the ethers differ from each other: for instance, acetate of methyl produces more heat than its isomer formate of ethyl; valerate of methyl, more than its isomer butyrate of ethyl; acetate of amyl, more than its isomer valerate of ethyl. It is not easy to suggest any chemical reason for the existence of such differences as these; nor even to discover any empirical relations of a general kind among the experimental results.

* Favre and Silbermann assign to oil of lemons half the molecular weight of oil of turpentine, but without giving any reason for so doing.

[For the methods of calculating the heating powers of different kinds of fuel, and the temperature produced by its combustion, for practical purposes, see the article FUEL, ii. 722 *et seq.*]

Combustions in Chlorine, and direct combination of Chlorine, Bromine, and Iodine.—The following table gives the quantities of heat evolved by the direct union of various elements with gaseous chlorine:

Substance.	Product.	Units of heat evolved			Observer.
		by 1 grm. of substance.	by 1 grm. of chlorine.	by 1 at. (=35.5 grms.) of chlorine	
Hydrogen .	HCl	{ 24087 23783	678 670	24087 23783	Abria.
Phosphorus .	PCl(?)	3422(?)	607	21548	Favre and Silberman.
Potassium .	KCl	2655	2943	104476	Andrews.

Heat produced by reactions in the Wet Way.—Of the various reactions in the wet way, which have been studied calorimetrically, it will be most convenient to consider first those which take place between water and other bodies, since such actions intervene in many other cases also.

Dilution of Acids with Water.—The heat produced by the dilution of strong acids, especially sulphuric acid, has been the subject of many investigations, the most accurate of which are probably those of Favre and Silberman, Thomsen (Pogg. Ann. lxxxviii. 349; xc. 261; Jahresber. 1853, p. 30); and Favre and Quillard (Compt. rend. l. 1150). We give below a few of the results obtained.

Sulphuric acid, SO⁴H² = 98.

Thomsen determined the quantity of heat evolved by the mixture of strong sulphuric acid, and of the same previously diluted with different quantities of water, with an excess of water—that is, with so much that any further quantity did not increase the amount of heat evolved. He found that the addition of an excess of water

to 98 grms. (= 1 molecule)	SO ⁴ H ²	evolved 17,248 units of heats.
to 116	" SO ⁴ H ² .H ² O	" 10,848 "
to 152	" SO ⁴ H ² .3H ² O	" 6288 "
to 188	" SO ⁴ H ² .5H ² O	" 4480 "

Favre has determined, in conjunction with Silberman and with Quillard, the quantity of heat produced by the successive additions of known quantities of water to strong sulphuric acid. Both sets of experiments were made with the mercurial

calorimeter already described, and represented in fig. 531, p. 28. We give here the results published by Favre and Quillard as being the most recent.

Addition of Water to 98 grammes (1 molecule) of Sulphuric Acid.

Quantities of water added successively. Molecules.	Heat evolved on each successive addition of water.	Total quantity of water added. Molecules.	Total Heat evolved.	Quantities of water added successively. Molecules.	Heat evolved on each successive addition of water.	Total quantity of water added. Molecules.	Total Heat evolved.
1	946.68			1	885.30	5	13661.90
2	885.92			1	754.48	6	14416.38
3	1711.08			1	591.84	7	15008.22
4	2832.20			1	465.36	8	15473.58
5		1	6512.80	4	1063.66	12	16537.24
6	1842.40			4	483.02	16	17020.26
7	1338.10			4	222.46	20	17242.72
8		2	9756.80	4	141.58	24	17384.30
9	1009.40			4	86.96	28	17471.26
10	805.12			4	65.06	32	17536.32
11		3	11597.60	4	43.28	36	17579.60
12	1840.80			4	32.08	40	17611.68
13	1179.00	4	12776.60				

A little heat was still produced by the addition of the sixteenth molecule of water.

These numbers show that a given quantity of water added to sulphuric acid evolves the same quantity of heat, whether it be added all at once, or in successive small portions, and that the heat which a given quantity of water produces is, accordingly, less in proportion as the amount previously added is greater.

Nitric Acid, NO³H = 63.

The following table gives the results of Thomsen's experiments on the heat evolved on adding an excess of water to nitric acid, either undiluted or already containing a certain quantity of water. The numbers refer, as usual, to molecular proportions of acid and water expressed in grammes:—

NO ³ H mixed with excess of water evolved	7560 units of heat.
(NO ³ H + 0.421 H ² O) mixed with excess of water evolved	5680 " "
(NO ³ H + H ² O) " " " "	4088 " "
(NO ³ H + 1.5 H ² O) " " " "	3760 " "
(NO ³ H + 1.59 H ² O) " " " "	3464 " "
(NO ³ H + 2 H ² O) " " " "	2712 " "
(NO ³ H + 2.5 H ² O) " " " "	2184 " "
(NO ³ H + 3.5 H ² O) " " " "	1392 " "
(NO ³ H + 4.5 H ² O) " " " "	952 " "

It will be observed that the heat which can be obtained by the addition of water to nitric acid diminishes as the quantity of water already present in the acid is greater, but that the diminution takes place, at first, much less rapidly than in the case of sulphuric acid.

Acetic Acid, C²H⁴O² = 60.

The following results are those of Favre and Quillard: we give them in order to call attention to the absorption of heat (indicated by the minus sign in the second column) produced by the first quantities of water added:

Quantities of water added successively.	Heat evolved on each addition of water.	Total quantity of water added.	Quantities of water added successively.	Heat evolved on each addition of water.	Total quantity of water added.
1 H ² O	- 72.22		1 H ² O	+ 3.51	2 H ² O
"	- 33.13		2 "	5.97	2 1/2 "
"	- 17.66	- 135.00	3 "	11.28	3 "
"	- 11.99		4 "	23.45	4 "
"		- 135.16	5 "	27.47	5 "
"	- 16.65		6 "	82.47	7 1/2 "
"	- 8.22	- 24.87	7 "	54.73	10 "
"		- 25.18	8 "	87.72	15 "
"		- 3.56	9 "	40.54	20 "
		1 1/2 H ² O			

These numbers plainly show the simultaneous occurrence of two distinct actions—one of them attended with absorption of heat, the other with its production. The former action prevails at first, but gradually diminishes as more and more water is added, until, on the addition of the fourth half-molecule, its effect becomes less than that of the second, and a small evolution of heat takes place. From this point, until between five and seven-and-a-half molecules of water have been added, the calorific effect of a given quantity of water continually *increases* (contrary to what takes place with sulphuric and nitric acids), showing that the heat-absorbing action still takes place, but to a less and less extent, until more than five molecules of water have been added to each molecule of acetic acid.

When successive quantities of alcohol, up to ten molecules, are added to acetic acid, each addition causes absorption of heat; but the numerical results clearly indicate, in this case also, the simultaneous occurrence of distinct phenomena. Favre obtained the following results:

Molecules of alcohol successively added to 1 molecule of acetic acid	1	1	1	1	2	2	2
Units of heat absorbed on the addition of each successive quantity	91.91	0.91	7.35	14.88	31.85	41.47	64.60

Absorption of heat also frequently occurs on the dilution of saline solutions, a phenomenon with regard to which numerous quantitative determinations have been made by Favre. It is probable that in these cases, a change takes place more or less analogous to the liquefaction of a solid by solution: acetic acid, or a salt dissolved in a small quantity of water, may be conceived of as being imperfectly liquefied, so that further liquefaction, accompanied by the disappearance of a certain quantity of heat, takes place on the addition of more water. Viewed in this way, these phenomena appear to be comparable with the gradual melting, which, as we have seen (pp. 74 and 76), takes place in some solids under the direct action of heat.

Reaction of Acids and Bases in presence of water.—It will be easily understood that the thermal effects which may result from the reaction of different substances upon each other in presence of water, are even more complicated than any of those which have yet been considered, and therefore that the calorimetric study of these reactions is subject to still more numerous causes of error than that of the foregoing processes. In addition to the different specific heats of the reagents and products, and to the different quantities of heat absorbed by them in dissolving, or given out by them in combining with water, the conversion of soluble substances into insoluble ones, as a consequence of the chemical action, or the inverse change of insoluble into soluble bodies, are among the secondary causes to which part of the calorimetric effect may be due in these cases. The greater number of these disturbing causes may be got rid of, or at least very much reduced in amount, by effecting the reactions in the presence of comparatively large quantities of water, but then the difficulty of accurately measuring the total quantity of heat produced becomes greater.

The following table gives the number of units of heat evolved, according to Favre

Oxide of	Equivalents.	Units of Heat evolved with Various Acids:			
		Sulphuric.	Nitric.	Hydrochloric.	Acetic.
Potassium . . .	47	16083	15510	16656	13978

and Silbermann's experiments, in the transformation of equivalent quantities of various

metallic protoxides into neutral salts, the reaction taking place in all cases in presence of a large quantity of water, and the products being all soluble.

The heat evolved by equivalent quantities of potash and soda respectively, in forming neutral salts with the following additional acids, is shown in the next table:

Acids.	Potash.	Soda.	Acids.	Potash.	Soda.
Hydrobromic acid .	15510	15159	Valeric acid . .	13500	13500
Hydriodic acid .	15698	15097	Citric acid . .	13658	13178
Metaphosphoric acid }	16168	15407	Oxalic acid . .	14156	13752
acid }			Tartaric acid . .	13425	12651
Pyrophosphoric acid	16920	15655	Carbonic acid .	12878	..
Phosphoric acid .	17766	..	Hydrosulphuric acid }	6477	6550
Formic acid	13308			

Numerous determinations of a similar kind have also been made by Andrews (Trans. Roy. Irish Academy, xix.; Rep. Brit. Associat. 1849, p. 69; see also Miller's *Chemical Physics*, p. 352). The following is the most important of the conclusions at which he arrived:—"An equivalent of the same base, combined with different acids, produces nearly the same quantity of heat; but an equivalent of the same acid combined with different bases, produces different amounts of heat." It is, however, scarcely needful to point out, that such a difference as is here implied between the chemical behaviour of acids and bases does not really exist in nature, and that its appearing to be indicated by the experiments in question, could only result from the accident of the bases examined representing a greater range of varying chemical energy than the acids.

The results obtained on bringing together an alkali and an acid in various proportions are of considerable interest. They show clearly that, at least in the case of the most distinctly characterised acids, chemical action takes place only between definite atomic proportions of acid and alkali. The numbers given below represent the number of units of heat evolved by one equivalent of potash or soda (the quantity containing 39 pts. potassium, or 23 pts. sodium) when acted on by varying quantities of acid.

- 1 equivalent potash
- with 1 equivalent sulphuric acid gave 15609 units of heat.
- " 2 " " " " 15609 " "
- " 1 " " acetic " " 13935 " "
- " 2 " " " " 13823 " " (Favre and Silbermann).

The results of Thomsen's experiments (Jahresber. 1854, p. 30) with sulphuric acid and potash and soda are as follows:

Equivalents of acid	$\frac{1}{2}$	$\frac{3}{4}$	1	$\frac{3}{2}$	2	4
Heat evolved { Soda	5421	10656	15368	15320	15524	15216
{ Potash	4968	9880	15368	..	15248	

It will be seen that the evolution of heat increases sensibly in the same proportion as the quantity of acid used, up to one equivalent, but that beyond this point no further increase in the amount of heat evolved accompanies the augmentation of the quantity of acid. Hence it appears that acid sulphates of potassium and sodium are not formed in presence of a large quantity of water, a conclusion which agrees with Favre and Silbermann's observation, that the evolution of heat which takes place on adding one equivalent of base to a dilute solution of acid sulphate or sulphite of potassium, is the same as if the second equivalent of acid contained in the salt were employed in the free state. By experiments on the heat evolved on adding successive quantities of other acids—such as boric, silicic, phosphoric—to one equivalent of soda or potash, Thomsen found that the heat produced was at first nearly in proportion to the quantity of acid added, but that, as the latter was increased, the evolution of heat increased also, though in a continually slower ratio.

Evolution of Heat in the formation of Aqueous Solutions.—When a gas dissolves in water, the heat due to the chemical action is augmented by that due to the physical phenomenon of the liquefaction of the gas; so also, when a solid body is dissolved in water, the total thermal effect observed is due in part to the chemical action taking place between the water and the solid, and in part to the liquefaction of the substance dissolved. In the former case, the chemical and physical parts of the phenomenon both cause evolution of heat: in the latter case, the physical change occasions disappearance of heat; and if this effect is greater than that due to the chemical action, the ultimate result of the combined process is the production of cold, and it is this which

is most usually observed. The following tables contain the results of Favre and Silbermann's experiments, calculated for one gramme of gas or solid salt dissolved.

Solution of Gases in Water.

NOTE.—The sign *plus* (+) denotes evolution of heat.

The foregoing table includes numbers relating to the solubility of some salts which are, in reality, either quite insoluble or very slightly soluble in water. These numbers are deduced from a comparison of those which represent the heat of formation of these salts with the numbers expressing the heat evolved by the same bases with other acids. The heat of formation of salts which are insoluble, and therefore separate out in the solid form, is usually considerably greater than the heat of formation of soluble salts of the same bases and acids, and it is this excess which in the above table is given as the heat absorbed on solution by such salts as sulphate of barium, sulphate of strontium, &c.

Cold produced by Chemical Decomposition.—The proposition that the thermal effect of the reversal of a given chemical action is equal and opposite to the thermal effect of that action itself, has already been referred to (p. 108) as one which might with great probability be assumed as true. A direct consequence of this proposition is that the separation of any two bodies is attended with the absorption of a quantity of heat equal to that which is evolved in their combination. The truth of this deduction has been experimentally established in various cases by Woods (Phil. Mag. [4] ii. 368; iv. 370); Joule (*ibid.* iii. 481) and Favre and Silbermann, by comparing the heat evolved in the electrolysis of dilute sulphuric acid, or solutions of metallic salts, with that which is developed in a thin metallic wire by a current of the same strength; and by comparison of the heat evolved in processes of combination accompanied by simultaneous decompositions, with that evolved when the same combination occurs between free elements.

In the experiments of Woods, a voltaic current was first made to pass through a vessel containing dilute sulphuric acid, and the quantity of gas evolved in a given time was determined, and also the simultaneous rise of temperature, the strength of the current being measured at the same time by the tangent-compass (ii. 460). The electrolytic cell was then removed, and a thin platinum wire introduced between the poles, of such a length as to produce a resistance equal to that of the electrolyte. The quantity of heat evolved in this wire was then determined, and found to exceed that which was previously evolved in the electrolytic cell, by a quantity equal to that which would be evolved by the combination of the oxygen and hydrogen set free by the current in the previous experiment.

Joule made similar experiments on the decomposition of dilute sulphuric acid, sulphate of copper, and sulphate of zinc; and, regarding the difference in the quantity of heat evolved when the current traversed a circuit completely metallic, and when the metallic circuit was broken by the interposition of an electrolyte, as the heat absorbed by the separation of the elements of the electrolyte, he obtained numbers which agree very fairly with those found by other experimenters for the heat evolved in the union of the same elements, as shown in the following table, which gives the quantities of heat evolved or absorbed in the oxidation or reduction of 1 gramme of each metal, according to various experimenters.

	Joule.	Dulong.	Andrews.	Favre and Silbermann.	Grassi.	Woods.
Copper . . .	594	. . .	600	655	. . .	611
Zinc . . .	1185	1297	1315	1277	. . .	1307
Hydrogen . .	33553	34587	33808	34462	34666	

The proposition in question has also been confirmed by experiments of another kind. Thus, for instance, by determining the heat evolved when different metals were dissolved in water or dilute acid, Woods found that it was less than that which would be produced by the direct oxidation of the same metals, by a quantity equal to that which would be obtained by burning the hydrogen set free, or which was expended in decomposing the water or acid; and therefore that, when this latter quantity was added to his results, they agreed with the numbers given by experiments of direct oxidation. The quantities of heat evolved by 1 gramme of the several metals, when augmented by that corresponding to the decomposition of the water or acid, were as follows:—

Metal.	Heat by solution of 1 gramme.	Metal.	Heat by solution of 1 gramme.
Sodium . . .	3293	Tin . . .	595
Potassium . .	1745	Lead . . .	256
Zinc . . .	1307	Mercury . . .	118
Iron . . .	1204	Silver . . .	96
Copper . . .	611	Bismuth . . .	95.5

Indirect methods of determining Heat of Combination.—Assuming the truth of the proposition that in the decomposition of a compound as much heat is absorbed as is liberated in its formation, it is obvious, from the foregoing examples, that the calorimetric effect of a given chemical change can be calculated if the effects of all those which occur simultaneously with it are known. Upon this principle, which is merely that adopted by Woods in the experiments described in the last paragraph, Favre and Silbermann have made a very extensive series of determinations of the quantities of heat evolved in reactions which could not have been easily investigated directly. Their experiments were made with the mercurial calorimeter, and the heat due to a given process was in some cases deduced from two distinct reactions. Thus, the heat of formation of oxide of zinc was deduced (1) from the solution of metallic zinc in dilute sulphuric acid, (2) from the solution of zinc in dilute hydrochloric acid. For the purposes of calculation, the former reaction was considered as consisting in the formation of oxide of zinc, with simultaneous decomposition of water, $\text{Zn} + \text{H}^2\text{O} = \text{ZnO} + \text{H}^2$, and in the subsequent formation of sulphate of zinc by the action of this oxide on the dilute sulphuric acid, $\text{ZnO} + \text{H}^2\text{SO}^4 = \text{H}^2\text{O} + \text{ZnSO}^4$. The heat absorbed by the calorimeter during the solution of 1 gramme of zinc was 567.9 gramme-degrees: this, according to the supposition, represented the heat of oxidation of the zinc + the heat of formation of sulphate of zinc from anhydrous oxide and dilute sulphuric acid—the heat absorbed by the decomposition of water. Calling the heat of oxidation of one

DETERMINATIONS OF HEAT OF COMBINATION. 115

gramme of zinc x , and calculating, from the direct determinations previously recorded, the calorimetric effects of the other processes, we have

$$x = 567.9 + 1060.4 - 335.5 = 1292.8.$$

Similarly, when 1 gramme of zinc was dissolved in dilute hydrochloric acid, 503.8 units of heat were absorbed by the calorimeter, and the following equation was obtained to represent the heat of oxidation of that weight of zinc:

$$x = 503.8 + 1060.4 - 274.3 = 1289.9;$$

Heat absorbed
by calorimeter.

Heat absorbed
by decomposition
of water.

Heat evolved by

hydrochloric acid on
oxide of zinc.

a result which agrees almost exactly with the foregoing.

This number having been obtained, the heat of oxidation of metallic copper could be deduced in a similar manner from the quantity of heat set free when a known weight of zinc was dissolved in a solution of sulphate of copper. In this way the number 684 was found for the heat of oxidation of 1 gramme of copper.

The following table gives the heats of combination of one equivalent of several metals with one equivalent of various metalloids, deduced from experiments of this kind:—

Metals.	Units of heat evolved by combining with				
	8 grammes oxygen.	35.5 grammes chlorine.	80 grammes bromine.	127 grammes iodine.	16 grammes sulphur.
Hydrogen . . .	34462	23783	9322	— 3606	2741
Potassium . . .	76238*	100960	90188	77268	45638
Sodium . . .	73510*	94847			
Zinc . . .	42451	50296			20940
Iron . . .	37828	49651			17763
Copper . . .	21885	29524			9133
Lead . . .	27675	44730	32802	23208	9556
Silver . . .	6113	34800	25618	18651	5524

Taking the heat developed in the formation of any given compound as a measure of the energy of the affinity of its constituents, a certain definiteness and precision of meaning are given to such terms as strong and weak, active and inert, which are often used in reference to chemical reagents in rather a vague sense; and on comparing the numbers representing the heats of formation of various compounds, they will be found to bear out in a general way the manner in which such terms are commonly applied. The results recorded in the above table, for instance, serve to explain certain facts which have often been quoted as anomalous and opposed to the commonly received idea that the affinities of chlorine are stronger than those of bromine or iodine, and the affinities of bromine stronger than those of iodine. The facts referred to are such as these: the observation of Fehling that in the fractional precipitation of a solution containing both chlorides and bromides with nitrate of silver, the whole of the bromine is contained in the first portions of the precipitate; the similar observation of Field (*Chem. Soc. Qu. J.* x. 234), and the decomposition of chloride of silver when brought in contact with an aqueous solution of bromide or iodide of potassium, described by the same chemist; and particularly the violent decomposition of chloride of silver, attended with evolution of heat, which takes place, as observed by Deville (*Ann. Ch. Pharm.* ci. 198), when aqueous hydriodic acid is poured upon it.

The precipitation of bromide or iodide of silver, to the exclusion of the chloride, in cases of fractional precipitation with nitrate of silver, and the conversion of chloride of silver into bromide or iodide by contact with an aqueous solution of iodide of potassium, may be considered as essentially the same phenomenon. When the latter transformation is expressed by an equation, the substances whose formulæ appear in the left-hand member of the equation are those which suffer decomposition; while those which are formed appear on the right-hand side; and on comparing the calorimetric values of the several terms, making due allowance for their state of solution or otherwise, we find that the sum of the calorimetric values on the left-hand side of the equation is less than the sum of the calorimetric values of the substances on the right-hand; thus indicating that, although the conversion of chloride of silver into bromide or iodide by simple substitution would be attended with absorption of heat, the combined effect of all the actions which take place in the experiments under consideration is to cause an evolution of heat.

* These numbers represent the formation of aqueous solutions of potash and soda: all the rest refer to anhydrous compounds.

Thus we have

Sums: $\frac{120478}{122709}$

therefore: heat evolved in the reaction = $122709 - 120478 = 2231$ gramme-degrees.

Sums: $\frac{107279}{115742}$

therefore: heat evolved in the reaction = $115742 - 107279 = 8463$ gramme-degrees.

Similarly, for the reaction of aqueous hydriodic acid on chloride of silver, we have:

Sums: $\frac{49804}{58843}$

therefore: heat evolved in the reaction = $58843 - 49804 = 9039$ gramme-degrees.

The heat evolved in a considerable number of processes of oxidation has been indirectly determined by Favre (J. Pharm. Chim. [3] xxiv. 241, 311, 412; Jahresber. 1863, pp. 22 *et seq.*), for the most part by effecting the oxidations in presence of water in the mercurial calorimeter, by means of hypochlorous acid, whose heat of formation, calculated for one equivalent of chlorine, he found by preliminary experiments to be - 7370 units.

For the details of this investigation we must refer to the original papers; the most important results obtained are as follows, calculated always for one equivalent of the element operated upon.

Substance.	Product.	Heat evolved.	Ratio.

It is obvious that, even supposing the principle upon which these indirect determinations are made to be quite correct, and all the interfering circumstances to have been taken into account, the results arrived at cannot be of the same degree of accuracy as those obtained by more direct methods: for the total uncertainty attaching to all the independent data from which they are deduced will be accumulated upon them. Moreover, although a comparison of the heat of chemical action, as determined directly, with that deduced indirectly, generally shows, in the simple cases in which it is possible to institute such a comparison, a degree of agreement which may be taken as a confirmation of the correctness of the principles whereby the calculated result is arrived at, and as proving that, at least in these cases, no modifying circumstance of any great importance has been overlooked in the calculation, still it cannot be considered as proved by existing experiments that the cold of decomposition is *always* equal to the heat of combination. On the other hand, it seems probable, on general grounds, that the calorimetric effect of a given chemical process is not an absolutely constant quantity, but that it is to some extent dependent on accompanying physical conditions. In particular, it seems likely that it must vary more or less with the temperature at which the chemical action takes place, and therefore—to take a particular example—that the heat evolved by the combination of mercury with oxygen, at a comparatively low temperature, is not equal to the heat absorbed by the decomposition of oxide of mercury at a higher temperature. The equality of these two quantities of heat would involve also the equality of the specific heat of oxide of mercury with the sum of the specific heats of its elements; otherwise, the quantity of heat needed to raise the temperature of a given quantity of mercury and oxygen from the ordinary temperature to a temperature above that at which oxide of mercury is decomposed, would be different, if the two substances remained uncombined during the process, from what it would be if they first entered into combination and afterwards separated again; and since the final condition of the mercury and oxygen would be the same in each case, the difference between the quantities of heat would have disappeared without producing any apparent effect. In the particular case that has been taken as an example, it is possible that the specific heats of the elementary bodies are together equal to the specific heat of the compound, or that the difference may be compensated by the difference in the latent heats of vaporisation of oxygen at the temperature of combination and at that of decomposition. But, although this may be the case, experimental proof that it is so is still wanting; and even if it were afforded here, or for any other particular substance, there would still not be sufficient warrant for assuming as a generally established fact that the cold of decomposition is equal to the heat of combination, independently of the conditions under which these processes respectively occur. In connection with these considerations, it is perhaps worth while to draw attention to the fact that the heat of combustion of hydrogen, deduced by Joule from the electrolysis of water at the ordinary temperature, is decidedly less than that found by other experimenters who determined directly the heat of combustion at a high temperature (see p. 114). These experiments are perhaps not sufficiently comparable in other respects to justify us in attaching much importance to this result; but, taking it as it stands, it is in harmony with the fact that the specific heat of water-vapour is less than the sum of the specific heats of its constituents.

The laws by which Thomsen considers that the development of heat in chemical action is governed, appear to involve views similar to those above explained. The fundamental propositions assumed by him are as follows:—The intensity of the chemical energy of the same body at a constant temperature is unchangeable; the whole quantity of heat developed in a given chemical action is a measure of the chemical energy therein exerted, and is proportional to the difference between the total chemical energy of the reagents and the total chemical energy of the products.

Heat produced by Chemical Decomposition.—There are a few phenomena which are, at least apparently, exceptions to the general rule that heat is evolved in combination and absorbed in decomposition. It was found, for instance, by Favre and Silbermann, that charcoal evolves more heat by burning in nitrous oxide than by burning in pure oxygen. The excess of heat in this case could only be due to heat evolved in the decomposition of the nitrous oxide, and direct experiments proved that this decomposition was attended with evolution of heat. They found further that heat is produced in the decomposition of peroxide of hydrogen by platinum, and from the experiments of Favre, already recorded, it appears that heat is absorbed in the oxidation of chlorine to hypochlorous or to chloric acid. Perhaps these and similar phenomena may be brought into harmony with the general rule, by taking into consideration the evolution of heat due to the combination of two similar atoms to form a molecule, and the corresponding absorption of heat due to the separation of the atoms constituting a molecule of an elementary body.

The influence of high temperature in promoting chemical action—as, for instance

between oxygen and hydrogen, which combine when heated, but are without action on each other in the cold—is not an exception of the kind here referred to. It is rather a thermometric than a calorimetric phenomenon; high temperature being a favourable condition for chemical action in these cases, but in no way its cause. At very low temperatures chemical action appears in all cases to be much retarded: as one illustration, it may be mentioned that when liquefied ammonia, cooled to about -65° , is poured upon concentrated sulphuric acid, the two liquids form separate layers, and for some time no action takes place between them (Loir and Drion). Phosphorus and iodine, which combine energetically and with vivid combustion at common temperatures, may be shaken together in a tube cooled by a freezing mixture, without exerting the slightest action on each other.

5. Relations of Heat to Electricity.

Electricity produced by Heat.—*Pyro-electricity developed in Crystals.*—To what has been already said on this subject in the article **ELECTRICITY** (ii. 411) we have only to add the results arrived at by Gauguain (Ann. Ch. Phys. [3] lvii. 6) in reference to the pyro-electricity of tourmalines. He finds that this phenomenon obeys the following laws:—(1.) When any number of tourmalines are united by their poles of the same name, they form a battery which produces, under any given circumstances, a quantity of electricity exactly equal to the sum of the quantities which the several tourmalines would produce separately under the same circumstances.

(2.) When several prisms of equal section are superposed, the quantity of electricity developed by the combination is merely equal to that which would be furnished, under the same conditions, by any one of the prisms taken separately.

(3.) The quantity of electricity produced by a prism of tourmaline is proportional to its sectional area, and is independent of its length.

(4.) The quantity of electricity which a tourmaline develops when its temperature is lowered a given number of degrees, is independent of the length of time in which the cooling is effected.

(5.) When a tourmaline is heated a given number of degrees, the quantity of electricity developed is precisely the same as that which would be produced if it were cooled to an equal extent.

Gauguin finds that the development of electricity, consequent on the alteration of the temperature of a tourmaline, is very much more marked if one pole of the crystal is placed in electric communication with the earth, than when the crystal is completely insulated.

Thermo-Electricity.—When two bars of dissimilar metals are soldered together at each end, a current of electricity generally circulates through the circuit formed by them, as long as the two soldering points are at different temperatures. The electromotive force developed at each joint is a function of the temperature, which, in the cases that have been specially examined, may be represented by the formula $E = a + bt + ct^2$, where t is the temperature, and a , b , and c are constants depending on the nature of the metals used. Consequently, the resultant electromotive force, when the temperatures of the joints are t and t' respectively, may be represented by

$$e = E - E' = b(t - t') + c(t^2 - t'^2) = (t - t')[b + c(t + t')],$$

which shows that the current vanishes not only when the joints are at the same temperature, or when $t = t'$, but also when the sum of their temperatures attains a value that is constant for the same pair of metals,—that is when $t + t' = -\frac{b}{c}$. (Avenarius,

Pogg. Ann. cxix. 406, 637.)

Heat produced by Electricity.—The laws regulating the development of heat by the sudden discharge of frictional electricity, or electricity of high tension, have already been treated of in the article **ELECTRICITY** (ii. 395), and in the same article (p. 470) it has been shown that the heat produced by a continuous current of electricity is the exact equivalent of the chemical action whereby the current is generated. In the application of this rule, the total chemical action throughout the circuit must be taken into account, electrolytic decomposition being counted positive or negative according as the direction of the current which would be generated by it, were it to take place independently of the battery, is the same as that of the battery or the contrary. As further explained in the article referred to, the heat developed in the unit of time by an electric current is related to the intensity of the current and to the resistance of the circuit in the manner expressed by the formula:

$$H = PR.$$

From this it follows that, by diminishing the resistance of the circuit, the electro-motive force remaining the same, the total heat, H , can be augmented indefinitely, the intensity, and therefore also the chemical action in the battery, increasing in proportion to the diminution of resistance. But in any single portion of the circuit, whose resistance is r , the development of heat will attain a maximum for a particular value of r .

The heat produced in this part will in fact be $H = I^2 r = \frac{E^2}{(R+r)^2} r$, the value of which last expression reaches a maximum when $R=r$, R being the constant resistance of the remainder of the circuit, including the battery. Hence, in order that as large a quantity of heat as possible may be generated in a given time in the conducting wire, the resistance r of the conducting wire must be made equal to the permanent resistance R of the remainder of the circuit. And, since the heating power of the current represents its total energy, it follows that the same proportion between the external and internal resistance of the circuit is the most advantageous that can be adopted for causing the current to produce changes of any other kind outside the battery.

Thermal phenomena of a particular kind occur when an electric current, instead of traversing a homogeneous conductor, passes from one substance to another. Then, in addition to the development of heat corresponding to the resistance of the conductor, according to the laws stated in the last paragraph, a further development or absorption of heat takes place, depending upon the direction of the current. If the current crosses the point of junction of two dissimilar portions of the circuit, in the same direction as the thermo-electric current which would be generated by the application of heat to this point, then the heat developed there is less than corresponds to the resistance of that portion of the circuit, or, in other words, heat is absorbed; if the current passes the point of junction in the opposite direction, the heat generated is more than what corresponds to the resistance.

With a junction formed of the same two metals, the development or absorption of heat thus occasioned is proportional to the intensity of the current by which the junction is traversed. With combinations of different metals, the extent to which this phenomenon occurs varies with the positions of the metals in the thermo-electric series (ii. 412), being greatest for those combinations which give the most intense thermo-electric currents.

6. Relations of Heat to Mechanical Energy.

In preceding parts of this article, we have seen that increase of volume and of elastic force are among the most universal of the effects of heat. In this way heat is constantly producing motion, and when this motion is concentrated in a given solid body, and a definite direction is given to it, as in the steam-engine, heat becomes by far the most important artificial source of mechanical power that we possess. Conversely, innumerable familiar facts supply us with illustrations of the production of heat at the expense of mechanical work. Thus, in all machines there is a certain loss of mechanical energy, the work performed by the machine never representing the full equivalent of the work needed to drive it. That portion of the mechanical energy supplied to the machine which is wasted, so far as the performance of useful work is concerned, is expended in overcoming the passive resistances by which the motion of the machine is opposed; such, for instance, as friction between contiguous surfaces not moving with the same velocity, or the rigidity of straps or cords used to transmit movement from one part to another. But, whenever motion is produced in opposition to friction, or a rigid body is forcibly bent, heat is generated; the mechanical energy expended in producing these effects is lost to the purposes of the machine, but the heat evolved is its representative. Percussion is another means by which mechanical energy can be destroyed and heat generated in its stead. These and similar facts have long attracted the attention of philosophers, and great importance has been attached to them in reference to most of the theories that have been suggested from time to time to explain the nature of heat and the effects which it produces. The following is a quotation from *Black's Lectures on Chemistry* (vol. i. pp. 31, 32), and relates to Bacon's investigations into the nature of heat contained in his treatise *De formâ Calidi*:—

"The only conclusion, however, that he" (Lord Verulam) "is able to draw from the whole of his facts, is a very general one, viz. that heat is motion.

"This conclusion is founded chiefly on the consideration of several means by which heat is produced, or made to appear, in bodies; as the percussion of iron, the friction of solid bodies, the collision of flint and steel.

"The first of these examples is a practice to which blacksmiths have sometimes recourse for kindling a fire; they take a rod of soft iron, half an inch or less in thickness, and, laying the end of it upon their anvil, they turn and strike that end very quickly on its different sides, with smart blows of a hammer. It very soon becomes

red hot, and can be employed to kindle shavings or wood, or other very combustible matter.

"The heat producible by the strong friction of solid bodies, occurs often in some parts of heavy machinery, when proper care is not taken to diminish that friction as much as possible, by the interposition of lubricating substances; as in the axles of wheels that are heavy themselves, or heavily loaded. Thick forests are said to have taken fire sometimes, by the friction of branches against one another in stormy weather. And savages, in different parts of the world, have recourse to the friction of pieces of wood for kindling their fires. . . .

"The third example above adduced in the collision of flint and steel, is universally known.

"In all these examples, heat is produced or made to appear suddenly, in bodies which have not received it in the usual way of communication from others, and the only cause of its production is a mechanical force or impulse, or mechanical violence."

From these and many other similar phenomena, it is abundantly clear that, by the expenditure of heat, mechanical work can be effected, and that heat can be produced by the expenditure of work. Dismissing, therefore, for the present, all considerations as to the ultimate nature of heat, we may say that heat and work are mutually convertible, and we have in this section to consider the conditions which regulate the transformation of one of these forms of energy into the other.

Work produced by Heat.—The measure of the work done by heat, when it causes expansion, is obviously the product of the resistance overcome into the space through which the expansion takes place; that is, if r denote the resistance, and v and v' the initial and final volumes of the body which undergoes expansion, the work done by the heat will be represented by

$$A = r(v' - v).$$

In estimating the resistance by which the expansion of a given body is opposed, it is needful to take into account, not only the external pressure upon its surface, but also, as has been already pointed out (pp. 40 and 73), the molecular forces which tend to maintain unaltered the relative positions of its ultimate particles. The work, A , performed by heat when it causes expansion, must therefore be considered as made up of the *internal work*, a_i , performed in opposition to internal molecular forces, and the *external work*, a_e , expended in overcoming external pressure. In solid and liquid

bodies the ratio, $\frac{a_i}{a_e}$, of the internal to the external work is very considerable, but in a

perfect gas, the resistance to expansion arising from the mutual attractions of the molecules is insensible, and therefore also the expenditure of work in overcoming this resistance is insensible: hence, in this case $\frac{a_i}{a_e} = 0$, or $a_e = A$. But since it is the

external work only which is available for the production of external effects, the consideration of the transformation of heat into mechanical energy is much simpler in the case of gases than in that of liquid or solid bodies; it is further much the most important practically, for although the heat employed in the performance of internal work upon solids or liquids is not necessarily lost ultimately, it is, for the time at least, totally unavailable. We may perhaps compare the transformation of heat into work with the commercial transformation of labour into wealth: then, a perfect gas will represent a medium of transformation comparable with an industrial process which requires no previous expenditure on the part of the workman to enable him to exchange his labour for wages; while a solid or liquid will represent a medium of transformation comparable with a process which can only be carried out by the previous investment of a considerable capital. The capital thus "sunk" may be realised again at some future time, but it represents a certain quantity of labour, which, for the time being, cannot be transformed into wealth.

In order that work may be continuously performed by heat, it is not enough that a portion of air or other gas should be expanded once for all in a cylinder closed by a piston, or in any other similar apparatus. It is true that motion would be thus produced, and that this might be the full equivalent of the heat expended, but the process would soon come to an end. Practically, the extent to which a gas can be expanded so as to produce motion, is very limited, both by the size of the apparatus that can be used and by the temperatures that are attainable. In order that the process may be continuous, the action of the machine, by means of which the transformation is effected, must be periodic: after a certain cycle of changes, all its parts must return to the same relative positions and condition as they had at first, and the air or gas must return to its original pressure and temperature. Such a cycle might evidently be repeated indefinitely, and if any transformation of heat into work were effected by it, the same amount of transformation would take place each time the cycle was completed. At

pages 50 and 51, we saw that in the passage of a gas through a succession of conditions, with respect to temperature, pressure, and volume, which can be represented graphically by a rectangle, and are such that the final state of the gas is the same as its state at the beginning of the process, a certain quantity of heat is expended, which is proportional in amount to the area of the rectangle representing the succession of changes; but it was not there explained what becomes of the heat thus expended.

Returning to the consideration of this case, and using the same notation as before, it is plain that, during the passage of the gas from the state A to the state B, through the intermediate stages represented by the lines AD, DB, a quantity of work is performed, which is represented, in kilogramme-metres, by

$$A = p'(v' - v);$$

and that while the gas returns from the condition B to the condition A, along BCA, there is expended a quantity of work represented by

$$A' = p(v' - v);$$

and, therefore, during the whole cycle ADBCA, a quantity of work is ultimately gained equal to

$$A - A' = (p' - p)(v' - v).$$

But, by the last equation on page 51, the amount of heat expended at the same time is

$$Q - Q' = \frac{D}{Ha} (c' - c)(p' - p)(v' - v);$$

therefore, between the heat expended and the work produced, there exists a relation expressed by the equation

$$Q - Q' = \frac{D(c' - c)}{Ha} (A - A') \dots (n).$$

If we assume that the difference between the specific heat under constant pressure and the specific heat at constant volume is constant for each gas, and is inversely proportional to its density (a relation which is implied in equation (a), p. 42), the coefficient of $(A - A')$ in this expression is constant; we may therefore represent it by $\frac{1}{E}$,

and write equation (n) thus:

$$Q - Q' = \frac{1}{E} (A - A') \quad \text{or} \quad E(Q - Q') = A - A'.$$

That is to say, the heat expended is proportional to the work performed, and *vice versa*; so that for each kilogramme-degree of heat expended, a quantity of work is performed equal to E kilogramme-metres.

The value of E can be deduced from equation (n) by introducing the numerical values of the constants, namely:

$$H = 10,333 \text{ kilogr.}, \quad a = 0.003665, \quad D = 1.293 \text{ kilogr.} \\ c = 0.2374, \quad \text{and } c = 0.168 \text{ (p. 42).}$$

These values give us:

$$E = 423;$$

that is to say, when heat is transformed into work, every kilogramme-degree of heat (1000 of the heat-units hitherto employed in this article) consumed generates 423 kilogramme-metres of work; or, more generally, the heat needed to raise the temperature of any given weight of water from 0° to 1° C., is equivalent to the amount of mechanical energy required to raise 423 times the same weight of water through one metre from the surface of the earth.

The ratio E is therefore called the mechanical equivalent of the unit of heat, and its reciprocal is, as we shall see, the thermal equivalent of the unit of work.

That the relation between the heat expended and the work generated is necessarily constant, whatever the process may be by which one is transformed into the other, results from the following considerations. If by one process a unit of heat could be made to perform E units of work, and by another process $E' + e$ units of work could be generated by the same quantity of heat, a portion of the mechanical energy produced in this second process might be expended in reversing the first, so as to regenerate the

Fig. 547.

original quantity of heat: thus by combining the two processes, the first being worked backwards, each unit of heat expended would reproduce itself and ϵ units of work in addition; there would thus be generation of mechanical energy without any corresponding annihilation of any other form of energy. (The principle here implied, that a given quantity of work is capable of giving rise to as much heat as is needed for its own production, results from the above equation (n), but it will be further considered in what follows.)

Nevertheless, in consequence of the unavoidable defects of all experimental processes, the values of E deducible by different methods are not exactly equal, but the agreement between them is quite sufficient to establish the fundamental principle of the real constancy of the relation between heat and work. A table giving the results of the most important determinations of this ratio will be found further on under the head Heat produced by Work.

Under all circumstances, the quantity of heat which must be employed in order to effect the transformation of a given amount of it into work considerably exceeds the quantity transformed. In the example above considered, the total quantity of heat imparted to the gas was Q ; but of the work, A , generated by this amount of heat during the passage of the gas from the state A to the state B , a certain portion, A' , was employed, during the return of the gas to its initial state, in regenerating the quantity of heat Q' . The useful work performed was, therefore, $A - A'$, and the quantity of heat transformed was $Q - Q'$, and the ratio of this to the total heat employed, namely, $\frac{Q - Q'}{Q}$, represents the efficiency of the process of transformation, or the value

of the engine in which it takes place as a source of mechanical energy. The maximum value which this fraction is capable of attaining, depends on the range of temperature passed through by the fluid which is the medium of transformation. This can be most easily demonstrated in a case where the changes of the volume of the gas take place at constant temperatures; that is, where it is kept at one temperature during the whole process of expansion and at another during the whole process of contraction.

These conditions are approximately realised practically in the air-engine invented by the Rev. Robert Stirling, in 1816. This engine consists essentially of two cylinders; a larger one to which the heat is applied, which we may call, for distinction, the heating cylinder, and a smaller one, which may be called the working cylinder, wherein the transformation of heat into work takes place. The bottom of the working cylinder is connected by a pipe without a valve with the top of the heating cylinder. Within the heating cylinder is a plunger, composed of non-conducting materials, which occupies nearly half its length, and between it and the sides of the cylinder are passages by which the air can pass from one end to the other when the plunger is raised or lowered. In the working cylinder is a piston which fits it air-tight; this piston and the plunger of the other cylinder are both attached by connecting rods to cranks fixed to the same axle, but making an angle of ninety degrees with each other. The heating cylinder is closed at the top, and the rod from which the plunger hangs passes through an air-tight stuffing box; the working cylinder is open at the top. Heat is applied to the bottom of the heating cylinder, and the upper part is kept cool.

The action of the engine is as follows: Suppose the plunger to be at the top of the heating cylinder, and consequently, the piston in the working cylinder in the middle of its stroke; then, if heat is applied to the bottom of the heating cylinder, the air contained there below the plunger will be expanded, and will press the piston upwards; but the motion of the piston being communicated through the axle to the plunger, the latter will descend, and displacing the heated air from the bottom of the heating cylinder, drive it into the cool space at the top. The elastic force of the air being thus diminished, the piston will be forced down by the pressure of the air upon its upper surface; the plunger now returning to the top of the heating cylinder, the air will be driven to the bottom, where it will be again heated, and the piston will be again forced up by its expansion. Thus by the alternate heating and cooling of the same quantity of air, the motion of the engine is kept up.

In consequence of the manner in which the piston and plunger are respectively connected with the axle, each attains its maximum velocity while the other is at rest, so that the action of the engine during one revolution may be considered as essentially made up of four periods: in the first, the temperature of the air is raised, its volume remaining the same, and consequently its pressure increasing; in the second, the air expands, performing work, but so much heat is imparted to it during the expansion, that its temperature remains constant; in the third period, the temperature of the air is reduced to what it was at the beginning of the first period, its volume being unaltered, and therefore its elastic force being diminished; and in the fourth, it is compressed to its original volume, the heat generated by the compression being withdrawn, so that the air remains at the same temperature throughout the whole process. These four

successive operations, constituting together one cycle in the action of the engine, may be represented by a diagram such as *fig. 548*, where the abscissa OA represents the volume v_0 of a unit of weight of air at the initial temperature t_0 , and the ordinate AM represents the corresponding pressure p_0 . The air is first heated,

Fig. 548.

without change of volume, from the temperature t_0 to the temperature t_1 ; during this operation, its elastic force increases to p_1 , represented in the diagram by the ordinate AP ; and to effect this change a quantity of heat equal to $c(t_1 - t_0)$ must be imparted to it, c being the specific heat of air at a constant volume; but as no expansion takes place, no work is performed. Next, the air expands from the volume v_0 to the volume v_1 , represented by the abscissa OB . Since the temperature of the air is kept constant while it expands, the pressure varies inversely as the volume, a relation represented by the hyperbolic arc PQ , so that the final pressure of the expanded air is represented by the ordinate BQ . During this operation, external work is performed, which is obviously proportional to the area $APQB$, contained between the arc PQ , the axis of abscissæ, and the two ordinates AP and BQ . But in order to prevent the cooling of the gas during its expansion, a quantity of heat, q , must be given to it, of which the mechanical equivalent is exactly the external work which this area represents. In the third operation, the air is cooled to its initial temperature t_0 , its volume remaining unaltered, and therefore no work being generated or expended. The pressure is thus reduced from BQ to BN , and a quantity of heat requires to be withdrawn equal to $c(t_1 - t_0)$. Lastly, the air is compressed, while kept at the constant temperature, t_0 , to its original volume v_0 . To effect this, work must be expended and heat must be removed from the air. The relation between volume and pressure being represented by the hyperbolic arc NM , the work needed for the compression of the air is represented by the area $AMNB$, and is precisely the mechanical equivalent of the quantity of heat, q' , which must be withdrawn from the air in order to maintain its temperature constant during the process.

Accordingly, during the first two operations, the air receives a quantity of heat equal to $c(t_1 - t_0) + q$, and develops a quantity of external work geometrically represented by the surface $APQB$. In the two following operations the air loses a quantity of heat equal to $c(t_1 - t_0) + q'$, and there is expended a quantity of work geometrically represented by the surface $AMNB$. The ultimate useful expenditure of heat is, therefore, $q - q'$, and the available quantity of work generated is represented by the area $MPQN$, or the difference between $APQB$ and $AMNB$. The total expenditure of heat, during the complete cycle of operations, is q ; the quantity q' given out by the air during its compression at the temperature t_0 cannot in any way be made available for the maintenance of the action of the machine, and may therefore be considered as entirely lost. The quantity of heat $c(t_1 - t_0)$, which the air gives out when cooled from the temperature t_1 to the temperature t_0 , may, on the contrary, be employed to heat another quantity from t_0 to t_1 , and, therefore, does not make part of the ultimate expenditure. The reason why this portion of heat can be recovered, while the quantity q' cannot, is, that it is heat of a higher temperature, whereas q' , being heat of the temperature t_0 , is useless for heating any body to a temperature higher than t_0 . The ratio of the useful expenditure of heat to the total

expenditure is, therefore, $\frac{q - q'}{q}$.

The values of the quantities q and q' can be found as follows:—representing the mechanical equivalent of heat by E , we have, as a consequence of the above discussion,

$$Eq = \text{surf. } APQB, \text{ and } Eq' = \text{surf. } AMNB,$$

and consequently

$$\frac{q - q'}{q} = \frac{\text{surf. } APQB - \text{surf. } AMNB}{\text{surface } APQB}.$$

But PQ and MN , being each an arc of a rectangular hyperbola of which the lines of no volume and no pressure, OY and OX , are the asymptotes, it follows that the surface

APQB is to the surface AMNB as AP to AM. Therefore, $\frac{q - q'}{q} = \frac{AP - AM}{AP}$
 $= \frac{p_1 - p_0}{p_1}$. But p_1 and p_0 are the pressures exerted by the same mass of gas,
 under the same volume, v_0 , at the two temperatures t_1 and t_0 ; consequently,
 $\frac{p_1}{p_0} = \frac{a + t_1}{a + t_0}$ (by equation b, p. 45), and—

$$\frac{q - q'}{q} = \frac{p_1 - p_0}{p_1} = \frac{(a + t_1) - (a + t_0)}{a + t_1} = \frac{t_1 - t_0}{t_1},$$

t_1 and t_0 representing the absolute temperatures (see p. 52) corresponding to the centigrade temperatures t_1 and t_0 .

A similar investigation of any other engine in which work is generated by the expenditure of heat in causing the alternate expansion and contraction of a gas, would lead to the same expression for its maximum efficiency; hence, in every air-engine, whatever its mode of action, provided no heat is spent uselessly in causing changes of temperature, the ratio of the useful expenditure of heat to the total expenditure is equal to the difference of the absolute temperatures between which the engine works, divided by the highest of these temperatures.

The agreement of this theoretical deduction with the results of practical experience, is one of the most conclusive arguments that can be brought forward in favour of the view which regards heat as a mode of energy convertible into mechanical energy, and in opposition to the older view, according to which heat is regarded as an indestructible entity, and the production of mechanical energy by it, as depending upon its transference from a hotter to a colder body. According to this latter theory, the efficiency of an air-engine ought to be much greater than that of a steam-engine,—a conclusion which has not, however, hitherto been confirmed in practice. Taking a special example, the quantity of heat transformed into work, compared with the total heat supplied to a steam-engine, might be calculated upon this theory, as follows:—Let the engine be supposed to be worked at a pressure of 5 atmospheres, and consequently at the temperature 162°. Each kilogramme of saturated steam supplied to the cylinder at this temperature requires for its formation, according to Regnault's experiments (p. 97), 653 kilogramme-degrees of heat, *minus* the heat contained in the water with which the boiler is fed. If we suppose the engine to be worked expansively, down to the pressure of the atmosphere, and that the steam remains saturated during the expansion, it will escape into the atmosphere with the temperature 100°, and when cooled again to the temperature t , of the water supplied to the boiler, each kilogramme will give out $637 - t$ kilogramme-degrees of heat: under these conditions, therefore, the steam only loses, during its expansion in the engine, $(653 - t) - (637 - t) = 16$ degrees of heat out of the whole quantity contained in it. If t , the initial temperature of the water, be 10°, for example, 643 kilogramme-degrees of heat will have been required to generate each kilogramme of steam, and the fraction $\frac{16}{643}$, or not quite $\frac{1}{40}$, will represent the proportion of the total heat which has been converted into mechanical energy. The value of this fraction may be increased somewhat by adding a condenser to the engine, so as to obtain a greater range of expansion. If, for example, the temperature of the condenser is 40°, and the steam expands in the cylinder until its tension is the same as that in the condenser, or 55 millimetres, conditions which are never quite attained in practice, the quantity of heat given up to the condenser by each kilogramme of steam will be $619 - 40 = 579$ kilogramme-degrees; and if the boiler is fed with the condensed water at the temperature 40°, the formation of this quantity of steam will have required $653 - 40 = 613$ kilogramme-degrees. In this case, therefore, $613 - 579 = 34$ parts of heat will be converted ~~into~~ work out of every 613 parts imparted to the boiler: accordingly $\frac{34}{613}$, or very nearly $\frac{1}{18}$, will be the fraction representing the efficiency of the engine.

This calculation (borrowed from Regnault, *Mém. Acad. Sciences*, xxvi. introd. pp. v. vi.), it will be observed, supposes that all the heat which is not regained in the condenser, or contained in the steam which escapes into the atmosphere, has been converted into work: nevertheless, the efficiency of the engine comes out much below what is actually attained in practice. By careful experiments on large engines, of upwards of 100 horse-power, in which the loss of heat by radiation and conduction, or by other accidental causes, was estimated and allowed for, as accurately as possible, Hirn found that the difference between the quantity of heat supplied to the boiler, and that absorbed by the condenser, amounted to between $\frac{1}{10}$ and $\frac{1}{8}$, on an average to about $\frac{1}{9}$, of the former quantity. Practically, therefore, the steam engine is between twice and three times as efficient a machine as would appear from the above calculation.

The key to this contradiction between theory and practice, lies in a false assumption that has been made in the calculation. It was assumed that, when saturated steam

expands in the cylinder of a steam-engine, it remains in the state of saturated steam, and the heat contained in it was estimated, in accordance with this supposition, from Regnault's determinations of the total heat of saturated steam at various temperatures. In fact, however, saturated steam, if it performs external work while expanding, suffers partial condensation at the same time, and the latent heat of vaporisation of the steam which condenses becomes available for the production of work in the cylinder. It is not therefore saturated steam which escapes from the cylinder of an engine working under the conditions we have supposed, but a mixture of steam and water, containing a quantity of heat, less than the total heat of vaporisation of an equal weight of saturated steam at the same temperature by the latent heat of vaporisation of the proportion of water present. The necessity of this condensation was deduced by Rankine in 1849, and soon afterwards by Clausius, as a necessary consequence of the existence of the mechanical equivalent of heat, and shown to be the principal cause of the accumulation of water in unjacketed steam-cylinders, which had long been known as a practical inconvenience in the working of steam expansively. The beneficial effect of employing superheated steam, and of enclosing the cylinder in a steam-jacket, is that the steam can then expand, performing external work, without undergoing liquefaction. The condensation of aqueous vapour, when it does work on expanding, is distinctly seen in the formation of a mist under an air-pump receiver, containing moist air, when the piston of the pump is raised.

The fact that a considerable part of the heat supplied to a steam-boiler is consumed in converting the water into steam, is not therefore a reason why an air-engine, in which no portion of heat is similarly expended in causing a change of state, should be more efficient than a steam-engine; and the investigation of the conditions under which work is generated in the steam-engine leads to the general result, that the efficiency of any heat-engine is independent of the nature of the fluid which is the medium of transformation of heat into work, and which may be air, steam, or any other vapour or gas; but that, supposing the reception of heat to take place wholly at one temperature, and the rejection of heat wholly at another, the heat transformed into mechanical energy, is to the whole heat received by the fluid, as the range of temperature is to the absolute temperature at which heat is received, and that, between given limits of temperature, the maximum efficiency is attained when the reception and rejection of heat take place, in the manner just stated, at the highest and lowest temperatures respectively.

The most conclusive confirmation of this result is that when it is applied to the calculation of the mechanical equivalent of heat from Hirn's experiments on large steam-engines already referred to, the mean number found is 413, which differs by only 2½ per cent. from that deduced at the beginning of this section from the thermodynamic properties of air.

Heat produced by Work.—In the introduction to this article (p. 16), it is pointed out as a general fact that heat may be generated by reversing any of its effects. A process by which heat is made to generate work may, therefore, by reversal, become a process for the conversion of work into heat. But, as mentioned at the place quoted, mechanical energy may be transformed into heat by non-reversible processes, such as its expenditure in friction or percussion. There are also indirect methods of transforming work into heat which cannot be reversed, step by step; for instance, mechanical energy, used to give motion to a magneto-electric machine, can be caused to generate electricity, and this electricity, if not expended in effecting chemical changes or in reproducing mechanical energy, takes the form of heat in traversing the conducting wire, although by applying heat to the homogeneous conductor, electricity could not be regenerated. This, therefore, is an indirect, non-reversible, process of transformation. But it is found that whether the process by which mechanical energy, or work, is converted into heat is direct or indirect, reversible or non-reversible, the quantity of heat generated by a given quantity of mechanical energy expended is, within the limits of experimental error, always the same, and, within similar limits, the same as the quantity of heat required to regenerate the original quantity of mechanical energy.

The simplest mode of transforming work into heat, is perhaps the compression of a gas, by which means, as in the familiar experiment of the fire-syringe, a temperature sufficiently high to inflame easily combustible substances can be produced without difficulty. The generation of heat in this manner can be made a continuous process, by alternately compressing the gas at a high temperature and allowing it to expand at a low temperature. The reversal of the four operations represented by the diagram, *fig.* 547, p. 121, would constitute such a process, and by the application of reasoning such as that previously employed in the consideration of this case, it is evident that the work which it would be necessary to expend, in order to effect this reversal, would be represented by $A - A'$, and that the heat generated thereby would be

$$Q - Q' = \frac{1}{E} (A - A'),$$

E , being as before, the mechanical equivalent of heat.

The expenditure of mechanical energy in compressing liquid and solid bodies is also attended with the production of heat. According to Thomson, the thermal effect of compression may be expressed by the formula :

$$\theta = \frac{\tau \alpha p}{E c},$$

where θ is the effect in question, τ the absolute temperature, α the coefficient of expansion by heat, p the pressure, E the mechanical equivalent of heat, and c the specific heat of the substance. This formula has been verified by Joule (Proc. Roy. Soc. ix. 496) by experiments on water and upon oil, the temperatures varying in the first case between 1.2° C. and 40.4° , and the pressures between 15.64 and 25.34 atmospheres; in the experiments on oil the temperature was always about 17° and the pressures varied from 7.92 atmospheres to 25.34. In the experiments on water at 1.2° pressure caused a lowering of temperature instead of a rise, as in the other experiments, — a result which agrees with the fact that water contracts by heat at this temperature. Similarly, when weights are laid upon metallic pillars, heat is evolved, and is absorbed when they are removed, the quantity evolved or absorbed increasing with the weights employed (Joule, *ibid.* viii. 564). Conversely, the stretching of metallic wires causes heat to disappear. Joule found (*ibid.* viii. 365) that an iron wire, $\frac{1}{4}$ inch in diameter was cooled $\frac{1}{2}$ degree C. when stretched by a weight of 775 lb. Similar results were obtained with cast iron, hard steel, copper, and lead. The thermal effects were in all cases found to be almost identical with those deduced from Professor Thomson's theoretical investigation, the particular formula applicable to the case in question being

$Q = \frac{\tau \alpha p}{E}$, where Q is the heat absorbed in a wire one foot long, and the other symbols

have the same significations as above. Vulcanised india-rubber, which, when stretched, contracts by heat (p. 73), became hotter when the stretching weight was applied, and colder when it was removed. Similar results have been obtained by Edlund, (Ann. Ch. Phys. [3] lxi. 245), whose experiments lead to the following general conclusions:—

1. When a metal is stretched, without exceeding its limits of elasticity, a cooling effect is produced proportional to the mechanical force employed to stretch it.

2. If the metal afterwards return to the original volume, performing in so doing a quantity of external work equal to that expended in stretching it, it is heated to the same extent as that by which it was previously cooled, and consequently proportional to the mechanical force by which the metal was kept in the stretched state before contracting.

3. If on the other hand, the metal resumes its original bulk without performing external work, it is more strongly heated than in the previous case, and the difference between the two heating effects is proportional to the external work performed, in the one case, by the metal during its contraction.

4. From these three principles, it follows that when a metal passes from the volume V_0 to the volume V_1 , without exceeding the limits of perfect elasticity, the accompanying calorific effect does not depend solely upon the initial and final volumes, but also upon the manner in which the entire change takes place.

EXPERIMENTAL DETERMINATION OF THE MECHANICAL EQUIVALENT OF HEAT.—It is obvious that any of the processes whereby work is transformed into heat, or heat into work, may serve for the determination of the numerical ratio existing between the unit of work and the unit of heat, provided the process is such as to admit of the accurate measurement of the work or heat expended and of the heat or work produced. The earliest attempt to ascertain the value of this ratio appears to have been made by Count Rumford. His experiments described in his essay, entitled *An Experimental Inquiry concerning the Source of the Heat which is excited by Friction* (read before the Royal Society, January 25, 1798, and published in the Phil. Trans. also in "Essays, Political, Economical, and Philosophical," by Benjamin Count of Rumford," 3 vols. 8vo. Lond. 1798–1802, vol. ii. p. 469), were made by pressing a blunt steel borer against the bottom of a cavity made in a brass cylinder which was caused to revolve, while the borer was kept stationary. Considering the state of opinion at the time as to the probable nature of heat, these experiments, and especially the conclusions drawn from them by their author, are very remarkable, but it is only of late years that they have attracted the attention which they deserve. In the most complete experiment, the brass cylinder was placed inside a wooden box containing 18.77 lb. avoirdupois of water; the temperature of the water at the beginning of the experiment was 60° F. and was found to rise continuously when the cylinder was set in motion, until at the end of $2\frac{1}{2}$ hours the water boiled. Rumford states the results of this experiment in a tabular form, taking account of the weights and specific heats of the brass cylinder and steel borer, and gives the total quantity of heat produced, exclusive of the amount accumulated in the wooden box, and of that which was lost by radiation, as amounting

to raise the temperature of 26.58 lb. of water 180 degrees Fahrenheit, or from the freezing to the boiling point; he then quotes experiments by Crawford and by himself, from which he concludes "that the quantity of heat produced equably, or in a continuous stream," (if I may use that expression), by the friction of the blunt steel borer, at the bottom of the hollow metallic cylinder, in the experiment under consideration, was greater than that produced equably in the combustion of nine wax candles, each of an inch in diameter, all burning together, or at the same time, with clear bright flames."

The two paragraphs which follow this are especially remarkable, as they show that Rumford distinctly saw the source of this heat in the mechanical energy which was expended during its production:—

"As the machinery used in this experiment could easily be carried round by the force of one horse (though, to render the work lighter, two horses were actually employed in doing it), these computations show further how large a quantity of heat might be produced, by proper mechanical contrivance, merely by the strength of a horse, without fire, light, combustion, or chemical decomposition; and, in case of necessity, the heat thus produced might be used in cooking victuals.

"But no circumstances can be imagined, in which this method of procuring heat would not be disadvantageous; for more heat might be obtained by using the fodder, necessary for the support of a horse, as fuel."

After bringing forward arguments and direct experiments to prove that the evolution of heat cannot have been due to an alteration in the capacity for heat of the particles of metal detached from the larger solid masses by the friction, and that it cannot have been furnished by the air, nor by the water, nor by the pieces of metal by which the cylinder and borer were supported, he says:—"It appears to me to be extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated, in the manner the heat was excited and communicated in these experiments, except it be motion."

According to Joule's reduction of these results, they indicate that the heat required to raise the temperature of a pound of water one degree Fahr., is equivalent to the mechanical energy represented by 1034 foot-pounds. This number differs considerably from that deduced from the more accurate experiments to be described below; but the difference is of the kind that might have been anticipated, and, considering the manner in which Rumford's experiments were made, it is not excessive. It will be seen that these were not of a kind to furnish accurate data for determining the quantitative relation between heat and work, and it even seems likely that the idea of instituting a comparison between these two quantities first occurred to Rumford after the experiments were finished, his idea, during their performance, having been rather qualitative than quantitative, and his primary object, as indicated in the title of his paper, to ascertain the nature of the source of the heat developed by friction. But, although the numerical results of this investigation were not sufficiently definite to possess any great value, the investigation, as a whole, is of great importance as indicating a distinct stage in the development of ideas concerning the nature of heat and its relations to other forms of energy; and it is for this reason that we have devoted to it so comparatively large a share of space.

These ideas seem to have advanced but little beyond this point until about the year 1842. In that year J. R. Mayer introduced into science the expression "mechanical equivalent of heat" (Ann. Ch. Pharm. xlii. 233; Phil. Mag. [4] xxiv. 371), and thereby—probably as much as by the calculation of the numerical value of this equivalent, founded upon the then inaccurately known ratio of the two specific heats of air—contributed to promote the general adoption of the view that heat and work are mutually convertible. In the same year, Colding, of Copenhagen, communicated to the Royal Society of Denmark experiments on the production of heat by friction, from which he concluded that the evolution of heat was proportional to the mechanical energy expended, and independent of the nature of the substances between which the friction took place. But it was Joule who was the first to publish experiments which were at the same time sufficiently varied and sufficiently accurate to attract the general attention of scientific men, and to be accepted by them as definite proof that the transformation of mechanical energy into heat, or of heat into mechanical energy, takes place in every case according to a constant numerical ratio.

Joule's first experiments, bearing directly upon the subject, were published in 1843 (Phil. Mag. [3] xxiii. 441). In this investigation he showed that the heat evolved by the electric current, furnished by a magneto-electric machine, is proportional to the mechanical energy expended; and that the work done by an electro-magnetic engine is derived from the work of chemical affinity in the battery, work which would otherwise be evolved in the form of heat. From these facts he drew the conclusion, "That the quantity of heat capable of increasing the temperature of a lb. of water by one degree

of Fahrenheit's scale, is equal to, and may be converted into, a mechanical force capable of raising 838 lb. to the perpendicular height of one foot." In a subsequent paper, read before the Royal Society in 1844 (*Phil. Mag.* [3] **xxvi.** 375, 379), he showed that the heat absorbed and evolved by the rarefaction and condensation of air is proportional to the amount of mechanical energy evolved and absorbed in those operations, and obtained a numerical result closely agreeing with that of the electro-magnetic experiments just referred to. In 1845 and 1847 (*ibid.* **xxvii.** 205; and **xxxi.** 173) he determined the heat evolved by the friction of water, sperm-oil, and mercury, and obtained the numbers 781.5, 782.1, and 787.6, by experiments on these liquids respectively, as representing the number of foot-pounds which is equivalent to the heat required to raise the temperature of 1 lb. of water 1° Fahrenheit.

Still more elaborate and careful experiments were made by Joule, in 1849 (*Phil. Trans.* 1850, p. 61; *Chem. Soc. Qu. J.* **iii.** 316), upon the friction of water, mercury, and cast-iron, by a method similar to that adopted in those last mentioned. The apparatus employed in this investigation, for the experiments upon water, consisted of a brass paddle-wheel furnished with eight sets of revolving vanes, working between four

Fig. 549.

Fig. 550.

sets of stationary vanes. This revolving apparatus, of which *fig. 549* shows a vertical, and *fig. 550* a horizontal section, was firmly fitted into a copper vessel (see *fig. 551*) containing water, in the lid of which were two necks, one for the axis to revolve in without touching, the other for the insertion of a thermometer. A similar apparatus, but made of iron, and of smaller size, having six rotatory and eight sets of stationary vanes, was used for the experiments on the friction of mercury. The apparatus for the friction of cast-iron consisted of a vertical axis, carrying a bevelled cast-iron wheel, against which a bevelled wheel was pressed by a lever. The wheels were enclosed in a cast-iron vessel filled with mercury, the axis passing

Fig. 551.

through the lid. In each apparatus motion was given to the axis by the descent of leaden weights *w* (*fig. 551*) suspended by strings from the axes of two wooden pulleys, one of which is shown at *p*, their axes being supported on friction-wheels *a*, and the pulleys were connected by fine twine with a wooden roller *r*, which, by means of a pin, could be easily attached to or removed from the friction apparatus.

The mode of experimenting was as follows: The temperature of the frictional apparatus having been ascertained, and the weights wound up, the roller was fixed to the axis, and the precise height of the weights ascertained; the roller was then set at liberty, and allowed to revolve till the weights touched the floor. The roller was then detached, the weights wound up again, and the friction renewed. This having been repeated twenty times, the experiment was concluded with another observation of the temperature of the apparatus. The mean temperature of the apartment was ascertained by observations made at the beginning, middle, and end of each experiment. Corrections were made for the effects of radiation and conduction; and, in the experiments with water, for the quantities of heat absorbed by the copper vessel and the paddle-wheel. In the experiments with mercury and cast-iron, the heat-capacity

of the entire apparatus was ascertained by observing the heating effect which it produced on a known quantity of water in which it was immersed. In all the experiments corrections were also made for the velocity with which the weights came to the ground, and for the friction and rigidity of the strings. The thermometers used were capable of indicating a variation of temperature as small as $\frac{1}{100}$ of a degree Fahrenheit.

The following table contains a summary of the results obtained by this method; the second column gives the results as they were obtained from weighings made in air; the third column, the same results reduced to weighings in a vacuum.

Material employed.	Equivalent in air.	Equivalent in vacuo.	Mean.
Water	773.640	772.692	772.692
Mercury	{ 773.762 776.303	{ 772.814 775.352 }	774.083
Cast-iron	{ 776.997 774.880	{ 776.045 774.930 }	774.987

In the experiments with cast-iron, the friction of the wheels produced a considerable vibration of the frame-work of the apparatus, and a loud sound; it was therefore necessary to make allowance for the quantity of force expended in producing these effects. The number 772.692, obtained by the friction of water, is regarded as the most trustworthy; but even this may be a little too high; because even in the friction of fluids it is impossible entirely to avoid vibration and sound. The conclusions deduced from these experiments are:

1. *That the quantity of heat produced by the friction of bodies, whether solid or liquid, is always proportional to the force expended.*

2. *That the quantity of heat capable of increasing the temperature of 1 lb. of water (weighed in vacuo, and between 55° and 60° F.) by 1° F., requires for its evolution the expenditure of a mechanical force represented by the fall of 772 lbs. through the space of 1 foot.*

Or, the heat capable of increasing the temperature of 1 gramme of water by 1° C., is equivalent to a force represented by the fall of 423.55 grammes through the space of 1 metre. This is consequently the equivalent of "a unit of heat."

Since, in consequence of the researches that have been mentioned, the attention of scientific men has been prominently called to the mutual equivalence of heat and work, several investigations have been made, either for the express purpose of ascertaining the numerical ratio expressing that equivalence, or involving determinations from which that ratio can be calculated. In the following table, taken from Verdet's *Exposé de la Théorie Mécanique de la Chaleur* (Paris, 1863), the most trustworthy determinations of the mechanical equivalent of heat are put together. The numbers here given represent the number of kilogramme-metres which is equivalent to 1 kilogramme-degree centigrade, or the number of gramme-metres which is equivalent to 1 gramme-degree.

Table of determinations of the Mechanical Equivalent of Heat.

DYNAMICAL THEORY OF HEAT.

For very long, two rival theories have been held regarding the nature of heat: on the one hand, heat has been viewed as having a material existence, though differing from ordinary matter in being without weight, and in other respects; on the other hand, it has been regarded as a state or condition of ordinary matter, and generally as a condition of motion. From the latter part of the last century, until the modern researches upon the mechanical equivalent, the former view had by far the greater number of adherents. Its popularity may be traced chiefly to the teaching of Black and Lavoisier. By the former of these philosophers, the various capacities for heat, or specific heats, of different bodies, seem to have been regarded as analogous to the various proportions of the same acid required to neutralise equal quantities of different bases; while the solid, liquid, and gaseous states were explained by him as representing so many distinct proportions in which heat was capable of combining with ordinary matter. Very similar views were advocated by Lavoisier: he regarded all gases as compounds of a base characteristic of each, with *caloric*, and supposed that when, as the result of chemical action, they assumed the liquid or solid state, this caloric was set free and appeared as sensible heat. Caloric was thus the physical representative of phlogiston, in the same way as oxygen was its chemical representative: the physical portion of the phenomena previously attributed to dephlogistication, being regarded by Lavoisier as caused by the liberation of caloric, just as the chemical portion was explained by him as combination with oxygen. Thus he uniformly speaks (*Traité élémentaire de Chimie*) of the "decomposition" of oxygen-gas by combustible substances, into oxygen (which combines with the combustible) and caloric (which is set free). It is true that Lavoisier guards himself against definitely expressing his belief in the existence of caloric as a substance, but he enumerates it in his list of elements, and seeks to explain all calorimetric phenomena by the analogy of the combination or separation of elementary bodies. Hence, whether regarded by him as necessarily material or not, it became, for his followers, "an imponderable element."

It will be seen that heat was compared to a material substance, by both Black and Lavoisier, in order to explain its then known quantitative relations; and from this point of view, the conception introduced by them had the great advantage of being more easily grasped than any which the advocates of the immaterial nature of heat had to offer in its place. It was much easier to conceive of definite quantities of an exceedingly subtle substance or fluid, than of definite quantities of motion which was itself undefined as to its nature. It was a direct consequence of the material view, that heat should be considered as indestructible and as incapable of being produced, and therefore that the total quantity of heat in the universe should be regarded as at all times the same.

The greatest difficulty which the upholders of the substantial existence of heat had to meet, was its production by mechanical means, a phenomenon of which, as we have seen, several instances were distinctly recognised. Here it was not easy to deny the actual generation of heat, and to explain the effects as depending merely on its altered distribution. Nevertheless, the evolution of heat by friction and percussion was generally considered, by the advocates of the material view, as in some way resulting from a diminution in the capacities for heat of the bodies operated upon; and this explanation derived considerable support from the remark, made by Black, that a piece of soft iron, which has been once made red hot by hammering (see p. 119), cannot be so heated a second time until it has been heated to redness in a fire and allowed to cool. In this case, certainly, it seemed as though the hammering forced out heat from the mass of iron, like water from a sponge, and that a fresh supply was taken up when the iron was put in the fire. But, as has been shown already, this explanation did not satisfy Rumford, who, in the investigation described above, made direct experiments upon the specific heat of the chips of metal detached by the friction, and found it to be identical with that of brass under ordinary circumstances. An experiment which proved, if possible, still more decisively, that the heat generated by friction cannot be ascribed to a diminution in the specific heats of the substances, was made by Davy, in 1799, the year following the publication of Rumford's researches. Davy arranged two pieces of ice, so that they could be caused to rub against each other under the exhausted receiver of an air-pump, but so that it was impossible for heat to be imparted to them by conduction, and found that by friction they were rapidly converted into water, that is to say, into a liquid whose specific heat was twice as great as that of ice. From this experiment Davy drew the same conclusion that Rumford had drawn from his own results, and expressed himself in very similar terms:—"The immediate cause of the phenomena of heat then is motion, and the laws of its communication are precisely the same as the laws of the communication of motion." (*Elements of Chemical Philosophy*, London, 1812, pp. 94, 95.) Similar views were very forcibly

advocated by Dr. Thomas Young in his *Lectures on Natural Philosophy*; but, by the majority of scientific men, facts such as we have been referring to, though recognised as difficulties in the way of the material theory of heat, were not allowed to cause its rejection. The ease and apparent precision with which the quantitative phenomena of latent and specific heat could be explained, or at least expressed, upon this theory, still caused it to be generally preferred to one which gave a less definite and, as it seemed, more hypothetical explanation of these phenomena. The mechanical, or dynamical theory, which regarded heat as consisting in a state of molecular motion, cannot be said to have been definitely established until it also was made quantitative,—until it was shown that exact numerical laws regulated the production of heat by work or of work by heat, equally with its production during solidification, or disappearance during fusion. This, as we have seen, was effectually accomplished by Joule, and chiefly as the result of his investigations and of others conducted in the same spirit, philosophers have now been compelled to extend their ideas of quantity from matter to energy, and thus has arisen the new science of Energetics, or the quantitative study of the transformations of energy (as chemistry is the quantitative study of the transformation of matter), comprehending and uniting all the different branches of physical science.

We cannot attempt to give anything like an adequate idea of the state of development which the mechanical theory of heat has now reached; but, in order to illustrate the general nature of the theory, and to show in what sort of way the conception that "heat is motion" has been applied to the explanation of such phenomena as have formed the subject of this article, we give here an outline of the view of the constitution of gases which this theory affords, first put forward, in its present form, by Joule (see *Ann. Ch. Phys.* [3] l. 381) and subsequently developed by Krönig (*Pogg. Ann.* xcix. 315) and Clausius (*ibid.* 363), and of the explanation of the relations existing between solids, liquids, and gases, which has been deduced from it by the last-named philosopher. The account which follows, of these applications of the dynamical theory, is taken from Watt's *Supplement to Graham's Elements of Chemistry*. It will be seen that the explanations of phenomena which this theory affords, are at least equally definite with those which can be given upon the view of the material nature of heat.

First, then, it is assumed that the particles of all bodies are in constant motion, and that this motion constitutes heat, the kind and quantity of motion varying according to the state of the body, whether solid, liquid, or gaseous.

In gases, the molecules—each molecule being an aggregate of atoms—are supposed to be constantly moving forward in straight lines, and with a constant velocity, till they impinge against each other or against an impenetrable wall. This constant impact of the molecules produces the expansive tendency or elasticity, which is the peculiar characteristic of the gaseous state. The rectilinear movement is not, however, the only one with which the particles are affected. For the impact of two molecules, unless it takes place exactly in the line joining their centres of gravity, must give rise to a rotatory motion; and, moreover, the ultimate atoms of which the molecules are composed may be supposed to vibrate within certain limits, being, in fact, thrown into vibration by the impact of the molecules. This vibratory motion is called, by Clausius, *the motion of the constituent atoms* (*Bewegungen der Bestandtheile*). The total quantity of heat in the gas is made up of the progressive motion of the molecules, together with the vibratory and other motions of the constituent atoms; but the progressive motion alone, which is the cause of the expansive tendency, determines the temperature. Now, the outward pressure exerted by the gas against the containing envelope arises, according to our hypothesis, from the impact of a great number of gaseous molecules against the sides of the vessel. But at any given temperature, that is, with any given velocity, the number of such impacts taking place in a given time, must vary inversely as the volume of the given quantity of gas; hence *the pressure varies inversely as the volume or directly as the density*, which is Boyle's law.

When the volume of the gas is constant, the pressure resulting from the impact of the molecules is proportional to the sum of the masses of all the molecules multiplied into the squares of their velocities, in other words, to the so-called *vis viva* or *living force* of the progressive motion.

If, for example, the velocity be doubled, each molecule will strike the sides of the vessel with a two-fold force, and its number of impacts in a given time will also be doubled; hence the total pressure will be quadrupled.

Now we know that when a given quantity of any perfect gas is maintained at a constant volume, it tends to expand by $\frac{1}{273}$ of its bulk at zero for each degree centigrade. Hence the pressure or elastic force increases proportionally to the temperature reckoned from -273° C.; that is to say, to the absolute temperature. Consequently, the *absolute temperature is proportional to the vis viva of the progressive motion*.

Suppose a vessel of the form of a rectangular parallelepiped, the lengths of whose sides are x, y, z , to contain n gas-molecules, each having the mass m . Suppose, also, the space enclosed by this vessel to be divided into $\frac{n}{6}$ equal cubes; and at a given instant let there be in each of these cubes six gas-molecules, moving severally in the directions $+x, -x, +y, -y, +z, -z$, and with the common velocity c . Let it also be supposed that the molecules exert no mutual action upon each other, but pass without hindrance from side to side of the vessel. It is required to determine the pressure, which the gas exerts against one of the sides, yz , of the vessel. The pressure arising from the impact of a single gas-molecule is mca , if a denote the number of impacts which take place in a unit of time. Now, a molecule moving at right angles to yz , or parallel to x , strikes against yz every time that it passes over the space $2x$; therefore

$$a = \frac{c}{2x}.$$

To find the total pressure P upon yz , the quantity, mca , must be multiplied by the number of molecules which move parallel to x , which number, since two atoms out of every six are parallel to x , is $\frac{n}{3}$. Hence $P = m \cdot c \cdot \frac{c}{2x} \cdot \frac{n}{3}$. And the pressure p upon a unit of surface of the side yz , is $p = m \cdot c \cdot \frac{c}{2x} \cdot \frac{n}{3} \cdot \frac{1}{yz}$; or if we put $xyz = v$, and leave out the constant factor :

$$p = \frac{nm c^2}{v}.$$

This expression shows that the pressure exerted upon a unit of surface is the same for each side of the vessel; also, that the pressure is inversely in proportion to the volume of the gas, which is Boyle's law.

The product, mc^2 , or the *vis viva* of an atom, is the expression of the temperature reckoned from the absolute zero, or -273°C .

If, in the preceding value of p , we put $mc^2 = \tau$, we have

$$p = \frac{n\tau}{v},$$

that is to say, when the volume is constant, the pressure varies directly as the absolute temperature. (Krönig.)

If, for two different gases, we suppose p, τ and v , equal, it follows from this expression, that n also must be the same for both. That is to say, at the same temperature and pressure, equal volumes of different gases contain the same number of molecules. Hence also, the mass, m , of a molecule is proportional to the specific gravity, s , of the gas: or, the molecular weights of different substances are proportional to their vapour-densities (taken at temperatures at which the vapours have the properties of true gases).

Clausius, taking into consideration the *vis viva* of the vibratory and rotatory movements as well of the progressive movements, arrives at the expression, $p = \frac{nm c^2}{3v}$,

or $pv = \frac{nm c^2}{3}$, which differs from that of Krönig only by a constant factor.

From this equation, it is possible to deduce the mean value of the absolute progressive velocity of the molecules of any gas for any given temperature. It gives, in fact, directly,

$$c^2 = \frac{3pv}{nm},$$

or, putting q for the weight of the gas, and g for the force of gravity,—

$$c^2 = \frac{3gpv}{q},$$

an expression which contains only numerically determinable quantities. Denoting by ρ the density of the gas compared with that of air at 0° , introducing into the formula the known values of the weight of a litre of air and of the force of gravity, taking p equal to the normal atmospheric pressure, and denoting the absolute temperature by τ , the value of c , expressed in metres, becomes

$$c = 485 \sqrt{\frac{\tau}{273\rho}},$$

which gives at 0°C , for Oxygen $c = 461$ metres per second
 „ Nitrogen $c = 492$ „ „
 „ Hydrogen $c = 1844$ „ „

Hence, the velocity of translation of the molecules of a gas is inversely as the square-root of its density, which gives Graham's law of the diffusion of gases, and the law of their velocity of entrance into a vacuum.

Moreover, as the motions of the constituent particles of a gas depend on the manner in which its atoms are united, it follows that in any given gas the different motions must be to one another in a constant ratio; and, therefore, the *vis viva* of the progressive motion must be an aliquot part of the entire *vis viva* of the gas; hence also the absolute temperature is proportional to the total *vis viva* arising from all the motions of the particles of the gas.

From this it follows that the quantity of heat which must be added to a gas of constant volume in order to raise its temperature by a given amount, is constant and independent of the temperature. In other words, the specific heat of a gas referred to a given volume is constant, a result which agrees with the experiments of Regnault, mentioned at p. 34. This result may be otherwise expressed, as follows: *The total vis viva of the gas is to the vis viva of the progressive motion of the molecules, which is the measure of the temperature, in a constant ratio.* This ratio is different for different gases, and is greater as the gas is more complex in its constitution; in other words, as its molecules are made up of a greater number of atoms. The specific heat referred to a constant pressure is known to differ from the true specific heat only by a constant quantity (see p. 42).

The relations just considered between the pressure, volume and temperature of gases, presuppose, however, certain conditions of molecular constitution, which are, perhaps, never rigidly fulfilled; and accordingly, the experiments of Magnus and Regnault (p. 48) show that gases do exhibit slight deviations from Gay-Lussac and Boyle's laws. What the conditions are which strict adherence to these laws would require, will be better understood by considering the differences of molecular constitution which must exist in the solid, liquid, and gaseous states.

A movement of molecules must be supposed to exist in all three states. In the *solid state*, the motion is such that the molecules oscillate about certain positions of equilibrium, which they do not quit, unless they are acted upon by external forces. This vibratory motion may, however, be of a very complicated character. The constituent atoms of a molecule may vibrate separately; the entire molecules may also vibrate as such about their centres of gravity, and the vibrations may be either rectilinear or rotatory. Moreover, when extraneous forces act upon the body, as in shocks, the molecules may permanently alter their relative positions.

In the *liquid state*, the molecules have no determinate positions of equilibrium. They may rotate completely about their centres of gravity, and may also move forward into other positions. But the repulsive action arising from the motion is not strong enough to overcome the mutual attraction of the molecules and separate them completely from each other. A molecule is not permanently associated with its neighbours, as in the solid state; it does not leave them spontaneously, but only under the influence of forces exerted upon it by other molecules, with which it then comes into the same relation as with the former. There exists, therefore, in the liquid state, a vibratory, rotatory and progressive movement of the molecules, but so regulated, that they are not thereby forced asunder, but remain within a certain volume without exerting any outward pressure.

In the *gaseous state*, on the other hand, the molecules are removed quite beyond the sphere of their mutual attractions, and travel onward in straight lines according to the ordinary laws of motion. When two such molecules meet, they fly apart from each other, for the most part, with a velocity equal to that with which they came together. The perfection of the gaseous state, however, implies: 1. That the space actually occupied by the molecules of the gas be infinitely small in comparison with the entire volume of the gas.—2. That the time occupied in the impact of a molecule, either against another molecule or against the sides of the vessel, be infinitely small in comparison with the interval between any two impacts.—3. That the influence of the molecular forces be infinitely small. When these conditions are not completely fulfilled, the gas partakes more or less of the nature of a liquid, and exhibits certain deviations from Gay-Lussac and Boyle's laws. Such is, indeed, the case with all known gases; to a very slight extent with those which have not yet been reduced into the liquid state; but to a greater extent with vapours and condensable gases, especially near the points of condensation.

Let us now return to the consideration of the liquid state. It has been said that the molecule of a liquid, when it leaves those with which it is associated, ultimately

takes up a similar position with regard to other molecules. This, however, does not preclude the existence of considerable irregularities in the actual movements. Now, at the surface of the liquid, it may happen that a particle, by a peculiar combination of the rectilinear, rotatory and vibratory movements, may be projected from the neighbouring molecules with such force as to throw it completely out of their sphere of action, before its projectile velocity can be annihilated by the attractive force which they exert upon it. The molecule will then be driven forward into the space above the liquid, as if it belonged to a gas, and that space, if originally empty, will, in consequence of the action just described, become more and more filled with these projected molecules, which will comport themselves within it exactly like the molecules of a gas, impinging and exerting pressure upon the sides of the envelope. One of these sides, however, is formed by the surface of the liquid, and when a molecule impinges upon this surface, it will, in general, not be driven back, but retained by the attractive forces of the other molecules. A state of equilibrium, not static, but dynamic, will therefore be attained when the number of molecules projected in a given time into the space above, is equal to the number which in the same time impinge upon and are retained by the surface of the liquid. This is the process of vaporisation. The density of the vapour required to ensure the compensation just mentioned, depends upon the rate at which the particles are projected from the surface of the liquid, and this again upon the rapidity of their movement within the liquid, that is to say, upon the temperature. It is clear, therefore, that the density of a saturated vapour must increase with the temperature.

If the space above the liquid is previously filled with a gas, the molecules of this gas will impinge upon the surface of the liquid, and thereby exert pressure upon it; but as these gas-molecules occupy but an extremely small proportion of the space above the liquid, the particles of the liquid will be projected into that space almost as if it were empty. In the middle of the liquid, however, the external pressure of the gas acts in a different manner. There also it may happen that the molecules may be separated with such force as to produce a small vacuum in the midst of the liquid. But this space is surrounded on all sides by masses which afford no passage to the disturbed molecules; and in order that they may increase to a permanent vapour-bubble, the number of molecules projected from the inner surface of the vessel must be such as to produce a pressure outwards, equal to the external pressure tending to compress the vapour-bubble. The boiling point of the liquid will, therefore, be higher as the external pressure is greater.

According to this view of the process of vaporisation, it is possible that vapour may rise from a solid as well as from a liquid; but it by no means necessarily follows that vapour must be formed from all bodies at all temperatures. The force which holds together the molecules of a body may be too great to be overcome by any combination of molecular movements, so long as the temperature does not exceed a certain limit.

The *production and consumption of heat* which accompany changes in the state of aggregation, or of the volume of bodies, are easily explained, according to the preceding principles, by taking account of the *work* done by the acting forces. This work is partly external to the body, partly internal. To consider first the internal work:

When the molecules of a body change their relative positions, the change may take place either in accordance with or in opposition to the action of the molecular forces existing within the body. In the former case, the molecules, during the passage from one state to the other, have a certain velocity imparted to them, which is immediately converted into heat; in the latter case, the velocity of their movement, and consequently the temperature of the body, is diminished. In the passage from the solid to the liquid state, the molecules, although not removed from the spheres of their mutual attractions, nevertheless change their relative positions in opposition to the molecular forces, which forces have, therefore, to be overcome. In evaporation, a certain number of the molecules are completely separated from the remainder, which again implies the overcoming of opposing forces. In both cases, therefore, work is done, and a certain portion of the *vis viva* of the molecules, that is, of the heat of the body, is lost. But when once the perfect gaseous state is attained, the molecular forces are completely overcome, and any further expansion may take place without internal work, and, therefore, without loss of heat, provided there is no external resistance.

But in nearly all cases of change of state or volume, there is a certain amount of external resistance to be overcome, and a corresponding loss of heat. When the pressure of a gas, that is to say, the impact of its atoms, is exerted against a movable obstacle, such as a piston, the molecules lose just so much of their moving power as they have imparted to the piston, and, consequently, their velocity is diminished and the temperature lowered. On the contrary, when a gas is compressed by the motion of a piston, its molecules are driven back with greater velocity than that with which they impinged on the piston, and, consequently, the temperature of the gas is raised.

When a liquid is converted into vapour, the molecules have to overcome the atmospheric pressure or other external resistance, and, in consequence of this, together with the internal work already spoken of, a large quantity of heat disappears, or is rendered *latent*, the quantity thus consumed being to a considerable extent affected by the external pressure. The liquefaction of a solid not being attended with much increase of volume, involves but little external work; nevertheless the atmospheric pressure does influence, to a slight amount, both the latent heat of fusion and the melting point.

We must here mention, in conclusion, a very remarkable consequence of the relation of mutual convertibility which, as we have endeavoured to show, exists between heat and other forms of energy. "Professor William Thomson has pointed out the fact, that there exists (at least in the present state of the known world) a predominating tendency to the conversion of all the other forms of physical energy into heat, and to the uniform diffusion of all heat throughout all matter. The form in which we generally find energy originally collected, is that of a store of chemical power, consisting of uncombined elements. The combination of these elements produces energy in the form known by the name of electric currents, part only of which can be employed in analysing compounds, and thus reconverted into a store of chemical power; the remainder is necessarily converted into heat: a part only of this heat can be employed in analysing compounds, or in reproducing electric currents. If the remainder of the heat be employed in expanding an elastic substance, it may be entirely converted into visible motion, or into a store of visible mechanical power (by raising weights, for example), provided the elastic substance is enabled to expand until its temperature falls to the point which corresponds to the absolute privation of heat; but unless this condition be fulfilled, a certain proportion only of the heat, depending upon the range of temperature through which the elastic body works, can be converted, the rest remaining in the state of heat. On the other hand, all visible motion is of necessity ultimately converted entirely into heat by the agency of friction. There is, then, in the present state of the known world, a tendency towards the conversion of all physical energy into the sole form of heat.

"Heat, moreover, tends to diffuse itself uniformly by conduction and radiation, until all matter shall have acquired the same temperature.

"There is, consequently, Professor Thomson concludes, so far as we understand the present condition of the universe, a tendency towards a state in which all physical energy will be in the state of heat, and that heat so diffused that all matter will be at the same temperature; so that there will be an end of all physical phenomena.

"Vast as this speculation may seem, it appears to be soundly based on experimental data, and to represent truly the present condition of the universe, so far as we know it." (Rankine, Phil. Mag. [4] iv. 359.)

* * For Radiation and Conduction of Heat, see RADIATION.

APPENDIX.

The following table gives the temperatures measured by the air-thermometer, at which, according to Regnault's experiments (Mém. Acad. Sciences, xxvi. 658), the vapours of the liquids enumerated in it exert a pressure equal to that of 760 millimetres of mercury:—

Substance.	Temperature	Substance.	Temperature.
Nitrous oxide	— 87·90°	Chloride of silicon	56·81°
Carbonic anhydride	— 78·2	Chloroform	60·16
Sulphuric acid	— 61·8	Methylic alcohol	66·78
Ammonia	— 38·5	Trichloride of phosphorus	73·80
Chlorine	— 33·6	Perchloride of carbon (CCl ₄)	76·60
Chloride of methyl	— 23·73	Alcohol	78·28
Oxide of methyl	— 23·65	Benzene	80·36
Sulphurous anhydride	— 10·08	Bromide of ethylene	131·60
Chloride of ethyl	+ 12·50	Oil of turpentine	159·15
Chloride of cyanogen	12·66	Oxalate of methyl	164·20
Chloride of boron	18·23	Oil of lemons	174·80
Ether	34·97	Mercury	357·25
Bromide of ethyl	38·37	Sulphur	448·00
Sulphide of carbon	46·20		

The next table, also from Regnault's experiments (*Op. cit.* pp. 327–332), gives the specific heats of various substances in different states of aggregation. Where, in the column indicating the temperature, some particular degree is given, the number repre-

sending the specific heat is the *elementary* specific heat at that degree of temperature,—that is, the quantity of heat required to cause a *very small* alteration of temperature in one gramme of the substance, compared with the quantity required to cause a like infinitesimal alteration of temperature in 1 gramme of water. When an interval of temperature is given, the specific heat is the mean specific heat within that interval:—

Substance.	Solid.		Liquid.		Gaseous.	
	Temperature.	Specific Heat.	Temperature.	Specific Heat.	Temperature.	Specific Heat.
Water .	— 78° to 0°	0·474	10°	1·0	128° to 220°	0·4805

HEAVY SPAR. *Barytes. Native Sulphate of Barium.* Ba^{SO_4} .—This mineral occurs in crystals belonging to the trimetric system. Ratio of axes $a : b : c$, 0.6206 : 1 : 0.7618; $\infty P : \infty P$ in the macrodiagonal principal section = $63^\circ 38'$; $\infty P_2 : \infty P_2$ in the same = $102^\circ 18'$; $P_{\infty} : P_{\infty}$ in the basal section = $74^\circ 36'$; $P_{\infty} : P_{\infty}$ in the same = $100^\circ 40'$. Figs. 552–556 represent frequently occurring combinations.

Fig. 552.

Fig. 553.

Fig. 554.

Fig. 555.

Fig. 556.

The crystals are sometimes prismatically elongated in the direction of one of the axes (figs. 553, 554), and sometimes reduced to the tabular form by shortening in one direction (see CRYSTALLOGRAPHY, ii. 149). Cleavage very distinct, parallel to ∞P_{∞} . The mineral occurs also massive, with fibrous or laminar structure; also granular. Hardness 2.5 to 3.5. Specific gravity 4.3 to 4.72. Colour white, or inclining to grey, blue, green, yellow, red or brown. Streak white. Lustre splendid, between resinous and pearly. Transparent, exhibiting various degrees of translucency down to perfect opacity. It is sometimes foetid when rubbed; an impure variety called *hepatite* exhibits this property in a peculiar degree. It decrepitates before the blow-pipe, and fuses with difficulty at the edges only. In the inner flame it is reduced to sulphide of barium, and then gives off sulphydric acid when treated with an acid.

Pure heavy spar contains 34.33 per cent. SO_3 and 65.67 Ba^2O ; but the mineral generally also contains small quantities of alumina, oxide of iron, silica, and carbonate of calcium. Sulphate of strontium is also a common ingredient. The variety called *calstronbaryte* contains 1 at. lime and 1 at. strontium to 9 at. barium.

It is a very abundant mineral, generally occurring in metalliferous veins, as in the lead-mines of Durham, Cumberland, and Westmoreland. It occurs also in secondary limestones, sometimes in distinct veins, and often in crystals associated with celestine and calcspar. In Staffordshire and Derbyshire is found an opaque, massive variety called *cark*, having an earthy appearance and dirty white colour. On the continent of Europe it is found chiefly at Felsőbánya and Kremnitz, at Freiberg, Marienberg, Clausthal, and Przibram, and at Roya and Roure in Auvergne. Rounded masses, composed of divergent columnar particles, occur at Mount Paterno, near Bologna, hence called *Bolognese stone*. At Freiberg, in Saxony, a variety occurs composed of indistinct prismatic crystals, having a pearly lustre, called *Stangenspath* by Werner. (For the American localities, see Dana, ii. 367.)

Heavy spar occurs altered to calcspar, spathic iron, cerussite, quartz, limonite red iron-ore, pyrites, psilomelane, göthite.

The white varieties of heavy spar are ground and used as a white paint, sometimes alone, but more generally mixed with white lead, the heavy spar alone not possessing sufficient opacity to form a good pigment.

HEBETIN. Anhydrous silicate of zinc. (See WILLEMITTE.)

HEDEBERGITE. A black variety of augite, containing a large quantity of iron, little or no magnesia, and no alumina. Specific gravity 3.5. Found chiefly at Tunaberg, in Sweden.

HEDERA HELIX. *Ivy.*—The seeds of this plant contain a nitrogenous substance resembling emulsin, also fat, two peculiar acids, sugar, a small quantity of pectin, and inorganic salts. From the fresh seeds, ether extracts a green oil, containing a solid and a liquid fat. The former is somewhat difficult to saponify, and yields by saponification a fatty acid, which, after repeated crystallisation from alcohol, melts at a temperature not above 30°, and forms a silver salt containing from 27.4 to 27.6 silver (Posselt). The acids contained in ivy-seeds are described in the next article.

HEDERIC ACID. An acid contained, according to Posselt (Ann. Ch. Pharm. lxi. 62) in the seeds of ivy (*Hedera helix*). It is obtained by treating the seeds with ether to remove fatty matters, and boiling the residue with alcohol, which dissolves the acid, and deposits it, after concentration, in needles or delicate scales, colourless, and insoluble in water and in ether. The acid is inodorous, but possesses in a high degree the acrid taste of ivy-seeds. It gives by analysis, 66.5 per cent. C, and 9.5 H; its rational formula is unknown. It gives off 5.42 percent. water at 100°, and chars without melting at a higher temperature. In contact with strong sulphuric acid it assumes a fine purple colour.

Hederic acid decomposes carbonates, and forms gelatinous salts, most of which are insoluble in water, but soluble in alcohol. Even the *potassium-* and *ammonium-*salts dissolve but sparingly in water, and are deposited as gelatinous precipitates when the solutions are left at rest. The *silver-salt* is deposited from boiling alcohol in white crystals.

Ivy-seeds likewise contain another acid, the presence of which greatly impedes the purification of hederic acid. This acid is uncrystallisable; soluble in water, alcohol and ether; forms soluble yellow salts; precipitates lead-salts, reduces nitrate of silver, and colours ferric salts green. It appears to belong to the family of the tannic acids.

HEDERINE. An alkaloid said to exist in ivy-seeds. (Vandamme and Chevallier, J. Chim. méd. [2] vi. 581.)

HEDYPHANE. A variety of green lead-ore in which the lead is partly replaced by calcium. Found at Långsbanshytta, in Sweden; also called *MIMETENE* (*q. v.*)

HELENENE. An oily hydrocarbon produced by distilling helenin with phosphoric anhydride. After rectification, it is yellowish, lighter than water, and has a faint odour resembling that of acetone. Boils between 285° and 295°. Gives by analysis 89.0 to 89.8 C, and 10.1 to 10.4 H, agreeing nearly with the formula $C^{18}H^{28}$ (89.8 C, and 10.2 H). Its formation may perhaps be represented by the equation:

The evolution of carbonic oxide has not, however, been actually observed.

Helenene heated with fuming sulphuric acid is converted into *sulpho-helenic acid*, the barium-salt of which contains 17.76 per cent. barium.

HELENIN. $C^{21}H^{32}O^8$.—A crystalline substance existing in the root of elecampane (*Inula helenium*); it was first observed by Geoffroy, afterwards examined by Dumas, and more especially by Gerhardt (*Traité*, iv. 296). It may be obtained by distilling the root with water, or better by boiling it with alcohol of 80 per cent.; filtering the solution at the boiling heat, and mixing it with three or four times its volume of cold water. The liquid, after twenty-four hours, deposits helenin in long quadrilateral prisms.

Helenin is perfectly colourless, and has very little taste or odour. It is insoluble in water, but very soluble in alcohol and ether. It melts at 72°, and boils between 275° and 280°, decomposing more or less at the same time.

Helenin is not attacked by alkalis in aqueous or alcoholic solution; but when heated with potash-lime, it yields a resinous compound, which remains combined with the potash. Strong sulphuric acid dissolves it with blood-red colour, forming a conjugated acid. Hydrochloric acid gas is absorbed by it in large quantity.

By *chlorine*, with the aid of heat, it is converted into *chlorhelenin*, perhaps $C^{21}H^{24}Cl^4O^8$; and by nitric acid into *nitrohelenin*. Phosphoric anhydride converts it into *helenene*.

HELIANTHIC ACID. $C^{14}H^{10}O^7, HO?$ —An acid obtained from sunflower seeds, belonging, according to Ludwig and Kromayer, to the tannic acid group. By boiling with moderately dilute hydrochloric acid in a stream of hydrogen, it is resolved into fermentable sugar, and an acid violet colouring matter.

HELIANTHUS ANNUUS. *The Sunflower.*—The peeled seeds of this plant

contain, according to Ludwig and Kromayer (Arch. Pharm. [2] xcix. 1, 286):
 1. Helianthic acid.—2. A fat oil, amounting to 40 per cent. of the peeled seeds.—
 3. A small quantity of fermentable sugar, uncrystallisable, and capable of reducing cupric oxide, only when the latter is present in considerable quantity in alkaline solution.—4. A substance soluble in alcohol, precipitated from this solution by ether in the form of a syrup, not directly fermentable, and not capable of reducing cupric oxide in alkaline solution, but convertible by boiling, either alone or with acids, into a substance which reduces cupric to cuprous oxide, and perhaps constituting a link between inulin and sugar.—5. Legumin.—6. A substance perhaps identical with inulin, insoluble in cold water and alcohol, and converted by boiling with dilute acids into a body which reduces cupric to cuprous oxide.—7. Mulders' horny vegetable albumin (a body resembling cellulose, soluble in strong sulphuric acid, and precipitable from this solution by water).—8. A mixture resembling cerebrin, and another resembling oleo-phosphoric acid.—9. Cellulose.

The nitrogenous substance, which is soluble in boiling alcohol, and remains as a gelatinous mass when the alcohol is distilled off, appears to be a compound of helianthic acid with a protein-substance, accompanied by a soapy compound.

The peeled seeds dried in the air at mean temperatures yielded 4.2 per cent. ash, of which 3.8 pts. were insoluble, and 0.4 soluble in water.

HELICIN. $C^{12}H^{10}O^7$. (Piria, Ann. Ch. Phys. [3] xiv. 287.)—A body produced by the action of very dilute nitric acid upon salicin:

also, together with benzoic acid, by boiling benzo-helicin with magnesia (Piria, Ann. Ch. Pharm. xvi. 380). To prepare it, 1 pt. of pulverised salicin is mixed with 10 pts. of nitric acid of 20° Bm. (specific gravity 1.157), and the mixture is left to itself in an open vessel. In about 24 hours the salicin is completely dissolved, especially if the mixture be stirred from time to time, and crystals of helicin collect at the bottom of the vessel. They must be pressed between paper and purified by washing with ether till the ether which runs off no longer reddens ferric salts. Salicin yields about two-thirds of its weight of helicin.

Helicin crystallises in small, white, very slender needles containing $\frac{1}{2}$ at. water. It is neutral, slightly bitter, sparingly soluble in cold water, dissolves very freely in boiling water; it is soluble also in alcohol, but is insoluble in ether. At 100° C. it gives off its water of crystallisation, amounting to 4.54 per cent. At 175° it melts, and at a higher temperature gives off vapours of hydride of salicyl. Under the influence of emulsin, or of dilute acids or alkalis at the boiling heat, it is resolved into glucose and hydride of salicyl:

At ordinary temperatures, the fixed alkalis and alkaline earths merely increase the solubility of helicin in water.

Benzo-helicin. $C^{20}H^{12}O^8 = C^{12}H^{10}(C^8H^2O)^2$.—This compound, which is related to helicin in the same manner as populin to salicin, is obtained by dissolving benzo-salicin (populin) in 10 or 12 times its weight of nitric acid of specific gravity 1.3. It crystallises in tufts of silky needles, which do not give off any water when heated. It dissolves in boiling water; and if the first drops of a solution filtered at the boiling heat crystallise on cooling, the crystallisation extends throughout the entire mass; but on again applying heat, and leaving the solution to cool slowly and quietly, it solidifies to a gelatinous pulp.

Benzo-helicin is not decomposed by emulsin, but alkalis and acids convert it into benzoic acid, hydride of salicyl, and glucose:

By boiling with magnesia (or other bases which do not act upon helicin), it is resolved into benzoic acid and helicin.

Bromhelicin, $C^{12}H^{10}BrO^7.H^2O$, is prepared like chlorhelicin, and exhibits similar reactions, but always separates from solution in the gelatinous form, and when dry, forms a dirty white powder without any appearance of crystallisation.

Chlorhelicin, $C^{12}H^{10}ClO^7$, exists in two modifications, which may be distinguished as α and β .

α Chlorhelicin is obtained by agitating helicin with water in a vessel filled with chlorine. The product is purified by pressure, washing with cold water, and solution in boiling

water, the liquid as it cools either depositing small needles of monohydrated chlorhelicin, $2C^3H^3ClO^7 \cdot H^2O$, or solidifying to an amorphous jelly containing a larger quantity of water.

α Chlorhelicin is inodorous, bitter, nearly insoluble in cold water, easily soluble in hot water and in alcohol. The crystals contain 3 per cent. water, which is rather more than the amount required by the formula just given ($2 \cdot 76$ per cent.), the excess probably arising from admixture of a small quantity of gelatinous α chlorhelicin. When heated to between 120° and 130° , they give off the whole of their water, and the remaining anhydrous α chlorhelicin, when raised to a higher temperature, gives off vapours of hydride of chlorosalicyl. This product is likewise obtained, together with glucose or its products of decomposition, on heating α chlorhelicin with dilute acids or alkalis, or by treating it with emulsin:

β Chlorhelicin. When chlorine is passed into an alcoholic solution of helicin, a white granular substance is obtained, which has the composition of α chlorhelicin, but is insoluble in water, nearly insoluble in boiling alcohol, and is not decomposed in the manner just mentioned by acids, alkalis, or emulsin.

HELICOIDIN. $C^{26}H^{51}O^{14}$ (Piria, Ann. Ch. Phys. [3] xiv. 292).—This substance, which may be regarded as a compound of helicin and salicin ($C^3H^3O^7$ + $C^3H^3O^7$), is obtained by treating salicin with nitric acid still more dilute than that which is used for the preparation of helicin, viz. of 12° Bm. (specific gravity 1.088). It may be purified by washing with cold water and crystallisation from boiling water. It forms needles resembling those of helicin, and containing $\frac{2}{3}$ at. water ($2C^{26}H^{51}O^{14} + 3H^2O$). Under the influence of emulsin it is decomposed similarly to helicin, yielding, however, saligenin in addition to glucose and hydride of salicyl:

Alkalis and acids act in the same manner, the latter, however, converting the saligenin into saliretin (C^3H^3O) by abstraction of water.

Helicin, salicin, and helicoidin are related to one another in the same manner as quinone, colourless hydroquinone, and green hydroquinone.

HELIOTROPE or *Bloodstone*. A variety of chalcedony, having a deep green colour with blood-red spots. It is used as a gem.

HELIX POMATIA. The *Garden or Vineyard Snail*.—The shell and operculum of this mollusc have been analysed by B. Wicke (Ann. Ch. Pharm. cxxv. 79), with the following results:—

	CaCO ₃	MgCO ₃	Earthy Phosphates.	Ferric Phosphate.	SiO ₂	Organic Substance.
Shell . . .	96.07	0.98	0.85	1.15	0.95 = 100.00	
Operculum .	86.75	0.96	5.36	0.16	0.35	6.42 = 100.00

W. Wicke (Ann. Ch. Pharm. lxxxvii. 224) found in the operculum 94.24 per cent. carbonate, and 5.73 per cent. phosphate of calcium, together with traces of ferric oxide and phosphate of magnesium. He supposes that the phosphate of calcium is contained chiefly in the small nodules which cover the surface of the operculum. Joy (*ibid.* lxxxii. 365) found in the shell, 98.5 per cent. carbonate of calcium and 1.5 organic matter, but no phosphoric acid, silicic acid, fluorine, magnesia, or alkalis. Gobley (J. Pharm. [3] xxxiii. 161) found that the shell contained 70 per cent. water, and when dried consisted almost wholly of carbonate of calcium, with small quantities of earthy and ferric phosphates, and animal matter.

In the animal itself, Gobley found a peculiar mucus, containing a small quantity of carbonate of potassium, which gives it an alkaline reaction, redissolves in water after drying, but loses this property after a while. Gobley also found, besides the salts usually occurring in the animal organism, a small quantity of chloride of ammonium, a peculiar compound of animal matter with carbonate of calcium, partially soluble in water, and traces of iodine. Beneke (Ann. Ch. Pharm. cxli. 249) found in the animal, a peculiar fatty substance called myelin, existing also in the brain and other organs of the higher animals, which swells up in peculiar forms when soaked in water.

HELLEBORINE. An azotised body contained in the root of black hellebore (*Helleborus hiemalis*). It is obtained by exhausting the root with alcohol, diluting the extract with a certain quantity of water, which precipitates a resin, and concentrating the filtered liquid.

It forms colourless crystals, having a harsh bitter taste, soluble in water and in alcohol, more soluble in ether. The solutions are neutral to test-paper. It is decomposed by heat, also by nitric and sulphuric acids. Heated with potash it gives off

ammonia. It is not precipitated from its solutions by acetate of lead, chloride of mercury, or iodide of potassium. (W. Bastick, Pharm. J. Trans. xii. 174.)

HELLEFLINTA. Called also *Leelite*. A variety of felspar, occurring at Gryphyttan, in Sweden, having a peculiar waxy lustre and deep flesh-red colour.

HELLENENE and **HELLENIN.** See **HELENENE** and **HELENIN** (p. 138).

HELMINTH. A variety of chlorite occurring in felspar and quartz. (Dana, ii. 294).

HELMINTHOLITE. A variety of limestone, generally of a dark colour, and distinguished by the beautiful red and green iridescence of the fossil shells which it contains. It is found in Carinthia, at Halle in the Tyrol, and other localities, and is made into a variety of ornamental articles. (Handw. d. Chem. iii. 848.)

HELVIN. *Tetrahedral Garnet.*—A mineral consisting of silicate of manganese, iron, and glucinum, combined with oxysulphide of manganese. It occurs in regular tetrahedrons. Hardness 6 to 6.5, rather greater than that of felspar. Specific gravity 3.1 to 3.3. Lustre vitreous, inclining to resinous. Colour wax-yellow, inclining to yellowish brown and siskin-green. Streak uncoloured. Subtranslucent. Fracture uneven. On charcoal, in the reducing flame, it melts, with intumescence, to a yellow opaque globule. When finely pulverised it is decomposed by hydrochloric acid, with evolution of sulphydric acid and separation of gelatinous silica.

Analyses: 1, 2. From Saxony, by C. Gmelin (Pogg. Ann. iii. 63). 3. From Norway, by Rammelsberg (*Mineralchemie*, p. 700):

	1	2	3
Silica	35.27	33.26	33.13
Sulphur	—	5.05	5.71
Alumina	1.44	12.03	11.46
Glucina	8.03	—	—
Ferrous oxide	8.00	5.56	4.00
Manganous oxide	42.12	41.76	49.12
Loss by ignition	—	1.15	—
	94.86	98.81	103.42

Hence Rammelsberg deduces the formula

which is reducible to the form of an orthosilicate united with a protosulphide,

Helvin affords the only known example of a native compound of a silicate with a sulphide. It is found in the gneiss of Schwarzenberg, in Saxony, associated with garnet, quartz, flints, and calspar: at Breitenbrunn, in Saxony; and on the Horte-kalle, a mountain in the Liesthal, near Drammen, in Norway.

HEMIBROMHYDRIN. See **BROMHYDRINS**.

HEMIEDRY. See **CRYSTALLOGRAPHY** (ii. 121, 128, 136, 140, 150, 156).

HEMILOGOUS SERIES. A name applied by Schiel (*Zeitschr. Ch. Pharm.* 1860, p. 44) to series of organic compounds, the terms of which differ from one another by $n\text{CH}_2$.

HEMIMORPHISM. Hemimorphous crystals, according to most authors, are those which are unsymmetrically terminated at the two ends of the principal axis, e. g. siliceous calamine (i. 714), sulphate of magnesium (ii. 150). Laurent, however (Compt. chim. 1849, p. 269), applied the same term to bodies which are similar, or to a certain extent analogous, in composition (*d'une certaine analogie dans leur composition*), and crystallise in forms (belonging to the same or to different systems) in which some of the dihedral angles are nearly equal, while the rest are very unequal.

HEMIMORPHITE. Syn. with **SILICEOUS CALAMINE** (i. 714).

HEMIPINIC ACID. $\text{C}^{10}\text{H}^{10}\text{O}^4$. (Wöhler [1844], Ann. Ch. Pharm. i. 17.—Blyth, *ibid.* l. 36 and 43.—Anderson, *ibid.* lxxxvi. 194.—Matthiessen and Foster, Proc. Roy. Soc. xi. 58; further, Phil. Trans. 1863; Chem. Soc. J. xv. 346.)—This acid is produced: 1. By the oxidation of opianic acid: $\text{C}^{10}\text{H}^{10}\text{O}^3 + \text{O} = \text{C}^{10}\text{H}^{10}\text{O}^4$, which may be effected by the action of peroxide of lead and sulphuric acid (Wöhler), or of aqueous dichloride of platinum (Blyth).—2. By the oxidation of narcotine with dilute nitric acid (Anderson), or with peroxide of lead and sulphuric acid, or per-

acid of manganese and hydrochloric acid (Wöhler), or with excess of aqueous dichloride of platinum (Blyth). In these reactions, the narcotine is first converted into opianic acid, which then suffers further decomposition.—3. Together with meconin, by the decomposition of opianic acid under the influence of caustic potash (Matthiessen and Foster):

Preparation.—1. Opianic acid is heated to the boiling point with water and peroxide of lead; dilute sulphuric acid is added drop by drop till carbonic acid begins to escape; the liquid is left to cool partially; sulphuric acid is then added by drops till all the lead is precipitated, and the filtrate is evaporated to the crystallising point. The first crystals are sometimes mixed with unaltered opianic acid, but are easily purified from it by their much greater solubility in water (Wöhler).—2. The mother-liquor resulting from the action of dilute nitric acid upon narcotine (*q. v.*), after the separation of meconin, cotarnine and opianic acid, contains hemipinic acid, which may be obtained by precipitating this mother-liquor with acetate of lead, and decomposing the precipitate with sulphydric acid. (Anderson.)

3. Opianic acid is mixed with a large excess of potash-ley; the liquid is evaporated nearly to dryness; and the resulting alkaline mass, consisting of meconin and hemipinate of potassium, is dissolved in a moderate quantity of warm water, and mixed with excess of hydrochloric acid, whereby the meconin is separated as an oil, carrying down with it the greater part of the hemipinic acid. The acidified liquid, when quite cold, is poured off from the solid cake of meconin and hemipinic acid formed at the bottom, and evaporated to a small bulk, so as to separate the greater part of the chloride of potassium; this salt is washed with alcohol; the alcoholic washings are mixed with the concentrated mother-liquor; and the fresh quantity of chloride of potassium thus precipitated is removed by filtration or decantation. The clear liquid is evaporated nearly to dryness over the water-bath; the residue thus obtained is again treated with alcohol to separate the last portions of chloride of potassium; and the alcoholic solution is filtered and evaporated. On dissolving the product of these operations, together with the original precipitate of meconin and hemipinic acid, in boiling water, and rendering the solution slightly alkaline by ammonia, nearly all the meconin crystallises out as the solution cools, while hemipinate of ammonium remains in solution, together with a small quantity of meconin. For complete purification, the solution of the ammonium-salt is precipitated by acetate of lead, and the hemipinate of lead, after thorough washing, is decomposed under water by sulphydric acid (Matthiessen and Foster). This mode of preparation is preferable to the oxidation process; because in the latter it is difficult to arrest the action at the right point, so that there is always a risk, either of leaving opianic acid undecomposed, or of losing a portion of the hemipinic acid by further oxidation. (See below.)

Properties.—Hemipinic acid crystallises in colourless oblique rhombic prisms (Wöhler), or large flat rhombohedrons (Blyth). It has a slightly acid astringent taste, and a strong acid reaction. It dissolves with difficulty in cold water, more easily in alcohol and in ether. The crystals effloresce in the air, and give off 13.73 per cent. (= 2 at.) water at 100° C. At 180° it melts, and solidifies to a crystalline mass on cooling. Heated between two watch-glasses, it sublimes in shining laminæ like benzoic acid.

Decompositions.—Hemipinic acid burns with a bright flame. Heated with peroxide of lead and sulphuric acid, it appears to be completely resolved into water and carbonic anhydride (Wöhler); distilled with excess of concentrated hydriodic acid, it is completely resolved into carbonic anhydride, iodide of methyl, and hypogallic acid (Matthiessen and Foster):

Heated with two or three times its weight of strong hydrochloric acid—either in a sealed tube to about 110°, or in an open vessel connected with a condenser, in such a manner that the condensed vapour flows back into the mixture, and with an apparatus for evolving hydrochloric acid gas, so that the liquid can be kept constantly saturated with acid, it is resolved into carbonic anhydride, chloride of methyl, and an acid having the composition $\text{C}^8\text{H}^8\text{O}^4$, homologous, therefore, with hypogallic acid:

This acid (not yet named) crystallises in long transparent prisms, nearly insoluble in cold water, not much more soluble in boiling water, more easily soluble in alcohol and ether. When heated, it begins to sublime without decomposition at about 200° C., and bears a temperature of more than 245° without alteration, but at a still higher temperature

it melts, and solidifies to a crystalline mass on cooling. It dissolves in strong sulphuric acid, and crystallises unchanged from a warm saturated solution; a cold solution is not precipitated by water. It gives no coloration with ferric chloride; with nitrate of silver it forms a white precipitate, which blackens on boiling. (Matthiessen and Foster.)

When the mother-liquor from which this acid has crystallised is subjected to the prolonged action of hydrochloric acid, hypogallic acid appears to be formed. (Matthiessen and Foster.)

Hemipinates.—Hemipinic acid is dibasic, its normal salts being represented by the formula $C^{10}H^8M^2O^6$. It is distinguished from opianic acid by forming insoluble salts with lead, silver, and iron. The ammonium-salt forms crystals permanent in the air.

The neutral potassium-salt is very soluble and difficult to crystallise.

The acid potassium-salt, $C^{10}H^8KO^6 \cdot \frac{3}{2}H^2O$, forms large hexagonal tables, easily soluble in water and alcohol, insoluble in ether. It gives off its water at 100° .

Barium-salt.—When a solution of hemipinic acid is neutralised with baryta-water, or when solutions of hemipinate of ammonium and chloride of barium are mixed together, the liquid remains clear for a long while if left to itself; but on boiling it for a short time, small, shining crystalline plates of hemipinate of barium are precipitated, and soon fill the liquid, provided the solutions used were not too dilute. The liquid on cooling redissolves this precipitate, and becomes almost or quite clear; but after standing for a few hours, or for a day or two, it again deposits hemipinate of barium, but this time in feathery tufts of very small silky needles; if the liquid be now again heated, these feathery crystals redissolve, and the crystalline plates again make their appearance. This reaction affords the means of recognising hemipinic acid, even when present in small quantity only. (Matthiessen and Foster.)

Ferric hemipinate is a precipitate of a fine orange-yellow colour (Blyth). The lead-salt is a white precipitate insoluble in water, but soluble in aqueous acetate of lead, whence it separates in transparent nodules (Wöhler). The silver-salt, $C^{10}H^8Ag^2O^6$, is a white precipitate insoluble in water.

Ethyl-hemipinic acid, $C^{10}H^8(C^2H^5)^2O^8 \cdot \frac{3}{2}H^2O$, is obtained by passing hydrochloric acid gas into a solution of hemipinic acid in absolute alcohol. It crystallises in bulky needles, which give off their water (9.6 per cent.) at 100° . It has a strong acid reaction, is very slightly soluble in cold water, rather more in boiling water. The aqueous solution precipitates ferric salts, but not lead- or silver-salts. The ethyl-hemipinates are difficult to purify. The barium-salt forms needles grouped in tufts. (Anderson.)

HEPATIN. Syn. with GLYCOGEN (ii. 906).

HEPATITE. A variety of heavy spar containing bituminous matter, and distinguished by the hepatic odour which it emits when rubbed or struck.

HEPTYL. C^7H^{15} . *Önanthyl*.—The radicle, not yet isolated, of heptylic or önanthylic alcohol and its derivatives.

HEPTYL, ACETATE OF. $C^7H^{15}O^2 = \begin{matrix} C^7H^{15}O \\ C^7H^{13} \end{matrix} \left. \vphantom{\begin{matrix} C^7H^{15}O \\ C^7H^{13} \end{matrix}} \right\} O$. (Bouis and Carlet, Compt. rend. lv. 140; Ann. Ch. Pharm. cxxiv. 363.—Schorlemmer, Chem. Soc. J. xvi. 217).—This compound is obtained:—1. By heating önanthol (heptylic aldehyde, $C^7H^{15}O$) with zinc and glacial acetic acid. The nascent hydrogen thereby liberated unites with the önanthol, forming heptylic alcohol; and this, with the excess of acetic acid forms acetate of heptyl. On washing the product with water, and agitating it with acid sulphite of sodium, to remove undecomposed önanthol, the acetate of heptyl is obtained as an oil floating on the surface (Bouis and Carlet).—2. By decomposing chloride of heptyl with acetate of potassium. The two substances, mixed with glacial acetic acid, are heated in sealed tubes to 150° — 160° C., for twelve hours. The products of the reaction are chloride of potassium, acetate of heptyl, and heptylene. On diluting the contents of the tubes with water, drying the light oily liquid which separates with chloride of calcium, and subjecting it to fractional distillation, the heptylene, which boils at 95° , is easily separated from the acetate of heptyl, the boiling point of which is much higher (Schorlemmer). Alcohol may be used in the preparation instead of glacial acetic acid, but it is less convenient, as the last portions of the chloride are then very slow to decompose, requiring a heat of 200° continued for several days. (Schorlemmer.)

Acetate of heptyl is a colourless oily liquid, lighter than water, having an agreeable fruity odour, and boiling at 180° (Bouis and Carlet), between 179° and 181° (Schorlemmer), which is about 10° higher than it should be according to Kopp's law (p. 90). It contains, according to the mean of Schorlemmer's analyses, 68.18 per cent. carbon, and 11.54 hydrogen, the formula requiring 68.35 carbon and 11.39

hydrogen.—By distillation with potash-ley, it yields acetate of potassium and heptylic alcohol.

HEPTYL, BROMIDE OF. This compound is slowly produced, with evolution of hydrobromic acid, when bromine is added to hydride of heptyl, and the mixture is either exposed to sunshine or heated in sealed tubes to 100° ; the action may be quickened by adding a little iodine. On distilling the product, a large quantity of undecomposed hydride passes over first, and, as soon as the temperature rises to 110° , the residue begins to decompose and blacken. (Schorlemmer, *loc. cit.*)

HEPTYL, CHLORIDE OF. $C^7H^{14}Cl$. (Petersen, Ann. Ch. Pharm. cxviii. 74. —Schorlemmer, Chem. Soc. J. xv. 423; xvi. 217, 426).—Obtained:—1. By the action of pentachloride of phosphorus on heptylic alcohol, and purified by washing and distillation in the usual way (Petersen).—2. By the action of chlorine, or better of chloride of iodine, on hydride of heptyl. Chlorine gas is passed, not in excess, into a solution of iodine in hydride of heptyl; the unattacked portion of the hydride is then distilled off, and the chloride of heptyl is separated by fractional distillation from the portion boiling between 140° and 160° (Schorlemmer).—3. In like manner, from ethyl-amyl ($C^4H^9.C^3H^7$), which is isomeric with hydride of heptyl. The product yields, by fractional distillation, two liquids of constant boiling point, *viz.*, chloride of heptyl, and monochlorinated chloride of heptyl, which are easily separated by distillation, as their boiling points differ by 40° . (Schorlemmer, Chem. Soc. J. xvi. 426.)

Chloride of heptyl is a colourless liquid, having an agreeable fruity odour, and burning with a smoky green-bordered flame. Specific gravity 0.891 at 19° . (Schorlemmer); 0.9983 at 55° (Petersen). Boiling point of the chloride obtained from castor-oil alcohol = 175° (Petersen); of that obtained from hydride of heptyl or from ethyl-amyl = 150° (Schorlemmer). This difference seems to point to the existence of two isomeric modifications of chloride of heptyl. Neither boiling point agrees very well with that calculated according to Kopp's law (p. 91): for the average difference for homologous chlorides of the alcohol-radicles, C^mH^{2m+1} , is about 30° , chloride of ethyl boiling at 11° , and chloride of amyl at 101° : hence chloride of heptyl should boil at about 161° .

Chloride of heptyl contains, according to Petersen's analyses, from 61.68 to 62.25 per cent. carbon, 11.01 to 11.28 hydrogen, and 26.46 chlorine, the formula requiring 62.45 C, 11.16 H, and 26.36 Cl. It is insoluble in water, but dissolves easily in alcohol and ether. Heated in a sealed tube with acetate of potassium and alcohol or glacial acetic acid, it yields acetate of heptyl (p. 141); and when heated in like manner with alcoholic sulphhydrate of potassium, it yields sulphhydrate of heptyl. It is scarcely acted upon by strong potash-ley, even when heated with it in sealed tubes to 180° for several days, only a small quantity of heptylene being formed, and not a trace of heptylic alcohol. (Schorlemmer.)

Monochlorinated Chloride of Heptyl, $C^7H^{14}Cl$. Cl, isomeric, if not identical, with chloride of heptylene, $C^7H^{12}Cl^2$, is obtained, together with chloride of heptyl, by the action of chloride of iodine on ethyl-amyl (see above). It boils at 190° , and gives by analysis 41.85 per cent. chlorine, the formula requiring 42.01. (Schorlemmer.)

HEPTYL, HYDRATE OF. $C^7H^{14}O - \frac{C^7H^{13}}{H} \left\{ O. \right.$ *Heptylic or Oenanthylic alcohol.*—This alcohol occurs, together with others, in the fusel-oil from the brandy distilled from marc of grapes (*Weintreber-fuselöl*). The portion of this liquid boiling above 133° C. contains several alcohols of the series $C^mH^{2m+2}O$, higher than amylc alcohol; and by subjecting it to repeated fractional distillation, a portion may be obtained which boils between 155° and 160° , and exhibits the composition and reactions of heptylic alcohol. (Faget, Bull. Soc. Chim. de Paris, 1862, p. 59; Ann. Ch. Pharm. cxiv. 355.)

Heptylic alcohol is likewise obtained:—1. By the action of nascent hydrogen on oenanthol, $C^7H^{14}O$ (Bouis and Carlet). The oenanthol is treated with zinc and glacial acetic acid, as already described (p. 143), and the resulting acetate of heptyl, distilled with potash, yields the alcohol.—2. From hydride of heptyl, that compound being first converted into chloride, the chloride into acetate, and the acetate into the alcohol by distillation with potash. (Schorlemmer.)

3. By distilling ricinoleate of potassium or sodium with excess of the caustic alkali (i. 98). When castor-oil is saponified with potash and the resulting soap (ricinoleate of potassium) is distilled with excess of solid potash, hydrogen is evolved, and an oily liquid passes over, containing an alcohol, or perhaps two, homologous with ethylic alcohol, together with an aldehyde or an acetone, while sebate of potassium remains in the retort. Bouis, who first observed this reaction, originally regarded the volatile oily product as octylic or caprylic alcohol (Compt. rend. xxxiii. 144; Ann. Ch. Pharm. lxxx. 304). Soon afterwards (Institut, 1851, p. 258; Ann. Ch. Pharm. lxxx. 306) he pronounced it to be heptylic alcohol; but ultimately (Compt.

rend. xxxviii. 935; xli. 603; Ann. Ch. Pharm. xcii. 395; xcvi. 34; in detail, Ann. Ch. Phys. [3] xlv. 77; xlviii. 99), after having succeeded in purifying the alcohol more completely than before, he returned to his first opinion, which was corroborated by the analysis of several derivatives of the alcohol by himself, and also by Moschnin (Ann. Ch. Pharm. lxxxvii. 111), Squire (Chem. Soc. Qu. J. vii. 108), and Cahours (Ann. Ch. Pharm. xcii. 399).—On the other hand, Railton (Chem. Soc. Qu. J. vi. 205), from a determination of the vapour-density, and Wills (*ibid.* 307), from an analysis of the alcohol, and from the examination of some of its compound ethers, concluded that it is heptylic alcohol. Somewhat later, Limpricht (Ann. Ch. Pharm. xciii. 242) showed that the oily distillate obtained as above contains a considerable quantity of a liquid which forms a crystalline compound with acid sulphite of sodium; and by distilling this compound with excess of caustic alkali, he obtained a liquid having the composition of octylic or caprylic aldehyde, $C^8H^{16}O$, which he accordingly regarded as the chief product of the distillation of ricinoleic acid with excess of potash. According to Städeler, however (J. pr. Chem. lxii. 241; Jahresber. 1857, p. 361), the compound $C^8H^{16}O$ is not caprylic aldehyde, but the isomeric compound, methyl- α -nanthyl, $CH^3.C^7H^{15}O$, belonging to the class of acetones (i. 31), and its formation takes place simultaneously with that of heptylic alcohol, in the manner shown by the equations:

The evolution of marsh gas, which the latter equation supposes, has not, however, been observed: the gas evolved appears to be in all cases pure hydrogen. Städeler's analysis of the alcohol agrees very closely with the formula of heptylic alcohol. Similar results have been obtained by Petersen (Ann. Ch. Pharm. cxvii. 69), who analysed the alcohol after carefully freeing it from methyl- α -nanthyl, and also some of its derivatives, all of which gave results agreeing with the 7-carbon formula. On the other hand, Dachauer (Ann. Ch. Pharm. cvi. 269), from his analyses of the carefully-purified alcohol and several of its derivatives, has come to the conclusion that the volatile products of the reaction are methyl- α -nanthyl and octylic alcohol, the formation of the latter differing from that of the former, only by the evolution of 2 at. hydrogen instead of four:

From these various statements it appears probable that both heptylic and octylic alcohol may be produced in this reaction. It must be observed, however, that the percentage of carbon in the two alcohols differs by only 1.4 per cent., and that the percentage of carbon in heptylic alcohol (72.4) might easily be raised to that of octylic alcohol (73.8) by the admixture of a certain quantity of methyl- α -nanthyl, which contains more carbon than either of them (75.0 per cent.), and is very difficult to separate from the alcohol. It is possible, therefore, that the alcohol obtained may be in all cases the heptylic, but that some chemists who have analysed it have not succeeded in completely removing the methyl- α -nanthyl. On the other hand, assuming the received formula of ricinoleic acid to be correct (and it is confirmed by Petersen's analyses, *loc. cit.*), the formation of the 7-carbon alcohol, together with sebatic acid, does not account for the whole of the carbon, unless we suppose marsh gas to be evolved, which has not been observed by any one. The subject, therefore, requires further investigation.

Preparation of Heptylic alcohol from Castor-oil.—The oil is saponified with caustic soda, and the ricinoleate of sodium, separated in the usual way by common salt, is distilled by small portions with excess of caustic soda, as long as the distillate continues to pass over colourless. The portion collected between 170° and 180° is rectified over solid potash, washed, and shaken up with a concentrated solution of acid sulphite of sodium; and the thick pulp which forms after a while is separated from the mother-liquor by pressing it and transferring it to a moist filter. The whole mass is then repeatedly agitated with ether, in which the alcohol is soluble, but the compound of the acetone with the alkaline sulphite is insoluble. The ethereal solution is then filtered off; the ether removed by distillation, the residual oil again mixed with strong solution of acid sulphite of sodium, and set aside for several days; the watery liquid again separated from the mass, which has now become gelatinous; this mass is exhausted with ether; and the oil obtained from this ethereal solution is again treated several times with sulphite of sodium, being ultimately left in contact with it for several weeks, or as long

as any small quantity of gelatinous precipitate continues to separate. The oil finally obtained after evaporating the ether is rectified over a small quantity of hydrate of potassium, then washed with water and dried. The product thus obtained is heptylic alcohol. (Petersen.)

Properties.—Heptylic alcohol is a colourless oily liquid, insoluble in water, soluble in common alcohol and in ether. Specific gravity 0.819 at 23° (Städeler). Vapour-density 4.34 (Petersen), 4.16 (Faget), 4.019, by determination in an atmosphere of hydrogen (Railton): by calculation (2 vol.) = 4.04. Boiling point 179° (Willis), between 177 and 177.5° (Städeler), 178.5° (Petersen), 165° (Bouis and Carlet), between 155° and 160° (Faget). These differences, as with the chloride, indicate the existence of two modifications of the alcohol. The calculated boiling point, according to Kopp's law, is 173° (p. 90), so that the heptylic alcohol obtained from castor-oil appears to be the normal compound, whereas the alcohol obtained from brandy fusel-oil, and that produced from œnanthol, appear to correspond with Wanklyn and Erlenmeyer's β -hexylic alcohol, inasmuch as the latter boils at 134°, and $137 + 19 = 156$.

The following table exhibits the composition of heptylic alcohol as determined by calculation and by analysis:

	Calculation.	Willis.	Städeler. mean.	Petersen.	Faget.	Schorlemmer, mean.
C ^v	84	72.4	72.79	72.21	72.43	72.25
H ¹⁶	16	13.8	13.67	13.99	13.84	14.24
O	16	13.8	13.54	14.12	13.73	13.51
C ^v H ¹⁶ O	116	100.0	100.00	100.00	100.00	100.00

Faget's alcohol was obtained from brandy fusel-oil (p. 144); Schorlemmer's was prepared from hydride of heptyl obtained from Boghead naphtha; the other three from castor-oil. Petersen observes that the purification of the alcohol did not always succeed so completely as in the sample whose analysis is above given; in one specimen he found 72.95 per cent. carbon and 13.37 hydrogen. Bouis, Moschnin, and Dachauer, as already observed, have obtained, by their analyses of the castor-oil alcohol, results agreeing more nearly with the formula C^vH¹⁶O, viz. Bouis, 73.5 C, 13.9 H; Moschnin, 73.6 C, 13.8 H; Dachauer, 73.8 C, 13.9 H (calc. 73.8 C, 13.8 H). See OCTYLIC ALCOHOL.

Decompositions.—1. Heptylic alcohol distilled with *chloride of zinc*, yields heptylene, C^vH¹⁴ (Bouis and Carlet).—2. Heated with *potash-lime*, it gives off hydrogen, and is converted into œnanthyllic acid, C^vH¹⁴O² (Faget).—3. With *pentachloride of phosphorus*, it yields chloride of heptyl (Petersen), and with *iodine and phosphorus*, iodide of heptyl (Schorlemmer).—4. With *sulphuric acid*, it forms heptyl-sulphuric acid, C^vH¹⁶SO² (Petersen).

HEPTYL HYDRIDE OF. C^vH¹⁶ = C^vH¹⁵.H.—This compound occurs, together with several of its homologues, in rectified American petroleum (Pelouze and Cahours, *Compt. rend.* lvi. 505; *Ann. Ch. Pharm.* cxxvii. 196.—Schorlemmer, *Proc. Lit. Phil. Soc. Manchester*, March 13, 1863; *Chem. Soc. J.* xvi. 216) and in the light oil obtained from the tar of cannel-coal (Schorlemmer, *Chem. Soc. J.* xv. 423): it is also produced, together with some of its homologues and other hydrocarbons, by distilling amylic alcohol with chloride of zinc. (A. Wurtz, *Compt. rend.* lvi. 1164, 1246; *Ann. Ch. Pharm.* cxxviii. 225.)

1. Rectified American petroleum may be separated by fractional distillation into the hydrides of twelve alcohol-radicles, from hydride of tetryl, C^{iv}H¹⁰, boiling at a few degrees above 0°, to hydride of pentadecetyl, C^{xv}H³², boiling between 255° and 260°, besides others of still higher boiling point (see HYDRIDES). When the liquid which remains after the separation of the hydrides of amyl, boiling at 30°, and hexyl, at 68°, is submitted to further rectification, the temperature remains constant for some time between 90° and 96°; and if the portion which passes over between these temperatures be collected apart and again carefully rectified, the quantity of material being somewhat considerable, a product may be isolated which, after purification by shaking it up with very concentrated sulphuric acid, washing with dilute carbonate of sodium, and dehydration with chloride of calcium, boils between 92° and 94°: this is hydride of heptyl. (Pelouze and Cahours.)

2. The mixture of oils obtained by distilling cannel-coal at as low a temperature as possible, is left in contact for several days with an equal volume of sulphuric acid, and frequently shaken; the oil is then poured off, washed with water, and distilled; and the distillate, consisting of benzene and benzylene (toluene), together with the hydrides of the alcohol-radicles, is repeatedly shaken with strong nitric acid, to convert the benzene and benzylene into nitro-compounds, until, on adding water to the liquid, no further separation of these compounds occurs. The portion unacted upon by the nitric acid is then washed with water, dried over potash, and repeatedly rectified over sodium. The liquid thus obtained yields by fractional distillation, hydride of amyl, C^{iv}H¹², boiling at

39°—40° C., hydride of hexyl at 68°—70° hydride of heptyl at 98°—99°, and hydride of octyl at 119°—120°. (Schorlemmer.)

3. The distillate obtained by heating amylic alcohol with chloride of zinc consists of amylene and compounds polymeric with it, together with hydride of amyl, and smaller quantities of the hydrides of hexyl, heptyl, &c., up to C^6H^{13} . Heptylene and hydride of heptyl are contained in the portion of the distillate boiling between 85° and 95°, and may be separated by converting the heptylene into a bromide and distilling, the hydride of heptyl then passing over first. (Wurtz.)

Hydride of heptyl is a thin mobile liquid, having a faint but pleasant odour, and burning with a slightly smoky flame. Specific gravity 0.7122 at 16°; 0.709 at 17.5° (Schorlemmer). Boils at 98°—99° (Schorlemmer), at 92°—94° (Pelouze and Cahours). Vapour-density by experiment, 3.49—3.59 (Schorlemmer), 3.616 (Pelouze and Cahours); by calculation (2 vol.) = 3.46. It gives by analysis 83.93 and 84.0 per cent. carbon, 16.13 and 16.1 hydrogen, the formula requiring 84 C and 16 H (Schorlemmer). By *chlorine*, and more quickly by *chloride of iodine*, it is converted into chloride of heptyl. Chlorine passed into hydride of heptyl forms, besides chloride of heptyl, small quantities of some other chlorine-compounds, which, when distilled with sodium, yield a liquid boiling at 95°—100°, and having the odour and composition of heptylene (Schorlemmer, Chem. Soc. J. xv. 424). With *bromine*, hydride of heptyl appears to yield bromide of heptyl (p. 144).

HEPTYL IODIDE OF. $C^7H^{15}I$.—Obtained by the action of iodine and phosphorus on heptylic alcohol (Schorlemmer, Chem. Soc. J. xvi. 219.—Petersen, Ann. Ch. Pharm. cxviii. 74). It is a colourless liquid, heavier than water, quickly turning brown in contact with the air, boiling at 190° (Schorlemmer), 192° (Petersen). Composition by analysis, 37.19 per cent. C, 6.73 H, and 56.18 I; by calculation, 37.17 C, 6.64 H, and 56.19 I. It is instantly decomposed by alcoholic nitrate of silver, the whole of the iodine being separated as iodide of silver. (Schorlemmer.)

HEPTYL SULPHYDRATE OF. $C^7H^{15}S = C^7H^{13}.H.S$.—Obtained by heating chloride of heptyl with alcoholic sulphhydrate of potassium in a sealed tube. Colourless liquid, boiling between 155° and 158°, having a mercaptan-like, as well as aromatic, odour, and exhibiting all the characteristic reactions of the mercaptans. (Schorlemmer.)

HEPTYLAMINE. $C^7H^{15}N = N.H^2.C^7H^{13}$.—Obtained: 1. By saturating iodide of heptyl with ammonia, heating the solution in the oil-bath, and removing the iodine with oxide of silver (Petersen, *loc. cit.*).—2. By heating chloride of heptyl with ammonia in sealed tubes to 120° for several days. The chlorides of the different heptyl-ammoniums are then formed, but chiefly chloride of heptyl-ammonium, $C^7H^{14}Cl$. This salt dissolves easily in water and alcohol, and crystallises in small scales. When distilled with caustic potash, it yields heptylamine, as a light oily liquid, having an ammoniacal aromatic odour, a burning taste, and boiling at 145°—147°. It is moderately soluble in water, and separates out again on addition of caustic potash. (Schorlemmer, Chem. Soc. J. xvi. 221.)

The *platinum-salt*, $2C^7H^{15}NCl.PtCl_4$, is slightly soluble in cold water, freely soluble in hot water, also in alcohol and ether, crystallising from these solutions in small yellow scales. Gives by analysis 30.7 per cent. platinum (Schorlemmer); 30.9 (Petersen); calc. 30.79.

HEPTYLAMYLIC ETHER. $C^{12}H^{24}O = C^7H^{13}.C^5H^{11}.O$. *Amylananthylic ether*.—Produced by the action of heptylate of sodium on an equivalent quantity of iodide of amyl, and obtained, though with some difficulty, by submitting the product to fractional distillation, as a colourless mobile liquid, boiling between 220° and 221°. Specific gravity = 0.608 at 20°. Vapour-density: obs. = 6.57; calc. (2 vol.) = 6.45. Analysis 77.0 per cent. C, and 13.8 H. Calculated composition, 77.4 C, 14.0 H, and 8.6 O. (Wills, Chem. Soc. J. vi. 316.)

HEPTYLENE. C^7H^{14} . *Oenanthylen*.—This hydrocarbon, homologous and polymeric with ethylene, is contained, together with others of the series C^6H^{12} , and hydrocarbons belonging to the series C^8H^{16+2} and C^8H^{16-2} , in the light oil obtained by the distillation of Boghead coal. By treating this oil with bromine in presence of water, the hydrocarbons C^8H^{16} are converted into heavy oily bromides, while the other hydrocarbons remain unaltered and may be distilled off. The remaining liquid separates, on standing, into three layers, the upper consisting of water with a little hydrobromic acid, the middle of the organic bromides, and the lowest of aqueous hydrobromic acid. The middle layer separated and distilled with alcoholic potash and with sodium, yields the hydrocarbons C^7H^{14} . The brominated oils obtained from the fractions of the original coal-oil which boiled between 71° and 77° and between 82° and 88°, yielded respectively hexylene boiling at 71° and heptylene boiling at 99° (Greville Williams, Phil. Trans. 1867 [3] 737; Ann. Ch. Pharm. cviii. 384). Heptylene is likewise obtained:—1. By decomposing chloride of heptylene with sodium at a gentle heat.

The sodium is added by small quantities; the liquid distilled off as soon as the quantity of chloride of sodium becomes so great as to interfere with the action; and the distillate is treated with fresh sodium, the last traces of chlorine being removed by repeatedly rectifying the product over perfectly bright sodium (Limpricht, *Ann. Ch. Pharm.* ciii. 80). The heptylene which Schorlemmer obtained by treating with sodium the chlorinated compounds produced, in addition to chloride of heptyl, by the action of chlorine on hydride of heptyl (p. 144), probably also resulted from the decomposition of chloride of heptylene.—2. By distilling heptylic alcohol with chloride of zinc: $C^7H^{14}O - H^2O = C^7H^{14}$ (Bouis and Carlet).—3. By heating chloride of heptyl with strong aqueous potash to 180° in sealed tubes for several days (Schorlemmer, p. 144).—Bouis, in 1855, by distilling ænanthol with strong sulphuric acid, obtained a hydrocarbon agreeing in composition with the empirical formula of the olefines, CH^2 , and supposed by him to be heptylene; but, as it boiled at 50° , it was probably either a lower member of the series, or a mixture.

Heptylene is a colourless mobile liquid, having a peculiar alliaceous odour; soluble in alcohol. Boils at 95° (Schorlemmer), at 99° (Gr. Williams). Specific gravity 0.718 at 18° (Williams). Vapour-density, obs. = 3.320 (Williams); calc. (2 vol.) = 3.386.

	Calculation.		Limpricht.	Schorlemmer.	
C^7	84	85.71	85.9	85.6	85.66
H^{14}	14	14.29	14.1	14.6	14.00
C^7H^{14}	98	100.00	100.0	100.2	99.66

Bromide of Heptylene. $C^7H^{14}Br^2$.—Obtained by direct combination. It is a liquid, heavier than water, which decomposes on distillation, with blackening and evolution of hydrobromic acid, but volatilises in presence of aqueous vapour, condensing as a nearly colourless liquid having the odour of bromide of ethylene. Gives by analysis 62.26 and 62.23 bromine, the formula requiring 62.01. (Schorlemmer.)

Chloride of Heptylene. $C^7H^{14}Cl^2$.—Produced by the action of pentachloride of phosphorus on ænanthol. When 1 at. ænanthol is gradually allowed to flow into 1 at. pentachloride of phosphorus contained in a tubulated retort, great heat is evolved, and a portion of the resulting oxychloride of phosphorus distils over immediately. As soon as the decomposition of the pentachloride is complete, the liquid is subjected to fractional distillation, the portion which boils above 150° being collected apart as long as it passes over colourless; in the retort there remains a small quantity of a brown thick liquid. The last distillate is washed with water to remove adhering oxychloride of phosphorus; and the oil which floats on the water is shaken up with acid sulphite of sodium, to remove undecomposed ænanthol, then dried with chloride of calcium, and rectified, the portion which boils between 180° and 200° being collected apart: on again rectifying this portion, pure chloride of heptylene passes over at 187° .

Chloride of heptylene is a transparent, colourless, mobile liquid, lighter than water, having a not unpleasant odour, like that of ænanthol. It boils at 191° (corrected). Gives by analysis 48.85 per cent. C, 8.00 H, and 42.06 Cl; the formula requiring 49.4 C, 8.2 H and 42.4 Cl.

When gently heated with sodium, it is decomposed with violence, yielding heptylene and chloride of sodium.—Boiled for some time with ethylate of sodium or alcoholic solution of potash, it is resolved into hydrochloric acid, chlorheptylene, $C^7H^{13}Cl$, and a hydrocarbon, probably C^7H^{12} :

It is not perceptibly decomposed by acetate of silver, even when continuously boiled with it, or heated to 250° in sealed tubes. (Limpricht, *Ann. Ch. Pharm.* ciii. 80.)

Chlorheptylene. $C^7H^{13}Cl$.—Obtained by the action of alcoholic potash or ethylate of sodium on chloride of heptylene. A very concentrated alcoholic solution of potash is distilled upwards with chloride of heptylene for a considerable time (the decomposition of 15 grammes of the chloride takes about a week);—or chloride of heptylene and ethylate of sodium are heated together in a sealed tube to 250° . The liquid obtained by either process is diluted with water, which separates impure chlorheptylene; and this crude product is dried by means of chloride of calcium and then subjected to fractional distillation. It begins to boil at 100° , the boiling point slowly rising to 160° , where it remains constant for a while and ultimately rises to 190° . The liquid which passes over below 100° is a hydrocarbon (see below); that which distils at 162° is chlorheptylene, and above that temperature the product consists chiefly of undecomposed chloride of heptylene. The complete separation of these liquids can only be effected by repeated rectification.

Chlorheptylene is a liquid resembling chloride of heptylene, having a similar odour, and boiling at 155° (corrected). It gives by analysis 63.6 per cent. C, 9.7 H, and 26.8 Cl, the formula requiring 63.2 C, 9.7 H and 27.1 Cl.

Sodium remains unaltered in chlorheptylene at ordinary temperatures; but on heating the liquid, a violent action suddenly takes place, chloride of sodium being formed, together with a hydrocarbon, probably C^7H^{12} .—The same hydrocarbon appears to be produced by the action of alcoholic potash on chloride of heptylene (see above). (Limpriht, Ann. Ch. Pharm. cii. 82.)

Iodide of Heptylene. $C^7H^{12}I = C^7H^{11}.HI$.—Obtained by heating heptylene with hydriodic acid in sealed tubes to 100° for twelve hours. It closely resembles iodide of heptyl, but boils at about 170° , or 20° lower than the latter. It soon turns brown when exposed to the air. Precipitated by alcoholic nitrate of silver, it yielded a quantity of iodide of silver corresponding to 55.73 per cent. iodine (calc. 56.19); and the filtrate, on being mixed with water, yielded a small quantity of a fragrant liquid, which consisted wholly or in a great part of nitrate of heptylene, $C^7H^{11}.NO^2H$, as on adding an alcoholic solution of potash, and heating gently, an abundant precipitate of nitrate of potassium was formed. (Schorlemmer, Chem. Soc. J. xvi. 220.)

HEPTYL-ETHYLIC ETHER. $C^7H^{12}O = C^7H^{11}.C^2H^5.O$. *Ethyl-ananthylic ether*. (Wills, Chem. Soc. Qu. J. vi. 312; * Petersen, Ann. Ch. Pharm. cxviii. 75).—Prepared by the mutual action of iodide of ethyl and heptylate of sodium in equivalent proportions:

It is a colourless mobile liquid, having a faint odour, and burning with a bright flame; insoluble in water, easily soluble in alcohol and ether. Boils at 177° (Wills). Specific gravity = 0.791 at 16° . Vapour-density, obs. = 5.095 (Wills); calc. (2 vol.) = 4.99.

	Calculation.		Wills.	Petersen.
C ⁹	108	75.00	75.16	74.44
H ²⁰	20	13.88	14.44	14.40
O	16	11.12	10.40	11.16
$C^9H^{20}O$	144	100.00	100.00	100.00

HEPTYLIC ALDEHYDE. Syn. with *CENANTHOL*. (q. v.)

HEPTYL-METHYLIC ETHER. $C^7H^{12}O = C^7H^{11}.CH^3.O$. *Methyl-ananthylic ether*. (Wills, Chem. Soc. J. vi. 314).—Obtained by the action of iodide of methyl on heptylate of sodium. It is a thin mobile liquid, having a strong odour, insoluble in water, easily soluble in alcohol and in ether. Boiling point between 160.5° and 161° . Specific gravity = 0.830 at 16.5° . Vapour-density (obs.) about 4.2; calc. (2 vol.) = 4.5. A specimen not quite pure gave by analysis 73.15 per cent. C, and 14.09 H, the formula requiring 73.85 C and 13.85 H.

HEPTYL-SULPHURIC ACID. $C^7H^{12}SO^4 = \left. \begin{matrix} (SO^2)'' \\ H \end{matrix} \right\} O^4$. (Petersen, Ann.

Ch. Pharm. cxviii. 72.—Bouis and Carlet, *ibid.* cxiv. 254).—When 2 pts. of heptylic alcohol are cautiously mixed with 1 pt. sulphuric acid, the mixture being kept cool so as to prevent the formation of sulphurous acid, the liquid ultimately separates into two layers, the upper of which contains heptyl-sulphuric acid. On neutralising it with carbonate, and at last very carefully with hydrate of barium, and concentrating at a gentle heat, heptyl-sulphate of barium separates in small, white, flexible, and generally scaly crystals, having a pearly lustre and bitter taste, very soluble in water, and not precipitated from the aqueous solution by alcohol or ether. The solution decomposes by evaporation unless the temperature be kept very moderate. The dry salt is permanent in the air, but, according to Petersen, begins to decompose at 80° , turning first red, then black, and emitting a very strong odour. According to Bouis and Carlet, on the other hand, it may be heated to 100° without decomposition. According to the mean results of Petersen's analyses, the salt dried over oil of vitriol contains 30.97 per cent. C, 5.19 H, 25.10 Ba, and 11.73 S, agreeing nearly with the formula $2C^7H^{12}.BaSO^4.H^2O$, which requires 30.83 C, 5.87 H, 25.14 Ba, 11.74 S, and 26.42 O.

HERAPATEITE. Syn. with Sulphate of Iodoquinine. (See QUININE.)

HERCINITE. An iron spinel, $FeO.Al^2O^3 = \left. \begin{matrix} Fe'' \\ (Al^3)' \end{matrix} \right\} O^4$. Specific gravity 3.91—3.95. (See SPINEL.)

HERDERITE. A very rare mineral, consisting of anhydrous phosphate of aluminium, and phosphate with fluoride of calcium; not yet analysed quantitatively. The crystals are trimetric. Hardness = 5. Specific gravity = 2.985. It resembles apatite in colour and lustre, but is distinguished by its lower specific gravity. Soluble in hydrochloric acid. Melts before the blowpipe to a white bead, with slight intumescence. (Dana, ii. 410.)

* The compound obtained by Wills is described at p. 342, vol. II. as octyl-ethyllic ether; but the balance of evidence is certainly in favour of the supposition that it contains heptyl, not octyl.

HERMANNITE. See RHODONITE.

HERRERITE. A mineral from Albarradon in Mexico, said by Herrera (J. pr. Chem. viii. 514) to contain 35.58 per cent. tellurium, 12.32 oxide of nickel, and 31.88 carbonic acid. According to Genth, however (*ibid.* lxi. 475), it is a cupriferos zinc-spar, containing 93.74 per cent. ZnCO_3 , 3.42 CuCO_3 , 1.50 MnCO_3 , 1.48 CaCO_3 , and 0.29 MgCO_3 .

HERSCHELITE. A mineral from Aci reale and Aci Castello in Sicily, having the same general formula as lime-harmotome (p. 14), viz. $\text{M}^2\text{O} \cdot \text{Al}^3\text{O}^3 \cdot 4\text{SiO}^2 + 5\text{H}^2\text{O}$, or $\text{M}^2(\text{al})^3\text{Si}^4\text{O}^{12} \cdot 5\text{H}^2\text{O}$, agreeing also in general formula with gmelinite (ii. 924) excepting in the amount of water, and crystallising, like the latter, in the hexagonal system.

Analyses 1 and 2 are of the mineral from Aci reale, by Damour (Ann. Ch. Phys. [3] xiv. 97); 3, 4, from Aci Castello, by v. Waltershausen (*Vulkanische Gesteine*, p. 260):

	SiO^2	Al^3O^3	Fe^2O^3	CaO	MgO	Na^2O	K^2O	H^2O
1.	47.39	20.90	. .	0.38	. .	8.33	4.39	17.84 = 99.23
2.	47.46	20.18	. .	0.25	. .	9.35	4.17	17.65 = 99.06
3.	45.89	18.20	1.14	4.84	0.35	5.72	3.72	17.86 = 97.72
4.	47.03	20.21	1.14	4.66	0.49	4.82	2.03	17.86 = 98.24

These analyses lead to the formulæ:

Damour.

v. Waltershausen.

According to v. Waltershausen, herschelite does not occur at Aci reale.

HESPERIDIN. A substance discovered by Lebreton (J. Pharm. xiv. 377), and contained in many fruits of the genus *Citrus*. It is most readily prepared from unripe Seville oranges, by removing the green rind and the inner part of the fruit, treating the white spongy inner coating with water at a temperature of 25 to 30°; concentrating the liquid, neutralising it with lime-water, and evaporating to a syrup; treating the residue with alcohol of 40 per cent.; then filtering, distilling off the alcohol, and agitating the bitter granular residue with 20 times its weight of distilled vinegar. The liquid on standing deposits hesperidin in warty masses, which may be washed with water and recrystallised from boiling alcohol.

Hesperidin thus purified forms white, silky laminae, inodorous, and having a bitter taste; sparingly soluble in cold alcohol, very soluble in boiling alcohol, insoluble in ether; dissolves in 60 pts. of boiling water, and separates again on cooling. The solutions are neutral to vegetable colours. It is soluble in warm concentrated acetic acid, insoluble in oils.

Hesperidin is decomposed by prolonged boiling with water, and then floats on the surface like melted wax. It is readily dissolved by caustic alkalis. Strong sulphuric acid dissolves it with orange-colour, gradually changing to red. Hot nitric acid converts it into oxalic acid and a bitter substance. The alcoholic solution is not precipitated by acetate of lead, but forms a brown precipitate with ferric sulphate.

Wiedemann has described, under the name *hesperidin*, a substance obtained from unripe oranges, differing from that above described in some respects, especially in not being soluble in alcohol.

HESITE. Telluric silver. (See TELLURIUM.)

HESONITE. Syn. with ESSONITE (ii. 507).

HETEPOLITE. See HETEROSITE.

HETEROCLINE or *Marceline*. A silicate of manganese occurring at St. Marcel in Piedmont, in oblique rhombic prisms of 128° 16', and containing 10.76 per cent. SiO^2 , 85.87 Mn^2O^3 , 3.38 Fe^2O^3 , 0.61 CaO , and 0.44 K^2O = 100.30. (Evrainoff, Pogg. Ann. xlix. 204.)

HETEROMERITE. An altered form of idocrase from Slatoust in Siberia, containing, according to v. Hauer, 43.29 SiO^2 ; 23.17 Al^3O^3 ; 6.10 Fe^2O^3 ; 23.78 CaO , and 3.05 MgO . Colour light green.

HETEROMORPHISM. The property, sometimes observed in compounds, of crystallising, in different forms, though containing equal numbers of atoms similarly grouped. Such is the case with sulphate of zinc, $\left. \begin{array}{l} \text{SO}^2 \\ \text{Zn} \end{array} \right\} \text{O}^2 + 7\text{H}^2\text{O}$, and ferrous sulphate, $\left. \begin{array}{l} \text{SO}^2 \\ \text{Fe} \end{array} \right\} \text{O}^2 + 7\text{H}^2\text{O}$; the former crystallising in the trimetric, the latter in the monoclinic

system. The cause of this difference in the examples just cited is probably that the elements—iron and zinc—are not isomorphous.

HETEROMORPHITE. *Feather ore.*—A sulphantimonite of lead, $\text{Sb}^{\text{S}}\text{S}^{\text{PbS}}$, which occurs in capillary forms resembling a cobweb; also massive. Specific gravity 5.67 to 5.9. Hardness 1 to 3. Lustre dull metallic. Colour lead-grey to steel-grey, sometimes iridescent. It is found at Wolfberg in the Eastern Hartz; also at Andreasberg and Clausthal; at Freiberg and Schemnitz; in the Anhalt at Pfaffenberg and Meiseberg; and in Tuscany, near Bottino. (Dana, ii. 76.)

HETEROSITE or *Hetepozite*. A hydrated phosphate of iron and manganese, found near Limoges, in dark brown or black masses, containing, according to Dufrenoy's analysis, 41.77 p. c. P^{O}_5 , 34.89 FeO, 17.57 MnO, 4.40 H^{O} , and 0.22 Si^{O}_2 (= 98.85), whence Rammelsberg (*Mineralchemie*, p. 331) deduces the formula $3(5\text{MO}.2\text{P}^{\text{O}}_5)$ or $3\left[\frac{2}{3}\text{FeO}\right] \cdot 2\text{P}^{\text{O}}_5 + 5\text{aq.}$

The same name is applied to an altered triphyllin from Chanteloub, Limoges, of brownish violet colour, specific gravity 3.41, and containing 32.18 p. c. P^{O}_5 , 31.46 Fe^{O} , 30.01 Mn^{O} , and 6.35 water (= 100), whence the formula $5\text{M}^{\text{O}}_2\text{O}.3\text{P}^{\text{O}}_5 + 5\text{aq.}$ (Rammelsberg, *loc. cit.*)

HEULANDITE. See STILBITE.

HEVEENE. The least volatile part of the products of the dry distillation of caoutchouc and gutta percha. It is an oily hydrocarbon, of an amber-yellow colour, acrid taste, and specific gravity 0.921 at 21° . Boils at 315° . Mixes in all proportions with alcohol, ether, and oils, both fat and volatile. It rapidly absorbs chlorine, and acquires thereby the consistence of wax. It is partly resinised by sulphuric acid, and then converted into an oil which boils at 228° , and is not attacked by strong acids (Bouchardat, Ann. Ch. Pharm. xxvii. 30). According to Greville Williams, it is probably polymeric with isoprene and caoutchin (ii. 961).

HEXACHLORXYLIN. A product of the action of chlorine on hydrate of phenyl. (See PHENYL.)

HEXACROLEIC ACID. $\text{C}^6\text{H}^8\text{O}^4$.—An acid polymeric with acrolein, and produced by dropping that liquid into an alcoholic solution of potash. The solution becomes heated to the boiling point; and on addition of an acid, yields hexacroleic acid as a yellow, amorphous, feebly acid substance, soluble in alkalis, alcohol and ether; insoluble in water, easily fusible, but not volatile without decomposition. Most of its salts are insoluble in water. (Claus, Ann. Ch. Pharm. suppl. ii. 117.)

HEXAMETAPHOSPHORIC ACID. See PHOSPHORIC ACID.

HEXAMETHYLENAMINE. $\text{C}^6\text{H}^{12}\text{N}^4 = \text{N} \begin{Bmatrix} \text{N}(\text{CH}^2)^2 \\ \text{N}(\text{CH}^2)^2 \\ \text{N}(\text{CH}^2)^2 \end{Bmatrix}$.—A volatile crystalline

base produced by the action of ammonia on dioxymethylene (Buttlerow, Ann. Ch. Pharm. cxv. 322). See METHYLENAMINES.

HEXETHYLENIC ALCOHOL. See ETHYLENE, HYDRATES OF (ii. 576).

HEXMETHYL-ETHYLENE-DIPHOSPHONIUM. See PHOSPHORUS-BASES

HEXYL. *Caproyl.* $\text{C}^6\text{H}^{12} = \text{C}^6\text{H}^{11}$.—The sixth alcohol-radicle of the series $\text{C}^n\text{H}^{2n+1}$. It is produced by the electrolysis of œnanthyllic acid:

To prepare it, a solution of œnanthylate of potassium is decomposed by a voltaic current, and the oil which separates is dried over chloride of calcium, and then distilled with alcoholic potash, which retains œnanthyllic acid, while the hexyl passes over with the vapours of alcohol, and may be purified by washing with water and rectification (Brazier and Gossleth, Chem. Soc. J. iii. 210). Wurtz (Ann. Ch. Phys. [3] xlv. 275), by electrolysis a mixture of 100 pts. œnanthyllic and 120 pts. valeric acid, neutralising with potash and cooling to 0° , obtained an oil which, after desiccation by chloride of calcium, yielded by fractional distillation, tetryl (C^4H^9), boiling between 100° and 140° , tetryl-hexyl ($\text{C}^4\text{H}^9.\text{C}^6\text{H}^{11}$), between 140° and 180° , and a portion boiling between 180° and 220° , consisting chiefly of hexyl.

Hexyl is a colourless oily liquid, of specific gravity 0.7574 at 0° . It boils at 202° , yielding a vapour whose density is 5.983 (Wurtz); calc. (2 vol.) = 5.8979. It is insoluble in water, but soluble in alcohol and ether.

It is not attacked by sulphuric acid, and may be distilled without alteration with moderately concentrated nitric acid; but by repeated distillation with a mixture of sulphuric and nitric acids, it is converted into an acid, probably caproic acid. It is

scarcely attacked by bromine, even in sunshine. Chlorine attacks it strongly, even in diffused daylight; hydrochloric acid being evolved, and a viscid substance formed, which gives off hydrochloric acid when distilled, and leaves a residue of charcoal. (Brazier and Gossleth.)

The compounds of hexyl were hardly known before the year 1861, the alcohol having been barely identified by Faget, in fusel-oil, in 1854 (Compt. rend. xxxvii. 730). At present, the known sources of hexyl-compounds are: (1) fusel-oil, containing the alcohol; (2) mannite and melampyrin, which, when reduced with hydriodic acid, give iodide of hexyl; and (3) petroleum and coal-tar oil, which contain hydride of hexyl. Whether the hexyl-compounds obtained from (1) and (3) are identical, is still an open question; but, without doubt, those derived from (2) are essentially different from the hexyl-compounds either of fusel-oil or of petroleum. The hexyl-compounds of fusel-oil and of petroleum have been distinguished by the prefix *Alpha*, those of mannite or melampyrin by *Beta*. The former compounds, so far as they have been yet examined, present the very closest analogies to those of the ethyl series; the latter depart in many ways from this standard: thus, they show a great tendency to evolve their olefine during reactions; and their alcohol has too low a boiling point, and when oxidised with dilute chromic acid, does not yield caproic acid, but breaks up into carbonic acid, water, butyric and acetic acids.

The hexyl-compounds derive peculiar interest from their having the same carbon-condensation as the sugars, and from their standing in close relation thereto, as the reaction of hydriodic acid with mannite proves, mannite being, as has long been known, a product of the reduction of glucose (ii. 864).

Berthelot has already remarked upon the peculiar readiness to react shown by tritylene. It is not unworthy of remark, that hexylene, which is paratritylene, likewise displays extraordinary energy.

Acetates of Hexyl.—*α* Hexyl-acetate is prepared by the action of *α* iodide of hexyl upon acetate of silver. It is a colourless liquid, lighter than water, and boiling at about 145° C. By the action of caustic potash, it has been transformed into an alcohol, boiling at about 150° (Cahours and Pelouze, Compt. rend. liv. 1246.)

β Hexyl-acetate is prepared by distilling *β* hexyl-sulphuric acid with a great excess of glacial acetic acid:—

It is an oil lighter than water, and very insoluble in water, having a peculiar smell, unlike the usual smell of an acetate of an alcohol-radicle. Boiling point 156°. It distils without decomposition. Digestion at 100°, with an alcoholic solution of potash, transforms it into *β* hexylic alcohol. Unlike *β* C⁶H¹³I, it yields no hexylene on digestion with alcoholic solution of potash. Sp. gr. at 0° = .8778 : at 50° = .8310; therefore expansion-coefficient for 50° = .0563. It forms a double compound with Na^βC⁶H¹³O (beta-hexylate of sodium—the body produced by treating *β* hexylic alcohol with sodium), which double compound is decomposed by water, giving *β* hexylic alcohol.

Hexyl-alcohols.—*α* Hexyl-alcohol (caproic alcohol), *α* C⁶H¹⁴O, was found by Faget, in fusel-oil (1854), but not purified by him. Cahours and Pelouze obtained it from hydride of hexyl, by converting that compound into *α* iodide of hexyl, thence forming *α* acetate of hexyl; thence, by means of caustic potash, the alcohol. The *α* hexyl-alcohol thus prepared boils at about 150°, and smells like amylic alcohol. (Compt. rend. liv. 1245.)

α hexylic alcohol yields caproic acid by oxidation. (Faget.)

β Hexyl-alcohol, *β* C⁶H¹⁴O.—Prepared by digesting *β* iodide of hexyl with oxide of silver and water: the *β* alcohol is then formed, together with *β* hexylic ether, and *β* hexylene. Or better, by shaking up *β* hexylene with sulphuric acid (previously diluted with one-third its volume of water), by which means *β* hexyl-sulphuric acid is produced, and this, distilled with a large excess of water, yields *β* hexyl-alcohol. It is a viscid liquid, having a refreshing, pleasant smell, very unlike that of amylic alcohol; boils at 137°, under bar. pressure of 755.5 millimetres. Specific gravity at 0° = 0.8327; at 16° = 0.8209; at 99° = 0.7482. It therefore expands somewhat rapidly.

Concentrated sulphuric acid converts it into para-hexylene, even at 0°, and does not form any hexyl-sulphuric acid, even after standing for some time. More dilute acid (strength about 87 per cent. SO⁴H²) forms *β* hexyl-sulphuric acid, which is capable of forming salts. Acid chromate of potassium and dilute sulphuric acid convert it into an aldehyde, which has no tendency to take up oxygen from the air, and when further oxidised with the same oxidising agent, yields, not caproic acid, but carbonic acid, water, butyric and acetic acids. The *β* variety of the alcohol has not been converted into the *α* variety; on the contrary, there is every reason to believe that the two bodies are radically different. (Wanklyn and Erlenmeyer, Chem. Soc. J. xvi. 221.)

Hexyl-aldehydes.—*a Hexyl-aldehyde*, $C^6H^{12}O$.—Unknown: it might perhaps be obtained by oxidation from the α alcohol of fusel-oil, or of that derived from the hexyl-hydride found in petroleum.

β Hexyl-aldehyde, $\beta C^6H^{12}O$.—Obtained by oxidising the corresponding alcohol with acid chromate of potassium and dilute sulphuric acid. It is a colourless limpid liquid of fragrant, penetrating odour; boils at 127° (bar. = 761.2 millimetres). Specific gravity at $0^\circ = 0.8298$, at $50^\circ = 0.7846$; coefficient of expansion between 0° and $50^\circ = 0.0576$. It forms a solid compound with acid sulphite of sodium; does not reduce ammonio-nitrate of silver; does not take up oxygen from the air. 100 parts of water dissolve about one part of β hexyl-aldehyde. When treated with *acid chromate of potassium* and dilute sulphuric acid, it yields no caproic acid, but butyric, acetic, and carbonic acids, and water (Wanklyn and Erlenmeyer, Chem. Soc. J. xvi. 307). A consideration of these reactions of β hexylic aldehyde leads to the conclusion that it is an acetone; for whilst the aldehydes take up oxygen from the air and yield by oxidation the corresponding acid, the acetones do not take up oxygen from the air, and yield lower acids (when oxidation is brought about).

This view of the case becomes increasingly probable when the history of acetic acetone, lately brought to light by Lieben, is considered. Acetone is reduced by hydrogen to tritylic alcohol; but the tritylic alcohol thus formed yields by oxidation, not propionic aldehyde, but common acetone.

β Hexyl-aldehyde will probably turn out to be either methyl-valeryl, $\left. \begin{matrix} CH^3 \\ C^6H^{10}O \end{matrix} \right\}$, or ethyl-butyryl, $\left. \begin{matrix} C^2H^5 \\ C^6H^{10}O \end{matrix} \right\}$.

Chlorides of Hexyl.—*a Hexyl-chloride*, $a C^6H^{11}Cl$, is obtained by Pelouze and Cahours, by the action of chlorine upon the hydride of hexyl existing in American petroleum. In addition to the α chloride of hexyl, further substitution-products are obtained. α Chloride of hexyl decomposes an alcoholic solution of *monosulphide of potassium*, giving a sulphide of hexyl, $\alpha (C^6H^{11})_2S$, boiling at 230° . With *sulphydrate of potassium*, it gives hexyl-mercaptan: boiling point 145° to 148° . With *cyanide of potassium*, it seems to give a cyanide of hexyl. (Compt. rend. x. 1241, *et seq.*)

β Hexyl-chloride is obtained by saturating the corresponding alcohol with dry hydrochloric acid, and heating in the water-bath under pressure. It is an oily liquid, lighter than water, boiling at about 120° , and yielding hexylene when digested at 100° with alcoholic solution of potash.

Hydrides of Hexyl.—*a Hexyl-hydride*, $a C^6H^{14}$, was found by Greville Williams in the products of the distillation of Boghead coal, and called by him (originally) propyl (with which it is isomeric); in 1862 he came to the conclusion that his propyl was hexyl-hydride (Chem. Soc. J. xv. 130). Pelouze and Cahours found the same substance in American petroleum (Compt. rend. liv. 1241), and obtained a chlorine substitution-product from it, which reacted as chloride of hexyl should do. From the chloride was indirectly obtained an alcohol (p. 162) boiling at about 150° , and like amyl-alcohol in odour. Schorlemmer obtained the hydride also from the products of distillation of Cannel coal. Its boiling point is 68° . Density of the liquid = 0.6745 at 18° (Williams); 0.669 at 16° (Pelouze and Cahours); 0.673 at 15.5° (Schorlemmer). The vapour-density corresponds closely with the formula C^6H^{14} . It is a colourless mobile liquid, having a fragrant odour. Chemically, like all bodies of its class, it is very inactive. Neither sulphuric acid nor nitric acid attacks it; chlorine and bromine only with difficulty. In the arts, a mixture of a hydride of hexyl with other hydrides goes by the name of *turpentine substitute*.

β Hexyl-hydride, βC^6H^{14} , is obtained indirectly from mannite. It may be prepared by digesting zinc with β iodide of hexyl and water or alcohol; or by exposing mercury and the iodide to the action of sunlight. In the latter case the reaction is:

In the former case hexylene also accompanies the hydride. In order to remove the hexylene, it is well to shake up with sulphuric acid, which enters into combination with the hexylene.

In smell, boiling point, and outward appearance, the β hydride resembles the α hydride very closely. In specific gravity, however, it appears to differ from the α compound, being lighter. At 15.5° its specific gravity does not exceed 0.6645. Its derivatives are probably quite distinct from those of the α hydride.

Iodides of Hexyl.—*a Hexyl-iodide*, $a C^6H^{11}I$, is obtained by Pelouze and Cahours from hydride of hexyl existing in American petroleum. It boils at 172° to 175° (being of higher boiling point than the β iodide), and smells like iodide of amyl. It is acted upon by light. It reacts with a variety of salts, forming ethers. The

alcohol which is indirectly obtained from it boils at 160° , and is believed by Pelouze and Cahours to be identical with Faget's alcohol extracted from fusel-oil (Compt. rend. liv. 1241, *et. seq.*) Wurtz has also obtained a hexyl-iodide by acting with hydriodic acid upon a variety of hexylene which seems to be distinct from the β hexylene of mannite.

β Hexyl-iodide is prepared by boiling mannite with a great excess of the strongest aqueous solution of hydriodic acid in a stream of carbonic anhydride (24 grms. mannite to 300 cub. cent. of acid, boiling at 126°C.); phosphorus may be added to the boiling liquid with great advantage. The iodide of hexyl appears in the form of an oily distillate, which should be freed from iodine and purified by distilling it in contact with water. When the operation is properly performed, very nearly the theoretical quantity of perfectly pure iodide of hexyl is obtained. The change which takes place is represented by:

Melampyrin (ii. 349) may be substituted for mannite in the above process; but the yield is not so good. The β iodide may also be prepared by digesting β hexylene with hydriodic acid.

β Iodide of hexyl is a colourless liquid, not to be distinguished by the smell from iodide of amyl. Specific gravity at $0^{\circ} = 1.4447$; at $50^{\circ} = 1.3812$; its co-efficient of expansion between 0° and 50° is 0.0460. The boiling point at 752 millimetres = 167.5°C. It is only very slightly decomposed by distillation, and is, on the whole, a very stable compound.

The almost invariable product of the reaction of this iodide is hexylene. With alcoholic solution of potash, it has given very nearly the theoretical quantity of hexylene:

With oxide of silver and water, acetate of lead, mercury, sodium, oxalate of silver, zinc and water, or zinc and alcohol, and finally, when heated to 190° with water alone, it invariably yields considerable quantities of hexylene, other products being formed at the same time, according to the reagent employed.

Bromine acts with great violence, replacing the equivalent of iodine in β iodide of hexyl.

β Hexyl-oxide, $\beta \left. \begin{array}{c} \text{C}^6\text{H}^{11} \\ \text{C}^6\text{H}^{12} \end{array} \right\} \text{O}$ is formed, together with the olefine and alcohol, when moist oxide of silver acts upon the corresponding iodide:

It is a thick, slightly yellow liquid, not miscible with water, and of a faint penetrating smell. Boils constantly between 203.5° and 208.5° , with the barometer at 751 millimetres.

Hexyl-sulphuric acids. — α Hexyl-sulphuric acid, $\alpha \left. \begin{array}{c} \text{C}^6\text{H}^{11} \\ \text{H} \end{array} \right\} \text{SO}^2$, is little known.

β Hexyl-sulphuric acid is obtained by the action of sulphuric acid (diluted with about one-third of its volume of water) either on β hexylene, or on β hexyl-alcohol. It is partially decomposed by dilution with water, and gives off β hexyl-alcohol. Salts of this acid have been obtained.

β Sulphhydrate of Hexyl, or β Hexyl-mercaptan, is obtained by digesting the β iodide with a concentrated alcoholic solution of sulphhydrate of potassium:

On adding water to the product of the reaction, the mercaptan separates as a clear, colourless, mobile liquid, not miscible with water and lighter than water. β Hexyl-mercaptan is formed in the theoretical quantity in this operation. As was mentioned above, an alcoholic solution of hydrate of potassium transforms β iodide of hexyl almost completely into hexylene and water; sulphhydrate of potassium, on the other hand, transforms the iodide into β sulphhydrate of hexyl. When an alcoholic solution of sulphide of potassium is used, there is also no formation of hexylene, but of a β sulphide instead, so that the sulphur-compounds of the β series are much more stable than the corresponding oxygen-compounds.

It is further noteworthy that β hexyl-mercaptan boils at 142° under a bar. pressure of 760 millimetres—being the point at which the α mercaptan ought to boil.

β Hexyl-mercaptan has the kind of smell characteristic of a mercaptan, only it seems not to be so persistent as the smell of common mercaptan. It acts upon oxide of mer-

carry with energy. Sodium attacks it, with evolution of a gas and formation of a white residue; no doubt the reaction is of the usual kind:

Very curiously, caustic potash, both solid and in aqueous solution, also attacks this mercaptan; and, still more curiously, a heat of 100° C. decomposes the compound formed with aqueous potash, occasioning separation of the mercaptan, which, however, recombines on cooling. J. A. W.

HEXYLENE. $\text{C}^{\text{H}^{18}}$.—Of this hydrocarbon there are also two modifications.

α **Hexylene.** It is doubtful whether Fremy's hydrocarbon, boiling at 55° and obtained by the distillation of hydroleic and metoleic acids, was hexylene. Greville Williams obtained hexylene from the products of the distillation of Boghead coal. It boiled at 71° (Phil. Trans. 1847). Wurtz seems to have obtained a variety of hexylene from fusel-oil.

β **Hexylene** is formed by the reaction of the corresponding iodide with most reagents. It is best prepared by the action of the iodide upon alcoholic solution of caustic potash, at 100°. In preparing it, the precaution should be taken to distil the alcoholic solution of hexylene from the iodide of potassium produced during the reaction, and to digest the distillate with fresh potash. The alcohol is subsequently removed by washing.

β Hexylene is a very mobile liquid, lighter than, and not miscible with, water. Boiling point 68° to 70°. Its odour is very unpleasant, just like that of amylene. Vapour-density, by experiment, 2·88 and 2·97 (theory requires 2·9022). It combines with bromine with great violence, forming $\text{C}^{\text{H}^{18}}\text{Br}_2$. With concentrated sulphuric acid it gives parahexylene. With sulphuric acid diluted with about one-third its volume of water, it gives *β* hexyl-sulphuric acid. *β* Hexylene seems to be a lighter liquid than *α* hexylene. J. A. W.

HIPPARAFFIN. $\text{C}^{\text{H}}\text{NO}$.—A product of the oxidation of hippuric acid, discovered by Schwarz (Ann. Ch. Pharm. lxxv. 201), further investigated by J. Maier, (*ibid.* cxxvii. 161), who has shown that hipparin is formed at the same time. To prepare it, hippuric acid is stirred up to a paste with dilute sulphuric acid, then mixed with peroxide of lead, and left to stand at a gentle heat for 12 to 24 hours. The mass is then washed with cold water; the residue exhausted with alcohol; the alcoholic solution evaporated; the residue washed with carbonate of soda to remove benzoic and undecomposed hippuric acid; and the residue boiled with water, which leaves hipparaffin undissolved and deposits hipparin on cooling. (Maier.)

Hipparaffin crystallises from hot alcohol in extremely soft slender needles, having a silky lustre and arranged in thick interlaced tufts. It has neither taste nor odour; dissolves sparingly in hot, and is quite insoluble in cold water, which does not even wet it; the solubility is not increased by addition of sulphuric acid, hydrochloric acid, ammonia or potash. It dissolves in strong sulphuric acid, and is precipitated by water without much alteration (Schwarz). Dissolves easily in strong sulphuric and nitric acid, and is not precipitated from either solution by water (Maier). It dissolves readily in boiling alcohol, and very readily in ether. It melts at 200° (Schwarz), 210° (Maier), solidifying in the crystalline form as it cools. At a higher temperature part of it distils without alteration, the residue turning black (Schwarz); a small quantity sublimates in slender needles even below 100°. (Maier.)

Hipparaffin burns with a bright smoky flame, leaving a small quantity of easily combustible charcoal. It is not decomposed by solution of iodine, or by hydrochloric acid and chlorate of potassium, or by aqueous chromic acid. It is but partially decomposed by fusion with hydrate of potassium; but on igniting it with potash-lime, benzene is produced, and the whole of the nitrogen is given off in the form of ammonia (Schwarz). Heated to 200°—220° in a stream of hydrochloric acid gas, it gives off a colourless oil, which solidifies in the crystalline form. Fuming nitric acid dissolves it, with evolution of gas, and the solution, concentrated after neutralisation with soda, yields a precipitate of benzoic acid. Heated with peroxide of lead and dilute sulphuric acid, it gives off all its carbon in the form of carbonic anhydride. (Schwarz.)

HIPPARIN. $\text{C}^{\text{H}}\text{NO}_2$. (J. Maier, *loc. cit.*)—The preparation is given in the preceding article. Hipparin crystallises in large silky needles united in barrel-shaped groups. Melts at 45·7°; solidifies at about 20°; burns with a bright flame; dissolves easily in alcohol, ether, and boiling water.

HIPPOPRAE RHAMNOIDES. The Sea Buckthorn.—This plant contains a yellow colouring matter which appears to be identical with quercitrin. It is obtained by exhausting the berries, after they have been well boiled in water and dried, with hot alcohol; mixing the hot filtered liquid with basic acetate of lead; decomposing

the precipitate with sulphydric acid; heating the whole; filtering when cold; and treating the precipitated sulphide of lead with hot alcohol: The colouring matter then dissolves, and remains on evaporation, as a brown-red brittle mass still retaining a little fat, from which it may be purified by treatment with ether, absolute alcohol, &c. It is then obtained as a yellow mass containing rudimentary crystals. The berries likewise contain oxalic and malic acids, a peculiar fat, &c., which are extracted by boiling them with water. (Bolley, Dingl. pol. J. cxlii. 143; Jahresber. 1861, p. 708.)

HIPPURAMIDE. $C^4H^5NO^2 = \left(\begin{array}{c} C^2H^3O \\ H^2 \end{array} \right) N^2$.—This amide is produced by the

prolonged action of ammonia on an alcoholic solution of hippurate of methyl, and remains when the solution is evaporated. It dissolves in 100 pts. water at ordinary temperatures, in 80 pts. wood-spirit, and 50 pts. alcohol; sparingly soluble in ether. By alkalis at the boiling heat it is resolved into ammonia and hippuric acid. (Jacquemin and Schlagdenhauffen, Compt. rend. xlv. 1011.)

HIPPURIC ACID. $C^4H^5NO^3 = \left(\begin{array}{c} H \\ C^2H^3O \\ (C^2H^3O) \\ H \end{array} \right) O \cdot N^*$. (Gm. xii. 69; Gerh. iii. 242).—

This acid exists in the urine of herbivorous animals, and in smaller quantity in that of man. Rouelle, towards the end of the last century, first observed that the urine of horses contained an acid bearing considerable resemblance to benzoic acid, and the observation was afterwards confirmed by Fourcroy and Vauquelin, who separated the acid by addition of hydrochloric acid; but its real nature and separate identity were first established by Liebig, in 1830 (Ann. Ch. Pharm. xii. 20). The urine of cows and horses does in fact contain, sometimes hippuric and sometimes benzoic acid, the former acid being easily converted into the latter by oxidation; and this change often taking place within the animal organism. When horses are kept in the stable, or only lightly worked, their urine contains hippuric acid; but when they are put to hard work, it contains benzoic acid.

Cows' urine, according to Boussingault, contains about 1·3 per cent. of hippuric acid; in that of horses, the maximum amount is about 0·38 per cent.; that of swine does not appear to contain hippuric acid; that of the camel and elephant yields a considerable quantity.

From the experiments of Henneberg, Stohmann, and Rautenberg (Ann. Ch. Pharm. cxiv. 181; Rép. Chim. pure 1863, p. 223; Jahresber. 1862, p. 541) it appears that the urine of oxen contains a maximum quantity of hippuric acid (2·1 to 2·7 per cent.) when the animals are fed on oat- and wheat-straw with a small admixture of beans. The straw and dried herb of leguminous plants reduced the amount to 0·4 per cent. With the hay of graminaceous plants intermediate results were obtained. The addition of a certain quantity of beans, starch, sugar, or oil, diminished the proportion of hippuric acid, and increased that of urea.

In human urine, the proportion of hippuric acid is but small under normal conditions, and about equal to that of uric acid (Liebig; Bence Jones); in certain diseases, as in diabetes, according to Lehmann, the amount is considerably greater; a vegetable diet likewise increases it. In the urine of a healthy man living on a mixed diet, Bence Jones (Chem. Soc. J. xv. 81) found, by Liebig's method of estimation (p. 168), from 0·03 to 0·04 per cent. hippuric acid; Thudichum (*loc. cit.* xvii. 55) found the same quantity under similar circumstances; but the amount was largely increased by eating greengages. Weismann (J. pr. Chem. lxxiv. 106; Jahresber. 1858, p. 672) and Wreden (J. pr. Chem. lxxvii. 146; Jahresber. 1859, p. 700) found much larger quantities; but the former appears to have operated on too small a quantity of urine, and the latter adopted a defective method of analysis (p. 159).

Formation.—1. By heating glycocine in a sealed tube with benzoic acid:

also by heating the zinc-salt of glycocine with chloride of benzoyl to 120° in a sealed tube, or by simply leaving the two compounds in contact for some time:

This formation of hippuric from benzoic acid likewise takes place when the latter acid is injected into the blood of a living animal, together with glycocine or glycocholate of sodium, or bile. When about 2 grms. of benzoic acid, and 30 c.c. of bile free from mucus were injected into the blood of a dog or cat, the urine was found to contain a considerable quantity of hippuric, but no benzoic acid; with a larger proportion of

* On the rational formula of hippuric acid, see FORMULÆ (H. 697).

benzoic acid, the excess passed into the urine together with the hippuric acid. Benzoic acid injected into the circulation alone, is not converted into hippuric acid. (Köhne and Hallwachs, *Jahresber.* 1859, p. 638.)

2. Benzoic acid is likewise converted into hippuric acid in the animal organism when introduced into the alimentary canal, hippuric acid being found in the urine after benzoic acid has been swallowed. Marchand, after taking 30 grains of benzoic acid, found 39.2 grs. of hippuric acid in his urine (by calculation, it should have been 44 grs.). Similar observations have been made by Al. Ure (*J. Pharm.* xxvii. 646), Keller (*Ann. Ch. Pharm.* xliii. 198), and Garrod (*Phil. Mag.* [3] xx. 501).

3. Quinic acid is also converted in the animal organism into hippuric acid (probably first into benzoic acid). When 8 grms. of quinate of calcium were swallowed over night, the morning urine was found to contain 2 grms. of hippuric acid. (Lautemann, *Ann. Ch. Pharm.* cxxv. 9.)

Preparation from horses' or cows' urine.—Hippuric acid exists in the urine in combination with ammonia. To obtain it, the fresh urine of cows or of horses which have been kept at rest, is concentrated by evaporation to $\frac{1}{4}$ or $\frac{1}{5}$ of its bulk and supersaturated with hydrochloric acid; it then, after a while, deposits a yellowish-brown precipitate of hippuric acid.

The evaporation of the urine, which is tedious, may be obviated by mixing it with a considerable excess of hydrochloric acid, the solubility of the hippuric acid being thereby greatly diminished. 100 pts. of cows' urine mixed with 2 or 3 pts. of crude hydrochloric acid soon deposits hippuric acid (Riley, *Chem. Soc. Qu. J.* v. 97). Another mode of expediting the process is to mix the fresh urine with milk of lime, boil for a few minutes and strain; then evaporate the solution of hippurate of calcium to $\frac{1}{4}$ or $\frac{1}{5}$ of its bulk, according to the previous concentration; and supersaturate with hydrochloric acid. (Gregory, *Ann. Ch. Pharm.* lviii. 125.)

The acid obtained as above has a brownish colour and disagreeable urinous odour, and requires further purification. This may be effected in several ways: 1. Schwarz (*Ann. Ch. Pharm.* liv. 29) boils the crude acid with milk of lime, which removes the greater part of the fibrin with which it is contaminated; precipitates the filtrate with carbonate of sodium, then boils and filters again, and mixes the filtrate with solution of chloride of calcium, the carbonate of calcium thereby precipitated carrying down the colouring matter; then filters a third time, and precipitates with hydrochloric acid. The hippuric acid thus purified is quite colourless.—2. The crude acid, mixed with 10 pts. of boiling water and excess of milk of lime, is submitted to pressure; the expressed liquid is mixed with solution of alum till it no longer exhibits an alkaline reaction, and left to cool to 40°; carbonate of sodium is then added as long as a precipitate continues to form; and the liquid is again separated by straining and pressure, and precipitated by hydrochloric acid: the hippuric acid thus obtained is washed with cold water, pressed and dissolved in boiling water, and the solution is mixed with blood-charcoal (1 oz. to a lb. of the acid), filtered through paper while still at the boiling heat, and left to crystallise (Bensch, *Ann. Ch. Pharm.* lviii. 267).—3. Löwe prepares hippuric acid by mixing fresh horse-urine with excess of sulphate of zinc; evaporating the liquid together with the precipitate to $\frac{1}{4}$ or $\frac{1}{5}$ of its bulk; filtering quickly; washing the precipitate with a small quantity of hot water; and decomposing the hippurate of zinc in the filtrate with dilute sulphuric or hydrochloric acid. Hippuric acid then separates in the form of a white magma, which may be washed with cold water, pressed between paper, and recrystallised from boiling water. The addition of sulphate of zinc to the urine preserves it from putrefaction, and enables the experimenter to wait till a considerable quantity is collected.

Properties.—Hippuric acid forms colourless transparent prisms, having an unctuous adamantine lustre, and often of considerable size. The crystals belong to the trimetric system. Ordinary combination, $\infty P : P \infty : P \infty$, with the modifying faces $\infty P \infty$ and $\infty P \infty$. Ratio of the axes, $a : b : c = 0.9742 : 1 : 1.606 : 1$. Inclination of the faces $\infty P : \infty P$ in the brachydiagonal principal section = 99° 59'; $P \infty : P \infty = 98^\circ 30'$; $P \infty : P \infty$ in the macrodiagonal principal section = 88° 30'. Cleavage tolerably easy, parallel to ∞P . Specific gravity = 1.308. Hippuric acid melts at a gentle heat, and solidifies in a crystalline mass on cooling. It has a slightly bitter taste, and reddens litmus strongly. It is sparingly soluble in cold water, 1 pt. of the crystals requiring 600 pts. of water at 0°. Boiling water and alcohol dissolve it readily; ether scarcely at all. Hippuric acid likewise dissolves, but very sparingly, in water containing hydrochloric acid. It dissolves with the greatest facility in water containing ordinary phosphate of sodium, in such quantity indeed as to change the reaction of the solution from alkaline to acid—a property which is also possessed by uric acid. This, according to Liebig, is the cause of the acid reaction exhibited by the urine of man and other animals in the recent state.

Decompositions.—1. Hippuric acid boils at 240°, yielding a crystalline product, con-

sisting in great part of benzoic acid and benzonitrile (cyanide of phenyl); a strong odour of hydrocyanic acid is likewise evolved, and a considerable quantity of charcoal remains in the retort. Dry hippuric acid, heated in a retort with dry chloride of zinc and quartz-sand, yields benzonitrile, carbonic anhydride, and charcoal (Gössmann, Ann. Ch. Pharm. c. 69):

2. Hippuric acid in alkaline solution is slowly oxidised by *ozone*, with formation of carbonic acid and a small quantity of formic acid (Gorup-Besanez, Ann. Ch. Pharm. cxxv. 217).—3. Pure hippuric acid is not altered by boiling with *water*; but when horse-urine is quickly evaporated, ammonia is given off, and the hippuric acid contained in it is converted into benzoic acid. Cows' urine does not yield benzoic acid when boiled.—4. Hippuric acid dissolves in strong *hydrochloric acid* at the boiling heat, and on continuing the ebullition, it is resolved into benzoic acid and glycocine:

The same decomposition is effected by boiling dilute *sulphuric acid*, by *nitric*, and even by *oxalic acid*.—5. Hippuric acid, boiled for half-an-hour with caustic *potash* or *soda*, is converted into glycocine and an alkaline benzoate. It is not decomposed by boiling with milk of lime.—6. The resolution of hippuric acid into benzoic acid and glycocine is likewise effected by the action of a *ferment* in presence of an alkali (Buchner, Ann. Ch. Pharm. lxxviii. 203).—7. By the action of *nascent hydrogen*, it appears to be resolved into hydride of benzoyl and glycocine (Erlenmeyer, Zeitschr. Ch. Pharm. 1861, p. 548).—8. *Nitrous acid* converts hippuric acid into benzoglycollic acid, with evolution of nitrogen gas:

This decomposition takes place when nitric oxide is passed into a solution of hippuric acid in nitric acid.—9. A cold mixture of strong *sulphuric acid* and fuming *nitric acid* converts hippuric acid into nitrohippuric acid. With *sulphuric anhydride*, it unites directly, forming sulphohippuric acid, $\text{C}^2\text{H}^2\text{NSO}^4$.—10. An aqueous solution of hippuric acid is not decomposed by *chlorine* gas; but on boiling it with a large excess of *bleaching powder*, decomposition takes place (Liebig). When chlorine is passed into a solution of hippuric acid in rather dilute potash, nitrogen is evolved, and benzoglycollic acid is produced (Gössmann):

11. By mixing it with *hydrochloric acid*, and adding *chlorate of potassium* by small portions, it is converted into a mixture of monochlorohippuric acid, $\text{C}^2\text{H}^2\text{ClNO}^3$, and dichlorohippuric acid, $\text{C}^2\text{H}^2\text{Cl}^2\text{NO}^3$ (R. Otto, Ann. Ch. Pharm. cxxii. 129).—12. When hippuric acid is gently heated with 1 at. *pentachloride of phosphorus*, oxychloride of phosphorus and hydrochloric acid are given off, and a brown residue is left, soluble in alcohol and in ammonia, and precipitated therefrom in the resinous state by hydrochloric acid; but on distilling 1 at. hippuric acid with 2 at. pentachloride of phosphorus, the products obtained are oxychloride of phosphorus, chloride of benzoyl, and two chlorinated compounds, $\text{C}^2\text{H}^2\text{ClNO}^3$, and $\text{C}^2\text{H}^2\text{Cl}^2\text{NO}^3$, differing from mono- and dichlorohippuric acids respectively by 1 at. H^2O (Schwanert, see p. 161).—13. When hippuric acid is boiled with *peroxide of manganese* and very dilute sulphuric acid, a large quantity of carbonic anhydride is evolved, benzoic acid separates on cooling, and the liquid is found to contain sulphate of ammonium.—14. Hippuric acid, boiled with *peroxide of lead* and water, yields benzamide, water, and carbonic anhydride (Fehling):

When hippuric acid is heated with peroxide of lead and excess of *nitric* or *sulphuric acid*, the products formed are carbonic anhydride and hipparaffin (p. 154); but when it is boiled with water and peroxide of lead, and sulphuric acid added in quantity only sufficient to decompose the resulting hippurate of lead, the only product obtained is benzamide (Schwartz).—15. Hippuric acid, gently heated with excess of caustic *potash*, yields a liquid which smells of benzene (no ammonia is evolved), is converted into crystalline scales by contact with hydrochloric acid, and, when distilled, yields pure benzene (Gerhardt). This liquid is perhaps benzonitrile.

Estimation of Hippuric acid in urine.—1. The urine is evaporated to a syrupy consistency over a water-bath; hydrochloric acid is added; and the hippuric acid is precipitated by adding the precipitate four or five times with ether (Liebig, Ann. Ch. Pharm. lxxviii. 203). According to Bence Jones (Chem. Soc. J. xv. 81), this method gives accurate results, provided sufficient urine is taken (about 400 c. c.), and a sufficient quantity of ether is used. Thudichum (Chem. Soc. J. xvii. 55) evaporates the urine to

a stiff syrup, pours it into a bottle while yet warm, taking up the last residues with the necessary amount of hydrochloric acid; and shakes up the whole briskly with large quantities of dry ether. The ethereal solution is then distilled, the reddish yellow residue mixed with a little water, and allowed to crystallise; and the crystals of hippuric acid thus obtained are washed with water till the washings are colourless then dried by pressure between blotting paper, afterwards by placing them over sulphuric acid, and finally at 100° in a water-oven. (See also Weismann, J. pr. Chem. lxxiv. 106; Jahresber. 1857, p. 637.)

2. Wreden (J. pr. Chem. lxxvii. 446; Jahresber. 1859, p. 700) estimates hippuric acid in urine by means of a standard solution of ferric chloride. The liquid is first neutralised and freed from phosphoric acid by means of baryta-water, and the iron solution is added till it no longer forms a precipitate, and a drop of the filtered solution produces a blue colour on a piece of filtering paper moistened with ferrocyanide of potassium. The amount of hippuric acid found in human urine by this method of estimation (average 0.38 per cent.) is much higher than that determined by Liebig's method (p. 166); and, according to Henneberg, Stohmann, and Rautenberg (Ann. Ch. Pharm. cxxiv. 181), the results are vitiated by the fact that a perfectly neutral solution of ferric chloride is decomposed by paper-fibre to such an extent, that paper soaked in a solution of yellow prussiate will not indicate the presence of a small quantity of iron; also, because the termination of the reaction cannot be distinctly perceived. Better results are obtained with ferric nitrate, after the urine has been freed from colouring matter and other bodies by nitrate of lead; but even in this case the process is sometimes rendered uncertain by the presence of other substances which exert a reducing action on the ferric oxide. Altogether, the mode of estimation by means of hydrochloric acid and ether appears to give the best results.

Hippurates. Hippuric acid is monobasic, the general formula of its salts being $C^6H^4MNO^3$. Most metallic oxides dissolve readily in the acid. The hippurates of potassium, sodium, ammonium and magnesium are very soluble and difficult to crystallise; their solutions form a cream-coloured precipitate with ferric salts, and white curdy precipitates with nitrate of silver and mercurous nitrate. A characteristic reaction of the hippurates is, that when fused with excess of potash or lime, they give off ammonia and yield benzene by distillation. Mineral acids decompose them, separating the hippuric acid.

Hippurate of Ammonium.—The neutral salt does not appear to exist. An acid salt, $C^6H^4(NH^1)NO^3.C^6H^4NO^3.H^2O$, is produced even when hippuric acid is mixed with excess of ammonia. It crystallises by concentration in square-based prisms with 4-sided summits. It dissolves in small quantities of water and alcohol, sparingly in ether, and performs gyrotatory movements when thrown on the surface of water.

Hippurate of Barium. $C^6H^4Ba^2N^2O^6 + H^2O$, forms prisms with rectangular base; soluble in water. It unites with benzoate of barium, forming a salt containing $C^6H^4Ba^2NO^3.C^6H^4Ba^2O^4 + 5H^2O$.

Hippurate of Calcium. $C^6H^4Ca^2N^2O^6 + 3H^2O$, crystallises sometimes in rectangular prisms, sometimes in laminæ. Specific gravity 1.318. It is soluble in 18 pts. of cold and 6 pts. of hot water.

Hippurate of Cobalt. $C^6H^4Co^2N^2O^6.5H^2O$, forms rose-coloured needles or nodules, which give off their water at 100° .

Hippurate of Copper. $C^6H^4Cu^2N^2O^6 + 3H^2O$, obtained by concentrating a mixture of sulphate of copper and hippurate of potassium, forms oblique rhomboidal prisms of an azure-blue colour, which turn green and give off their water of crystallisation when heated on the water-bath.

Hippurate of Iron (ferricum) is precipitated on mixing the concentrated solutions of hippurate of potassium and ferric chloride.

Hippurate of Lead. $C^6H^4Pb^2N^2O^6 + 2H^2O$ and $3H^2O$, is obtained by precipitating a cold solution of neutral acetate of lead with hippurate of potassium, as a curdy precipitate which dissolves but slowly in boiling water. If the boiling solution is well diluted, the salt is deposited in silky needles (containing 1 at. water) grouped in tufts; but these crystals, even when immersed in the solution, are quickly converted into rather broad, shining laminæ ($3H^2O$) having the form of quadrangular tables. The whole of the water is given off at 100° .

Hippurate of Magnesium. $C^6H^4Mg^2N^2O^6 + 5H^2O$, forms white nodules, which are soluble in water and give off $2H^2O$ at 100° .

Hippurate of Nickel. $C^6H^4Ni^2N^2O^6 + 5H^2O$, is crystallisable, insoluble in water, sparingly soluble in cold water, more soluble in boiling water and in alcohol. It becomes anhydrous at 100° .

Hippurate of Potassium.—The neutral salt, $C^6H^4KNO^3.H^2O$, forms prisms with rhomboidal base, soluble in water and in alcohol, and becoming anhydrous at 100° .

desiccation at 100° . To obtain it pure, it must be crystallised several times from alcohol and washed with ether.

The acid salt, $C^6H^4KNO^3 \cdot C^6H^4NO^3 \cdot H^2O$, forms brilliant laminae, which under the microscope are seen to consist of prisms with rectangular base, and the terminal edges truncated. They give off 4.77 per cent. water at 100° .

Hippurate of Silver, $2C^6H^4AgNO^3 \cdot H^2O$, prepared by adding nitrate of silver to hippurate of potassium, is soluble in water and crystallisable. It gives off its water (3.42 per cent.) at 100° .

Hippurate of Sodium, $2C^6H^4NaNO^3 \cdot H^2O$, is crystallisable, very soluble in hot water and in alcohol, sparingly in ether.

Hippurate of Strontium, $C^6H^4Sr^2N^2O^4 \cdot 5H^2O$, is crystallisable; sparingly soluble in cold water and alcohol; gives off its water at 100° .

Derivatives of Hippuric Acid.

Amido-hippuric acid. $C^6H^{10}N^2O^3 = C^6H^8(NH^2)NO^3$. (Schwanert, Ann. Ch. Pharm. cxii. 69.)—Obtained by passing sulphydric acid gas for a considerable time into a solution of nitrohippuric acid in saturated sulphide of ammonium, and acidulating the concentrated liquid with hydrochloric, or better with nitric acid. It crystallises in light white laminae, soluble in 300 to 370 pts. water at 20° , in 1200 pts. absolute alcohol at 15° , insoluble in ether. In boiling water and alcohol it dissolves easily; likewise in acids and in alkalis; the solutions quickly turn brown. With concentrated hydrochloric acid, it forms a *hydrochlorate* containing $C^6H^8N^2O^3 \cdot HCl$.

Chlorohippuric acids. (R. Otto, Ann. Ch. Pharm. cxvii. 129.)—These compounds are produced by the action of hypochlorous acid on hippuric acid. When 2 or 3 pts. chlorate of potassium are added to a mixture of 1 pt. hippuric acid and 6 to 9 pts. hydrochloric acid, a gentle heat applied, after the frothing has ceased, to complete the reaction, the liquid then heated to boiling and left to cool,—an oily yellowish mass is deposited, consisting of mono- and dichlorohippuric acids, their relative quantities depending, partly on the quantity of chlorate used, partly on the temperature of the liquid during the reaction. The two acids are separated, either by boiling with water, which dissolves chiefly the monochlorinated acid, or by repeated crystallisation of the calcium-salts obtained by neutralising the mixed acids with milk of lime.

Monochlorohippuric acid, $C^6H^5ClNO^3$, obtained by evaporating the alcoholic solution, after decolorisation with animal charcoal, forms a yellowish, viscid, inodorous mass, having an acid reaction; it is nearly insoluble in cold water, melts and dissolves in boiling water, and mixes in all proportions with alcohol and ether. It dissolves also in caustic alkalis, forming a solution which turns brown when heated.—By boiling with concentrated hydrochloric acid, it is resolved into glycocine and monochlorobenzoic acid.

The neutral potassium- and sodium-salts are uncrystallisable or crystallise with difficulty. The acid sodium-salt, $2(C^6H^5ClNaNO^3 \cdot C^6H^5ClNO^3) \cdot H^2O$, crystallises in concentrically grouped needles.—The calcium-salt, $C^6H^5Cl^2Ca^2N^2O^4 \cdot 4H^2O$, crystallises from alcohol in small shining scales.—The lead-salt, $C^6H^5Cl^2Pb^2N^2O^4$, melts at 100 – 120° , and crystallises from dilute alcohol in concentrically grouped needles.—The silver-salt is a white precipitate, which crystallises indistinctly from solution in water.

Dichlorohippuric acid, $C^6H^4Cl^2NO^3$, is very much like the monochlorinated acid, and after standing in contact with the air or under water, forms a soft granulo-crystalline mass, which deliquesces when warmed, and at 60° emits an aromatic turpentine-like odour.—By boiling with strong hydrochloric acid, it is resolved into glycocine and dichlorobenzoic acid.

Dichlorohippurate of sodium, $C^6H^4Cl^2NaNO^3 \cdot H^2O$, forms soft warty crystals, easily soluble in water, alcohol, and acids.—The barium-salt, $C^6H^4Cl^2Ba^2N^2O^4 \cdot 3H^2O$, crystallises in needles.—The calcium-salt, $C^6H^4Cl^2Ca^2N^2O^4$, crystallises from dilute solutions at ordinary temperatures, or at 60° , in needles containing 9 at. water; at higher temperatures, in hard white crusts with 5 at. water.—The neutral lead-salt, $C^6H^4Cl^2Pb^2N^2O^4 \cdot 4H^2O$, obtained by cold precipitation, separates from its aqueous solution in nodules. A basic lead-salt, $2C^6H^4Cl^2Pb^2N^2O^4 \cdot Pb^2O \cdot 6H^2O$, may be extracted by boiling absolute alcohol from the precipitate formed by dichlorohippuric acid and acetate of lead at the boiling heat. The silver-salt is a white precipitate, which separates from hot water in cauliflower-like masses.

Dichlorohippurate of Ethyl, $C^6H^4Cl^2(C^2H^5)NO^3$, obtained by treating the alcoholic solution of the acid with hydrochloric acid gas, is a heavy yellowish oil, nearly insoluble in water.

The calcium-salt having the composition, $C^6H^5Cl^2Ca^2N^2O^4 \cdot 5H^2O$, intermediate between mono- and dichlorohippurates, is obtained in spherical groups of needles by dissolving a mixture of the calcium-salts of the two acids. Its solution precipitated with silver yields a silver-salt of analogous composition.

Compounds produced by the action of Pentachloride of Phosphorus on Hippuric acid. (H. Schwanert, Ann. Ch. Pharm. cxii. 59.)—When 1 at. hippuric acid (in quantities not exceeding 10 grms.) is distilled with 2 at. pentachloride of phosphorus, scarcely anything but oxychloride of phosphorus passes over at first, but between 180° and 200° a viscid liquid distils over, and between 220° and 250° a mass which solidifies in the crystalline form. The liquid separated from the crystals gives off, on rectification, oxychloride of phosphorus up to 120°, then chloride of benzoyl, boiling at 196°, and an oil which boils at a temperature above 200°, and when left over oil of vitriol, solidifies to a crystalline mass whose composition is expressed by the formula, $C^8H^4ClNO^3 = C^8H^4ClNO^3$ (monochlorohippuric acid) — H^2O , which is also the composition of the crystals obtained by the first distillation.—This compound, when immersed in ether, deliquesces at a gentle heat to a yellowish oil, without perceptibly dissolving, and crystallises on cooling in flat four-sided monoclinic prisms bevelled at the ends with two faces. It melts between 40° and 50°, distils without alteration at 200°, is insoluble in water, but dissolves easily in alcohol, and crystallises therefrom with difficulty. The solution is not precipitated by chloride of platinum, mercuric chloride, or nitrate of silver. The compound is not decomposed by potash, either in aqueous or in alcoholic solution, but when repeatedly fused with hydrate of potassium, it is partially resolved into ammonia and benzoic acid; aqueous ammonia also decomposes it partially at 130°. It absorbs hydrochloric acid gas in quantity corresponding nearly with the formula, $C^8H^4ClNO^3.HCl$, but the hydrochlorate loses its acid, even when the alcoholic solution is evaporated over oil of vitriol.

Another chlorinated compound, $C^8H^4Cl^2NO^3 = C^8H^4Cl^2NO^3$ (dichlorohippuric acid) — H^2O , is obtained, though only in small quantity, by repeatedly rectifying the last portions of oil which pass over in distilling hippuric acid with pentachloride of phosphorus. It is likewise crystalline, but dissolves readily in ether.

Nitrohippuric acid. $C^8H^4N^2O^3 = C^8H^4(NO^2)NO^3$. (Bertagnini, Ann. Ch. Pharm. lxxviii. 100.)—This acid is produced by the action of a mixture of strong sulphuric and fuming nitric acid on hippuric acid. It is found in the urine after nitrobenzoic acid has been swallowed. To prepare it, 1 pt. of hippuric acid is dissolved, in the cold, in 4 pts. of the strongest nitric acid, and the solution is mixed, slowly, so as to avoid rise of temperature, with 4.9 pts. of strong sulphuric acid. The liquid is then left to itself for two hours, and diluted, still slowly, to avoid heating, with three times its volume of water; it then, after two hours, deposits an abundant crystallisation of nitrohippuric acid. The acid thus obtained has a yellow colour; for purification, it is treated with lime, the resulting calcium-salt is decomposed with hydrochloric acid, and the nitrohippuric acid is recrystallised several times.

Nitrohippuric acid crystallises in colourless silky needles, soluble in alcohol, ether, and water, especially in water containing phosphate of sodium. The crystals reddened litmus, melt at about 150°, and then decompose, giving off vapours of benzoic acid.

Hydrochloric acid converts nitrohippuric acid into glycocine and nitrobenzoic acid. A solution of nitrohippuric acid mixed with ammonia assumes a red colour under the influence of sulphydric acid, and deposits sulphur when neutralised by an acid. When dissolved in a saturated solution of sulphide of ammonium, and treated with sulphydric acid, it is converted into amido-hippuric acid, $C^8H^{10}N^2O^3$ (Schwanert, p. 160). Nitric oxide passed into a solution of nitrohippuric acid in nitric acid gives rise to the formation of a new acid, not yet examined. Nitrohippuric acid dissolves at ordinary temperatures in strong sulphuric acid, and on gently heating the solution and then diluting with water, nitrobenzoic acid is deposited. Nitrohippuric acid distilled with an equal weight of quick-lime yields a reddish, oily distillate having the odour of cinnamon. The acid heated with strong solution of potash, turns brown and gives off ammonia: at a higher temperature, the mixture gives off hydrogen and assumes a red colour.

The nitrohippurates are mostly soluble in water, some of them also in alcohol. Most of them crystallise in needles grouped round a common centre. When heated, they give off aromatic vapours. The following have been analysed:

Calcium-salt	$C^8H^{14}Ca(NO^2)N^2O^3.3H^2O$.
Cupric salt	$C^8H^{14}Cu(NO^2)N^2O^3.5H^2O$.
Lead-salt	$C^8H^{14}Pb(NO^2)N^2O^3$ (at 140°).
Silver-salt	$C^8H^7Ag(NO^2)NO^3$.
Zinc-salt	$C^8H^{14}Zn(NO^2)N^2O^3.6H^2O$.

Sulphohippuric acid. $C^8H^4NSO^3 = C^8H^4NO^3.SO^3$. (Schwanert, Ann. Ch. Pharm. cxii. 59.)—Produced by direct combination. Hippuric acid absorbs the sulphuric anhydride, forming a brown liquid; and by dissolving this product in water, and neutralising with carbonate of lead, decomposing the filtrate with sulphydric acid, it

evaporating, sulphohippuric acid is obtained as a brownish yellow, amorphous, deliquescent mass.

With *nitrous acid* it forms (not sulphobenzoglycollic, but) sulphobenzoic acid, $C^6H^5SO^2$, together with an oily substance probably containing glycollic acid.

Sulphohippuric acid is dibasic. Its neutral *barium-salt* contains $C^6H^5Ba^2NSO^4 \cdot H^2O$. By boiling the acid with hydrate of lead, a *lead-salt* is obtained corresponding approximately with the formula $C^6H^5Pb^2NSO^4$.

HIPPURIC ETHERS. Only two of these compounds have as yet been obtained, viz. the ethylic and methylic ethers.

Hippurate of Ethyl. $C^{10}H^{12}NO^3 = C^6H^5(C^2H^5)NO^3$. (Stenhouse, Ann. Ch. Pharm. xxxi. 148.)—Prepared by passing hydrochloric acid gas through a boiling solution of hippuric acid in alcohol of 80 per cent. The liquid thickens, assumes an oily aspect, and when diluted with water, deposits the ether in liquid drops, which soon solidify.

Hippurate of ethyl is crystallisable and has a sharp taste. Specific gravity 1.043. Melts at 44° and solidifies at 32° C. Sparingly soluble in water, very soluble in alcohol. Chlorine, with the aid of heat, converts it into a crystallisable chlorinated compound. Nitric and sulphuric acids decompose it at the boiling heat, producing enzoic acid. Alcoholic potash converts it into ethylic alcohol and hippurate of potassium.

Hippurate of Methyl. $C^{10}H^{12}NO^3 = C^6H^5(CH^3)NO^3$. (Jacquemin and chlagdenhauffen, Compt. rend. xlv. 1011.)—Prepared by passing hydrochloric acid gas into a solution of the acid in wood-spirit heated to 50° or 60° C., washing the resulting syrupy liquid with carbonate of sodium, and then treating it with ether, from which the compound crystallises by spontaneous evaporation.

Hippurate of methyl forms white, transparent needles, soluble in 120 pts. of cold water, and in 60 pts. water at 30° ; in boiling water it melts before dissolving. Alcohol and ether dissolve it in all proportions. It melts at 60° and decomposes at 250° , giving off ammonia and benzonitrile. With fuming nitric acid it gives off a combustible gas, probably containing nitrate of methyl. Alkalis decompose it, forming hippuric acid and methylic alcohols. Ammonia converts it into hippuramide.

HIRCIAC ACID. The name given by Chevreul (*Recherches sur les corps gras*, p. 151, 236) to an oily acid, slightly soluble in water, which he obtained from mutton-fat, and to which he attributes the peculiar taste and odour of that substance. The *potassium-salt* is very deliquescent; the *barium-salt* is sparingly soluble in water and contains 43.8 per cent. barium. The acid is probably nothing more than a mixture of several acids of the series $C^mH^nO^p$.

HISINGERITE. A hydrated silicate of iron occurring at Ridharhyttan in Sweden and other localities. A variety called *Gillingite* is found in the Gillinge mine at Ivärta-Kirchspiel in Sweden, and another called *Thraulite* at Bodenmais in Bavaria. These minerals all contain both protoxide and sesquioxide of iron, and are closely allied in composition; they are, however, but imperfectly crystallised, and have a dark colour, so that impurities in them easily escape detection. Moreover, it is possible that part of the protoxide of iron in the original mineral may be gradually converted into sesquioxide. Hence their constitution cannot be ascertained with certainty. The composition of hisingerite from Ridharhyttan (specific gravity 3.045) agrees however nearly with the formula $3(FeO \cdot SiO^2) \cdot 2(Fe^2O^3 \cdot 3SiO^2) + 6H^2O$. *Gillingite* is the same with 9 at. water; *Thraulite* is $3(FeO \cdot SiO^2) \cdot (Fe^2O^3 \cdot 3SiO^2) + 6H^2O$. A variety from Orjårfvi in Finland, much richer in protoxide of iron, may be represented by the formula $9(FeO \cdot SiO^2) \cdot (Fe^2O^3 \cdot 3SiO^2) + 9H^2O$. The following are analyses of these minerals:

	SiO ²	Fe ² O ³	FeO	CaO	MgO	H ² O
a.	33.07	34.78	17.59	2.56	0.46	11.64 = 100.0
b.	32.18	30.10	8.63	5.50	4.22	19.37 = 100.0
c.	31.28		49.12			19.12 = 99.52
d.	29.51	10.74	37.49		7.78	13.00 = 98.52

a, from Ridharhyttan by Rammelsberg (*Mineralchemie*, p. 852).—b, from the Gillinge mine by Rammelsberg (*ibid.*).—c, *Thraulite* from Bodenmais by v. Kobell (Pogg. Ann. xiv. 467).—d, from Orjårfvi by Hermann. (J. pr. Chem. xlii. 338.)

HISLOPITE. A grass-green limestone from Takli near Nagpur in Central India, of specific gravity 2.645, and containing 80.79 per cent. carbonate of calcium, 0.73 alumina, a trace of carbonate of magnesium, and 16.68 of an imbedded green silicate (p. 98-16), perhaps identical with glauconite. (S. Haughton, Phil. Mag. [4] xvii. 16.)

HITCHCOCKITE. A silicate of lead and aluminium from the Canton mine in Georgia. Specific gravity, 4.024. Contains 20.85 per cent. PbO , 27.40 PbO , 28.41

Al_2O_3 , 0.14 PbCl_2 , and 23.20 water (= 100.00), agreeing nearly with the formula, $3\text{PbO} \cdot \text{P}_2\text{O}_5 \cdot 2[(\text{Al}^{10})^{10}\text{P}_2\text{O}_5 \cdot 3(\text{Al}^{10})^{10}\text{H}_2\text{O}] + 18\text{H}_2\text{O}$. (Genth, *Sill. Am. J.* [2] xxiii. 424.)

HJELMITE. A mineral consisting chiefly of tantalate of yttrium and iron, found in the neighbourhood of Ytterby, together with garnet, gadolinite, &c. in a rock consisting of quartz, orthoclase, albite, and mica. It has a metallic lustre, granular fracture, pure black colour in the mass, blackish grey in powder. Hardness = 5. Specific gravity = 5.82. It exhibits no distinct indications of crystalline form or cleavage. Its analysis gave:

Ta_2O_5	SnO_2	CuO	CaO	YO	CeO	UO	FeO	MnO	MgO	H_2O
62.42	6.56	0.10	4.26	5.19	1.07	4.87	8.06	3.32	0.26	3.26 = 99.37

Before the blowpipe it decrepitates and flies to pieces, gives off water, and turns brown without melting, in the oxidising flame; by phosphorus-salt it is easily dissolved to a bluish-green glass; easily also by borax to a clear glass rendered opaque by flaming; by reduction on charcoal with carbonate of sodium, it yields metallic spangles. (Nordenskiöld, *Pogg. Ann.* cxi. 273; *Jahresber.* 1860, p. 780.)

HOERNESITE. A hydrated arsenate of magnesium from the Bannat, found imbedded in calcspar. It forms rhomboïdal laminae of 86° and 144° , bevelled on the sides, closely resembling the most common form of gypsum, and probably belonging to the monoclinic system, cleaving perfectly in the direction of the pinacoidal face, having a mother-of-pearl lustre on the cleavage-faces; white, transparent (translucent in the thicker parts), flexible in thin layers. Hardness = 0.5. Specific gravity = 2.474. Splinters of it melt even in the flame of a candle. An analysis by v. Hauser (*Rép. Chim.* pure, ii. 286) gave 24.54 per cent. MgO , 46.33 As_2O_5 , and 29.07 water (= 99.94), agreeing with the formula, $\text{Mg}^2\text{As}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$. (Haidinger, *Wien. Akad. Ber.* xi. 18.)

HOLCUS LAMATUS. For the composition of the ash of this grass, see GRASSES (ii. 943).

HOLMESITE. See CLINTONITE (i. 1026).

HOMEOMORPHISM. See ISOMORPHISM.

HOMICHLIN. A mineral closely related to barnhardtite (i. 508), and copper pyrites (ii. 77), from Plauen in the Saxon Voigtland (and other localities), where it forms, together with carbonate and silicate of copper, a vein of copper-ore imbedded in greenstone. It occurs sometimes in quadratic crystals, but more generally massive. Hardness between 4 and 5. Specific gravity = 4.472 to 4.480. Colour, brass-yellow, but with more of a bronze tint than copper-pyrites, and quickly acquiring a many-coloured tarnish. Streak black. According to an analysis by Richter, it contains 25.81 per cent. iron, 43.76 copper, and 30.21 sulphur, agreeing with the formula, $3\text{Cu}_2\text{S} \cdot \text{FeS}_2 \cdot 2\text{FeS}$. (Breithaupt, *Sill. Am. J.* [2] xxviii. 132; xxix. 373. *Ram-melsberg's Mineralchemie*, pp. 426, 987.)

HOMOCUMINIC ACID. $\text{C}^{11}\text{H}^{14}\text{O}_2 = \begin{matrix} \text{C}^{11}\text{H}^{13}\text{O} \\ \text{H} \end{matrix} \text{O}$. *Cyninic acid.* (Rossi, *Compt. rend.* lii. 403; *Ann. Ch. Pharm. Suppl.* i. 139.)—An acid homologous with cuminic acid, prepared by treating cyanide of cynyl, $\text{C}^{10}\text{H}^{12}\text{Cy}$ (obtained by the action of cyanide of potassium on the chloride, ii. 296), with potash-ley at the boiling heat:

It crystallises in small needles; melts at 52° ; distils without decomposition; dissolves sparingly in cold, easily in boiling water, also in alcohol and ether, reddens litmus and decomposes carbonates. The potassium-salt is deliquescent; the barium- and calcium-salts crystallise in needles; the magnesium-salt in nacreous scales; the silver-salt has the composition $\text{C}^{10}\text{H}^{12}\text{AgO}_2$.

The low melting point of this acid raises a doubt as to whether it is the true homologue of cuminic acid (which melts at 92°) or an isomer of that homologue related to it in the same manner as the acid $\text{C}^9\text{H}^{10}\text{O}_2$, obtained by Cannizzaro from cyanide of benzyl (probably α -toluyllic acid), is related to the true tolylic acid.

HOMOLACTIC ACID. This name was given by Cloez (*Compt. rend.* xxiv. 364) to an acid, isomeric if not identical, with glycollic acid, found in the mother-liquor which is obtained in the preparation of fulminating mercury. By neutralising this liquor with chalk, distilling off the volatile products (acetic ether, &c.), repeatedly crystallising the remaining solution by spontaneous evaporation, and decanting the liquid containing the more soluble salts, the calcium-salt of this acid was obtained in small light nodules resembling lactate of calcium.—The acid itself formed, when com-

* With tungstic anhydride.

centrated, a syrup which did not crystallise. The silver-salt crystallised in long thin laminae, sparingly soluble in cold water.

HOMOLOGOUS SUBSTANCES. This term is applied to organic compounds differing from one another in composition by CH^2 or any multiple thereof; for example, the *alcohols* $\text{C}^n\text{H}^{2n+2}\text{O}$, the *fatty acids* $\text{C}^n\text{H}^{2n}\text{O}_2$, and the *aromatic acids* $\text{C}^n\text{H}^{2n-2}\text{O}_2$. Bodies thus related exhibit, for the most part, a regular gradation of properties, both physical and chemical. Thus, in the series of fatty acids, formic acid, CH^1O_2 , and acetic acid, $\text{C}^2\text{H}^2\text{O}_2$, are watery liquids without any trace of viscosity; propionic acid, $\text{C}^3\text{H}^4\text{O}_2$, is slightly oily; butyric acid, $\text{C}^4\text{H}^6\text{O}_2$, valeric acid, $\text{C}^5\text{H}^8\text{O}_2$, and a considerable number of others exhibit more and more of an oily or fatty character as their atomic weights increase; while palmitic acid, $\text{C}^{16}\text{H}^{32}\text{O}_2$, and stearic acid, $\text{C}^{18}\text{H}^{36}\text{O}_2$, and a few others, are at ordinary temperatures solid fats, exhibiting higher melting points as they rise higher in the series; and lastly cerotic acid, $\text{C}^{27}\text{H}^{54}\text{O}_2$, and melissic acid, $\text{C}^{29}\text{H}^{58}\text{O}_2$, are of the consistence of wax. Similar relations are observed in the series of alcohols, corresponding with these acids. Moreover, the chemical energy of bodies thus related continually decreases as their molecules become heavier. Common alcohol is violently decomposed by potassium and sodium, with rapid evolution of hydrogen; but on the fatty alcohols, these metals act but very slowly. Similar differences of character are observed between the higher and lower terms of the fatty acid series. Formic and acetic acids are highly corrosive liquids, which unite energetically with bases, and decompose carbonates with the greatest ease; whereas the solid fatty acids, stearic, palmitic acid, &c., exert no action on the animal tissues, do not enter readily into direct combination with any bases excepting the strongest, and decompose carbonates but slowly.

Bodies belonging to the same homologous series exhibit, for the most part, regular gradations of boiling point and of atomic volume. With regard to the latter, Kopp has shown that compounds whose chemical formulæ differ by $n \text{ CH}^2$, differ in atomic volume by $n.22$ (i. 444). The relations of boiling point exhibited by homologous liquids are fully detailed in the article *HEAT* (p. 89).

Various attempts have been made of late years to build up the terms of homologous series, the higher from the lower. Frankland and Kolbe in 1847 (*Ann. Ch. Pharm.* lxxv. 288) showed that a cyanide of an alcohol-radicle of the series $\text{C}^n\text{H}^{2n+1}$, may be converted into the next higher acid by boiling with aqueous potash, the action consisting in the assumption of the elements of water, with elimination of ammonia, *e.g.*:

and generally

Another method of passing from an alcohol to the next higher acid was discovered in 1859 by Wanklyn (*Proc. Roy. Soc.* x. 21), who showed that sodium-ethyl (prepared from zinc-ethyl, which is itself obtained from iodide of ethyl, and this from ethylic alcohol) exposed to the action of carbonic anhydride, absorbs that gas, and is converted into propionate of sodium:

Neither of these reactions, however, affords the means of obtaining one alcohol of the series from the next below it, because no method has yet been discovered of converting a fatty acid into the corresponding alcohol.

The great problem of passing from one alcohol to that next above it has, however, been solved in a general way by Mendius (*Ann. Ch. Pharm.* cxxi. 129), whose method consists in exposing the cyanides of the alcohol-radicles to the action of nascent hydrogen, thereby converting them into the amines of alcohol-radicles higher than the radicles started from. In this manner, starting from hydrocyanic acid, he obtains methylamine, thus:

Methylamine treated with nitrous acid yields methylic alcohol (see *AMINES*, i. 174); this compound may be converted by well-known processes into cyanide of methyl; and this cyanide treated with nascent hydrogen yields ethylamine:

From this last compound, by similar processes, we may ascend to the tritylic or propylic stage, and thus, by a repetition of the same reactions, the series of alcohols

$C^H^{2n+2}O$ may be ascended, step by step. The general equation representing the passage from an alcoholic cyanide of this series to the next highest amine is:

This reaction will in all probability be found to succeed with cyanides derived from alcohols of the aromatic and other series, and thus a general method of producing an alcohol of any series from the one next below it may be obtained.

Carius (Ann. Ch. Pharm. cxxvi. 215), by heating ethyl-gas (C^H^{10}) to 100° with bromine, has obtained a liquid having the composition and boiling point of dibromide of tetrylene:

This compound, if really identical with dibromide of tetrylene, might be converted by known processes into hydrate of tetrylene; and this by the action of hydriodic acid into iodide of tetryl; whence, by distillation with potash, tetrylic alcohol might be obtained. This process appears then to give the means of mounting up the series by two steps at once. Lastly, Schorlemmer, by subjecting ethyl-amylic, $C^H^{10}.C^H^{11}$ (isomeric with hydride of heptyl, $C^H^{18}.H$), to the action of chloride of iodine, has obtained a chloride, $C^H^{18}.Cl$, which appears to be identical with chloride of heptyl obtained from the hydride of that radicle (p. 144). The problem of ascending from one alcohol to another in an homologous series appears therefore to be capable of solution in several different ways.

For speculations on the cause of homology, and the relations between homologous compounds of different series, see Carius (Ann. Ch. Pharm. cxxvi. 210).

HONEY. The honey of the common bee contains cane-sugar, inverted sugar (ii. 864), and an excess of dextroglucose. The proportion of cane-sugar varies with the age of the honey, as it is gradually converted into inverted sugar by the action of a ferment contained in the honey. According to Soubiran (Compt. rend. xxviii. 774), bees' honey contains, besides dextroglucose and a dextro-rotatory sugar capable of inversion (? cane-sugar), likewise an uncrystallisable sugar, possessing a lævo-rotatory power three times as great as that of inverted sugar. The honey of the *Polybia apicipennis*, a kind of wasp widely distributed in tropical America, yields cane-sugar in large crystals (H. Karsten, Pogg. Ann. c. 550). The honey of the Mexican honey-ant is, according to C. M. Wetherill (Chem. Gaz. 1853, 72), a nearly pure solution of uncrystallisable sugar, $C^H^{10}O$ (dried in vacuo); it has a slight acid reaction, and the volatile acid contained in it reduces oxide of silver like formic acid.

HONEY-STONE. See MELLITE.

HOP. (*Humulus Lupulus*).—The fruit of the hop is formed of small membranous cones, at the base of which is found a yellow bitter powder called lupulin (q. v.), containing, according to an analysis by Yves*, 36 per cent. resin, 12 wax, 11 of a peculiar bitter principle soluble in water and alcohol, 5 tannin, 10 extractive matter insoluble in alcohol, and 26 of residue insoluble in water. Yves found in hop-cones dried at $30^\circ C$, 10 per cent. of lupulin. According to Payen and Chevallier, the proportion of crude lupulin is 13 per cent., about 4 per cent. of which consists of minute particles of the cones themselves, resulting from the sifting.

Lupulin distilled with water yields valerianic acid and a volatile oil, containing a hydrocarbon, C^H^{10} , together with valerol, $C^H^{10}O$ (see HOPS, OIL OF). The resinous matter which remains after the distillation still retains a considerable portion of valerol, and, when distilled with slaked lime, yields valeraldehyde, $C^H^{10}O$.

Lupulin treated with alcohol yields, according to Payen, Chevallier, and Pelletan, about 66 per cent. of its weight. The dissolved portion consists almost wholly of resin, extractive matter, and tannin, the two latter soluble in water, whereas the resin, which forms about 52 per cent. of the lupulin, is insoluble. This resin, when purified by repeated solution in alcohol, precipitation by water, and drying, gives by analysis numbers which may be represented by the formula, $C^{14}H^{20}O^{11}$, together with a quantity of water varying between 1 and 6 H^2O , according as the resin has been more frequently dissolved in alcohol and reprecipitated by water.

The bitter principle isolated by Payen, Chevallier, and Pelletan, and called by them lupulite (or true lupulin), amounts to between 8.3 and 12.5 per cent. of the lupulin. It remains dissolved, together with malic acid, in the water in which lupulin has been digested. To isolate it, the free acid is saturated with chalk, the liquid evaporated to dryness, and the residue treated with ether, which dissolves a small quantity of resin. The lupulite is then separated from the malate of calcium by solution in alcohol, and evaporated to dryness. Lupulite thus prepared is white or yellowish, or sometimes reddish yellow, sometimes translucent, sometimes opaque. It has no odour, unless

* *Compte rendu du houblon*, par MM. Yves, Payen, Chevallier, Pelletan, Wagner, Vlaanderen: *Résumé* *présentant l'état de la question*, par E. Kopp. (Rép. Chim. app. 1866, p. 21.)

when strongly heated, in which case it exhales the odour of hops (perhaps in consequence of retaining a small portion of essential oil); it possesses the characteristic taste of hops. It has not been analysed. It is soluble in alcohol, but nearly insoluble in ether. By dry distillation it yields a considerable quantity of empyreumatic oil, but no ammoniacal products.

The tannin or astringent principle of the hop was for a long time regarded as identical with gallotannic acid, and as capable of conversion into gallic acid, and this change was supposed to account for the fact that old hops are not capable of clarifying beer. But, according to A. Wagner, gallic acid cannot be detected, even in very old hops quite unfit for making beer. He regards the tannic acid of hops as identical with morintannic acid, and finds that it amounts to between 3.2 and 5.7 per cent. of the hops.

According to Payen and Chevallier, the active principles of the hop do not reside exclusively in the lupulin, as was formerly supposed; they found, indeed, that hop-cones completely freed from lupulin, still yielded about 26 per cent. of substances soluble in alcohol.

To discover whether hops have been sulphured, Wagner treats them with granulated zinc, water, and pure hydrochloric acid. Any sulphurous acid that may be present is then reduced by the nascent hydrogen, and the liberated sulphur uniting with the hydrogen, forms sulphydric acid, which, if passed into a solution of nitroprussiate of sodium, generates a deep purple colour (ii. 257). This reaction will detect extremely small quantities of sulphurous acid; larger quantities may be detected by the odour, by the precipitation of iodine from a solution of iodate of potassium, and by various other reactions.

The ashes of hop-cones yield by analysis the following results:—

	Way and Ogston.*			H. Watts.†

The hops analysed by Watts were grown on a heavy clay soil near Hawkhurst in Kent. The crop was rather above the average, viz. 12 cwt. to the acre. By comparing this amount with the analysis of the ash, it is found that the hops grown on an acre of ground extracted from the soil 87 pounds of mineral constituents, including 12 to 13 oz. of phosphoric acid (P²O⁵), 17 lbs. potash (K²O), and 15 lbs. 10 oz. of silica. This is sufficient to account for the well-known exhaustive effect of this plant on the soil. (For the statistics of the growth of hops in this country, see *Ure's Dictionary of Arts, &c.*, ii. 460.)

HOPEITE. A cadmiferous zinc-ore from the calamine mines of Altenberg, near Aix-la-Chapelle. It has not been completely analysed, but appears to be a hydrated phosphate of zinc, containing a small quantity of cadmium. It forms transparent or translucent prisms, belonging to the trimetric system, having a greyish-white colour and vitreous lustre. It occurs also in reniform masses and amorphous. Specific gravity 2.76 to 2.86. Hardness 2.5 to 3. It is sectile. (Dana, ii. 419.)

HOPS, OIL OF. Hop-cones or lupulin distilled with water, yield an essential oil

* Journal of the Royal Agricultural Society, pt. i. (1849); Jahrbuch. 1849, p. 679.

† Phil. Mag. [3] xxxii. 54; Jahrbuch. 1847-8, p. 1077.

having the odour of thyme, and consisting, according to R. Wagner (Dingl. pol. J. cxviii. 217), of a hydrocarbon isomeric with oil of turpentine, and an oxygenated oil, apparently identical with valerol, $C^8H^{10}O$, and convertible by oxidation into valerianic acid, and perhaps also some of its higher homologues: hence the odour of old cheese, which hops acquire by keeping. The non-oxygenated oil is not altered by contact with the air, but the greater part of it is gradually dissipated by volatilisation.

According to Personne (J. Pharm. [3] xxvi. 2419; xxvii. 22), lupulin distilled with water, yields valerianic acid and an essential oil lighter than water, colourless and neutral after rectification, but becoming acid and resinous after some time. It begins to boil at $140^{\circ}C$, but the boiling point gradually rises to 300° . The portions distilling between 150° and 160° , and those which distil at about 300° , appear to have the same composition, viz. $C^8H^{10}O$. Both these portions of the distillate turn the plane of polarisation to the right; remain fluid at -17° ; dissolve without red colour in sulphuric acid; are converted by nitric acid into valerianic acid and a resinous substance; and when let fall by drops on melting caustic potash, yield a hydrocarbon, $C^{10}H^{14}$, and valerate of potassium. Hence, Personne regards the volatile oil of lupulin as analogous to essence of valerian, which, according to Gerhardt, consists of borneone, C^8H^{10} (l. 626), and valerol, $C^8H^{10}O$. The hydrocarbon from oil of hops is not, however, identical with borneone, inasmuch as it cannot be converted into borneol.

HORDEIN. Barley-starch obtained by kneading barley-meal in water, and leaving the liquid to settle, does not dissolve completely when warmed with acidulated water, but leaves a pulverulent substance, to which Proust gave the name *hordein*. It appears, however, to be, not a definite substance, but a mixture of starch, cellular tissue, and an azotised body.

HORDEUM VULGARE. *Barley.*—The composition of the grain of barley, as determined by various observers, has been already given in the article *CEREALS* (l. 825); also the composition of the ash of the grain, and of the straw and chaff, as determined by Way and Ogston, showing the limits between which the amounts of each constituent was found to vary. The following table (p. 168) contains a more detailed statement of the results of these ash-analyses.

HORN. See *HORN* TISSUE (p. 170).

HORNBLLENDE. *Amphibole.*—A mineral which plays an important part in the composition of rocks of the primitive and transition periods. Hornblende-rock and hornblende-slate consist almost entirely of it, and, in diorite (greenstone), syenite, hornblende-gneiss, &c., it enters as an essential constituent.

Hornblende forms prismatic crystals belonging to the monoclinic system. Ratio of axes, $a : b : c$, = $1.837 : 1 : 0.5401$. Inclination of the clinodiagonal (b) to the principal axis (c) = 75.10° . The angle $\infty P : \infty P = 55^{\circ} 30'$; $+P : +P$ in the clinodiagonal principal section = $148^{\circ} 30'$; $\infty P : \infty P = 76^{\circ} 59'$. Ordinary combination $\infty P. [\infty P\infty]. +P. \infty P$. (Fig. 556a.) Twins with face of composition parallel to $\infty P\infty$, as in the figure. Cleavage perfect, parallel to ∞P . It is also found imperfectly crystallised; fibrous or columnar, coarse or fine, with fibres often like flax; sometimes lamellar, also granular, coarse or fine, and usually strongly coherent; sometimes friable. Hardness 5 to 6. Specific gravity 2.9 to 3.4. Lustre vitreous to pearly on cleavage-faces; fibrous varieties often silky. Colour varying from black to white, through various shades of green, inclining to blackish-green; common hornblende, which contains much iron, is nearly black. Streak uncoloured or paler than the mineral. Sometimes nearly transparent, usually translucent to opaque. Fracture subconchoidal, uneven.

Fig. 556a.

The chemical composition of hornblende was formerly represented, in accordance with the results of older analyses, by the general formula $5M^2O.6SiO^2$ (or $4MO.3\frac{1}{2}SiO^2$); but Rammeisberg (*Mineralchemie*, pp. 426, 494,) has shown, by comparison of the more recent analyses by himself and others, that all hornblendes are metasilicates, of the general formula $M^2O.SiO^2$ or M^2SiO^2 . The metals included under the general symbol M are calcium, magnesium, iron and sodium, sometimes also manganese and potassium. These metals, replacing one another isomorphously, give rise to a great number of substances differing considerably in composition as well as in colour and other physical properties. A further variation is caused by the presence in many varieties of alumina, which enters, not in place of the protoxides M^2O , for the amount of the latter is not found to be in inverse proportion to that of the alumina, but in place of a certain portion of the silica, and in such proportion, according to Bonsdorff, that 1 at. SiO^2 may be regarded as isomorphously replaced by 1 at. Al^2O^3 ($2\frac{1}{2}SiO^2$ by $3Al^2O^3$), but according

The results of these analyses show that, in barley as in other cereals, the amount of ash is but little influenced by the nature of the soil, but is for the most part greatest in plants grown on clay soils. The amount of ash in the straw and chaff varies between wider limits than that of the grain; the latter varies as silica.

much in plants growing on the same as in those growing on different soils. The composition of the ash of barley-grain does not differ essentially from that of wheat (q. v.) in any respect excepting in containing a larger amount of silica.

to Rammelsberg, in the proportion of $2\text{Al}^2\text{O}^3$ for 3SiO^2 or Al^3 for Si^2 , the quantity of oxygen in the acid constituent of the mineral remaining unaltered.

Many varieties of hornblende likewise contain small quantities of fluorine, probably, according to Rammelsberg, in the form of a double fluoride of silicon and calcium, or magnesium. Titanium is also sometimes present in small quantity.

The pale varieties of hornblende containing no iron fuse readily before the blowpipe, with intumescence, forming a glass which is either transparent or exhibits various degrees of translucence down to milk-white opacity. With borax they form a colourless glass. The lighter coloured ferruginous varieties fuse alone, with more or less difficulty, to a dark yellowish glass, and give with borax a transparent glass tinged with iron. The darker green varieties afford a deeper iron colour. Hornblende containing alumina and a little iron, acts much like the non-ferruginous varieties; but the black varieties fuse to a brilliant black bead and give with borax a glass tinged with iron. *Anthophyllite* melts with difficulty to a glass coloured by iron.

The following are analyses and descriptions of the principal varieties of hornblende.

I. Hornblendes with little or no Alumina.

<i>Tremolite :</i>	SiO ²	MgO	CaO	FeO	MnO	Al ² O ³	Loss by ignition.

Ann. lviii. 168).—12. Hermann (J. pr. Chem. xlvii. 7).—A. Schlieper (Sil. Am. J. [2] ix. 410).

a. *Tremolite* or *Grammatite*, $\text{Ca}^{\text{Mg}} \left\{ \text{Si}^2\text{O}^2 = \text{Ca}^{\text{Mg}}\text{SiO}^2.3\text{Mg}^{\text{Si}}\text{SiO}^2 \right\}$, is white, or with a greyish, greenish, or yellowish tinge. Crystals often in long slender blades, either distinct and traversing the gangue, or aggregated in columnar and radiated masses. Specific gravity 2.93. Transparent or translucent. Found in the Tremola valley, Switzerland, and on the St. Gothard, in granular limestone or dolomite; in the Tyrol, the Bannat, at Gölösjo in Sweden, &c. *Calamite* is an asparagus-green variety of tremolite, found in prisms in serpentine, at Normarken in Sweden.

b. *Actinolite* (*Actinote*, *Strahlstein*).—This name includes hornblendes which are isomorphous mixtures of metasilicates containing chiefly magnesium, calcium, and iron, their general formula being $(\text{Mg}; \text{Ca}; \text{Fe})\text{SiO}^2$. Actinolite occurs in bright green, bladed crystals, or columnar forms; if in distinct rays, it is called *glassy actinolite*. The crystals are long slender prisms, breaking easily in the transverse direction. Specific gravity usually between 3.02 and 3.05. Actinolite occurs at Greiner in the Zillerthal; at Arendal in Norway; at Helsingfors, and several other places in Finland; at Taberg in Sweden, and in Pennsylvania. *Raphilite* is an asbestiform actinolite from Lanark in Canada.

Asbestos (i. 415), when of a white colour or some light shade, is usually a fibrous variety of tremolite or actinolite. The darker specimens are varieties of anthophyllite.

c. *Anthophyllite*.—This variety occurs in masses of a fine columnar structure, or made up of acicular fibres of brown or greyish brown colour, often with submetallic lustre. Specific gravity 2.9 to 3.16. The cleavage affords prisms of $124^\circ 30'$, like other varieties of hornblende. Anthophyllites are found at Kongsberg in Norway, Kupferberg in Bavaria, Perth in Upper Canada, and Cummington in Massachusetts.

The hornblendes included under this name vary considerably in composition; that from Kongsberg consists of $\text{Fe}^{\text{Mg}} \left\{ \text{Si}^2\text{O}^2 \right\}$, or $\text{Fe}^{\text{Mg}}\text{SiO}^2.3\text{Mg}^{\text{Si}}\text{SiO}^2$; that from Kupferberg contains twice as much magnesia, its formula being $\text{Fe}^{\text{Mg}}\text{SiO}^2.6\text{Mg}^{\text{Si}}\text{SiO}^2$. The minerals from Canada and Massachusetts are altered anthophyllites, the latter being approximately represented by the formula, $\text{Mg}^{\text{Fe}}\text{SiO}^2.3\text{Fe}^{\text{Si}}\text{SiO}^2$.

d. Cumingtonite is a rose-red granular hornblende from Cumington, Massachusetts, of specific gravity 3.42, and consisting of manganous silicate, Mn^2SiO_3 .

e. Arfvedsonite.—This is a black mineral found in Greenland, accompanying eudialyte. It was formerly regarded as a variety of hornblende, with which indeed it is isomorphous; but, according to Rammelsberg, it is a distinct species, whose formula is

$2(M^2O.SiO_3) + Fe^2O_3.3SiO_2$, or $(Fe^{2+})_{11}Si^{12}O_{43}$. Rammelsberg's analysis gives 51.22 per cent. SiO_2 , 23.76 Fe^2O_3 , 7.80 FeO , 1.12 MnO , 2.08 CaO , 0.90 MgO , 10.58 Na^2O , 0.68 K^2O , 0.16 water, and a trace of alumina.

II. Hornblendes containing Alumina.

1.—5. Rammelsberg (*Mineralchemie*, p. 490).—6. v. Waltershausen (*Vulkanische Gesteine*).

The minerals included under this head are mixtures of the isomorphous compounds, $M^2O.SiO_3$, $Fe^2O_3.3SiO_2$ and $3M^2O.2Al_2O_3$. (Rammelsberg.)

Common Hornblende.—This name is applied to the dark green and black aluminous varieties, whether in crystals or massive. Specific gravity 3.1 to 3.4. The name alludes to its toughness.—*Carinthin* is an aluminous and ferruginous hornblende from Carinthia. Specific gravity 3.127.

Uralite, from the Ural, has the cleavage structure and composition of hornblende, but the external form of augite, and is regarded as a pseudomorph. The two species are variously mingled in different specimens, showing the change in different stages of progress.

Diastatite is a hornblende from Wermland in Sweden, differing, according to Breithaupt, from common hornblende, by a degree in the angle of the prism. *Pargasite* includes crystallised varieties (crystals usually thick and stout); of high lustre, and rather dark shades of green. It is also granular.

Fine specimens of the dark-coloured hornblendes occur at Aussig and Treplitz in Bohemia; Tunaberg in Sweden, and Pargas in Finland. In Corsica there is found a variety of hornblende (*Verde di Corsica duro*) which admits of a high polish.

Altered forms of Hornblende.—Alterations of hornblende are mostly like those of augite. Varieties often occur, containing water of hydration, especially asbestiform or anthophyllite varieties. The ferruginous change by oxidation is common, and all varieties are exposed to alteration from infiltrating waters, holding carbonates, silicates, &c., in solution, thus giving rise to magnesian, ferruginous, magnesio-ferruginous (chlorite), alkaline, or aluminous forms. Talc, steatite, serpentine, chlorite, mica, pinitite, chabasite, limonite, magnetite, occur as hornblende pseudomorphs.

HORNBLende-ROCK is a rock consisting either wholly of hornblende or of that mineral mixed with quartz, and occasionally containing mica, iron pyrites, magnetic iron ore, and garnet. *Hornblende-slate* is a slaty variety of hornblende rock. These rocks belong to the oldest formations; they seldom form extended beds, occurring more generally in masses subordinate to granite, gneiss, &c.

HORN-LEAD. *Cerussine*. Native chlorocarbonate of lead, $PbCl^2.PbCO_3$, so called from its external resemblance to horn.

HORN-QUICKSILVER. Native sub-chloride of mercury. (See MERCURY.)

HORN-SILVER. Native chloride of silver. (See SILVER.)

HORNSTONE. A variety of quartz resembling flint, but more brittle, and with a more splintery fracture. It is often called *Chert*. It is often found as a petrification on wood, and is used for making mortars and various other articles.

HORNY TISSUE. *Epidermose*.—The epidermis of animals, hair, wool, silk, feathers, nails, claws, hoofs, horn, scales, &c., are composed, for the most part, of a substance containing less carbon, but more nitrogen and sulphur than the aluminoids. The epithelium which coats the internal cavities of the animal body, is also similarly constituted.

The substance, called horny tissue or epidermose, which forms the basis of all these structures, is obtained, though very far from pure, by exhausting the parts containing it with boiling alcohol and ether, after they have been comminuted as much as possible. This treatment removes the fatty matters, together with the greater part of

the salts and other foreign matters, but it does not ensure the perfect homogeneity of the undissolved residue. It is known, indeed, that the horny tissues are composed of a number of superposed layers, cell-walls and nuclei, which are perhaps not all of the same nature, but yet cannot be separated by the solvents above mentioned.

The substance thus obtained from the various horny tissues, has been analysed by Mulder, Scherer, Frémy and several other chemists, the results of whose analyses, though not agreeing very closely, still show that the substance forming the basis of these several tissues has, in all probability, the same chemical composition.

The proportion of ash is about 1 per cent.

Horny tissue melts when heated, and burns with a bright flame, exhaling a peculiar odour.

When exposed to the action of boiling water in a Papin's digester, it gradually dissolves, yielding an extract, which does not gelatinise on cooling. By simple maceration in water, cold or warm, the horny tissues are gradually loosened, and exhibit a cellular structure more or less distinct.

Caustic potash easily dissolves horny tissue, eliminating ammonia, especially with aid of heat, and forming a yellow solution, which, when treated with acids, gives off sulphuric acid and yields a white precipitate. When fused with *hydrate of potassium* it gives off hydrogen, and forms acetic, butyric, and valerianic acids, also leucine, tyrosine, &c. Strong solutions of caustic potash or soda are the best reagents for bringing out the cellular structure of the different horny tissues, epidermis, nails, horn, &c.

Strong *sulphuric acid* causes horny tissue to swell up, and partly dissolves it when heated. The solution diluted with water becomes turbid when neutralised with an alkali, or mixed with ferrocyanide of potassium. Prolonged ebullition with dilute sulphuric acid yields tyrosine, leucine, ammonia, &c.

Nitric acid, especially if hot, colours horny tissue yellow, and ultimately dissolves it; on addition of ammonia, the yellow solution acquires a darker colour, and finally assumes an orange tint. According to v. Laer, xanthoproteic acid is formed in the first instance, then saccharic, and finally oxalic acid.

Fuming *hydrochloric acid* produces with horny tissue the same blue or violet coloration as with albuminous substances, and gradually dissolves the tissue on boiling. According to v. Laer, hair immersed even in cold concentrated hydrochloric acid dissolves in the course of some weeks.

Acetic acid does not dissolve horny tissue, but only causes it to swell up.

When *chlorine* is passed into water containing in suspension horny tissue (prepared from hair), the tissue undergoes no change in external appearance, but after drying it is harsh to the touch, and dissolves completely in ammonia, with evolution of nitrogen.

HORSE-CHESTNUT. *Aesculus Hippocastanum*.—The bark of this tree contains two fluorescent substances, *aesculin* (i. 60) and *fraxin* or *pavuin* (ii. 708). Pelletier and Caventou found in it a greenish fat oil, a red-brown resin, a bitter yellow substance, a peculiar red substance, tannin, and woody fibre.

The fully developed leaves contain *quercitrin*, which is also found in the ripe

* (1.) Scherer, Ann. Ch. Pharm. xi. 55.—(2.) v. Laer, *ibid.* xiv. 156, 157.—(3.) Schlossberger (Gerhardt's *Travail*, iv. 157).—(4.) Mulder's *Chemische Unterzuch*, No. 2, p. 270.—(5.) Kemp, Ann. Ch. Pharm. xliii. 115.—(6.) Frémy, Ann. Ch. Phys. [3] xlviii. 47.

seeds, but not in the undeveloped leaves, or in the coatings of the buds, or in the bark of the stem and branches; the leaves which fall in autumn contain only traces of it. (Rochleder, Wien. Akad. Ber. xxxi. 565.)

The seeds contain, according to Tipp (Vierteljahrschr. pr. Pharm. iii. 19), starch (about 14 per cent.), mucilage, gum, a non-drying oil, saponin, a tannic acid which turns iron-salts green, phosphoric acid, and calcium-salts. Frémy found in the seeds, saponin, a yellow colouring matter [quercitrin] and a crystallisable bitter substance. Attempts have been made at various times to render the starch of horse-chestnut seeds fit for food by freeing it from the bitter substance by means of a weak alkaline ley. According to Flandin (Compt. rend. xxvii. 391) this is best effected by kneading the peeled and bruised seeds with water containing from $\frac{1}{100}$ to $\frac{1}{50}$ of their weight of carbonate of soda, and then washing them; perfectly white starch then separates, which may be used as an addition to wheat-flour. According to Belloc, the same result may be obtained by the use of pure water. But according to Flandin, the alkali is required to remove an acrid substance and an acid resin, as well as the bitter principle. (Compt. rend. xxviii. 83, 138.)

The cotyledons of horse-chestnut seeds have lately been examined by Rochleder (Wien. Akad. Ber. xiv.; Rép. Chim. pure, 1863, p. 219), who finds, in the alcoholic extract, a bitter substance, argyrescin, an amorphous yellow colouring matter, and a substance which he calls aphrodescin, formerly regarded by Frémy as saponin. These substances are extracted by successive treatment with alcohol, acetate of lead, water, and ether.

Argyrescin, $C^{24}H^{40}O^{24}$, is soluble in water and in alcohol, and is precipitated by ether from its solution in absolute alcohol. When the aqueous solution is evaporated, it remains in the form of a gummy mass. From its solution in weak alcohol, it separates on evaporation in microscopic crystals, having a silvery lustre. The crystals have the composition $2C^{24}H^{40}O^{24} \cdot H^2O$. It dissolves in strong sulphuric acid, forming a solution which turns red when mixed with water. It is fusible, and burns with a very smoky flame.

Argyrescin is resolved by acids into argyrescetin and glucose:

and by alkalis into æscinic acid, $C^8H^{10}O^8$, and propionic acid:

With alkalis, however, an intermediate product is sometimes obtained, namely, an acid whose barium-salt has the composition $C^{24}H^{40}Ba^2O^{24}$, thus:

This new acid likewise exists, ready-formed, in the cotyledons.

Aphrodescin, $C^{22}H^{30}O^{22}$, is soluble in water, and is precipitated from the hot solution by hydrochloric acid in bulky flocks. It is distinguished from saponin by its solubility in alcohol, and by its reaction with alkalis, which is similar to that of argyrescin, excepting that it yields butyric instead of propionic acid, thus:

Æscinic acid, $C^8H^{10}O^8$, is obtained by precipitation from its salts, as a gelatinous mass, becoming pulverulent when dry. When boiled with a quantity of alcohol not sufficient to dissolve it completely, it becomes partly crystalline, but does not alter in composition. By drying at 130° in a current of carbonic anhydride, it undergoes a decomposition, which Rochleder represents by the improbable equation $C^{12}H^{18}O^{12} = C^8H^{10}O^8$ (æscinic acid) + $C^4H^6O^4$.

Æscinate of potassium, $C^8H^{10}KO^8$, is crystallisable.—The potassium-salt has the composition $C^8H^{10}Ba^2O^{22}$.—The lead-salt contains a still larger proportion of base.

Argyrescin, aphrodescin, and æscinic acid heated with hydrochloric acid, are resolved into sugar and a new substance, telescin $C^{20}H^{30}O^{14}$, or a product containing $C^{20}H^{30}O^{14}$. When these decompositions take place in alcoholic solutions, the products formed are not constant, because the telescin may then be further resolved into manuitan (?) and a compound isomeric with quinovic acid.

Æscinic acid, or rather telescin, dissolved in alcohol, mixed with hydrochloric acid, and boiled till a red colour is produced, undergoes a final decomposition, yielding a solution from which water throws down flocks of æscigenin, $C^{20}H^{30}O^{14}$, isomeric with choloïdic and with quinovic acid. This substance is soluble in sulphuric acid, and on adding sugar to the solution, a red colour is produced similar to that exhibited by the biliary acids when similarly treated.

The action of hydrochloric acid on an alcoholic solution of telescin or æscinic acid sometimes also yields an intermediate product $C^{20}H^{30}O^{14}$, which is isomeric with

quinovin, and may be regarded as a compound of æscigenin with 2 at. propionic acid:

This view of its composition is supported by the formation of a compound, $C^{25}H^{40}O^7$ [$C^{25}H^{40}O^8$], containing the elements of æscigenin and acetic acid, by the action of chloride of acetyl on æscigenin.

Rochleder considers it probable that æscigenin or its compounds may exist in other plants, and that cyclamein and digitaliretin may belong to this group of compounds.

The ash of the different parts of the horse-chestnut tree has been analysed by E. Wolff (J. pr. Chem. xlv. 385; Jahresber. 1847-8, p. 1078), for the purpose of determining how the proportion of the different mineral constituents are modified in passing from one organ to another, and how these constituents are distributed throughout the several organs. To eliminate any local character from the results, the organs subjected to examination were selected from trees growing on two very different soils; one a stony porphyritic soil, the other a moist forest soil often overflowed, very rich in vegetable mould, and much more favourable to the growth of the trees than the former.

The mineral constituents were extracted by first charring the substance in a muffle heated not quite to redness, and exhausting the charcoal, first with water, then with dilute hydrochloric acid, drying the carbonaceous residue, and incinerating it completely in the muffle. The ash was then likewise exhausted with hydrochloric acid, and the united hydrochloric extracts, the aqueous extract, and the insoluble residue, were separately analysed. The results are given in the table on page 173.

The ash of the wood, bark and leaves of the horse-chestnut has also been analysed by E. Staffel (Ann. Ch. Pharm. lxxvi. 379; Jahresber. 1850, p. 661), chiefly with the view of determining whether the amount of the several inorganic constituents in the plant and its different organs varies with the season of the year. The method of analysis was similar to that adopted by Wolff, excepting that the charcoal was exhausted with water alone.

Ash of Horse-chestnut (Staffel).

HORSE-FLESH ORE. A term applied by the Cornish miners to certain varieties of purple copper.

HOUGHITE. A hydrated aluminate of magnesium, occurring, as the material of pseudomorphous spinel, near Oxbow, and in Rossie, near Somerville, St. Lawrence county, New York. The crystals are in all conditions, from the pure spinel to octahedrons with rounded edges and pitted or irregular surfaces; it also occurs in flattened nodules. It is perhaps identical with *Volknerite* (q. v.). (Dana, ii. 135.)

HOVITE. A mixture of collyrite (i. 1084) with a hydrated carbonate of aluminium and calcium, found in the Upper chalk, in the neighbourhood of Hove, near Brighton. It is very soft and friable, having an earthy fracture and low specific gravity. (J. H. and G. Gladstone, Phil. Mag. [4] xxiii. 461; Jahresber. 1862, p. 743.)

* With a trace of manganic oxide.

HOWARDITE A meteoric mineral, described by C. U. Shepard. (Sill. Am. J. [2] vi. 402.)

HUANOKINE $C^{10}H^{12}N^2O$.—An alkaloïd, isomeric, or perhaps identical, with cinchonine; obtained from *China de Huanoco plana*, a cinchonâ-bark found in the Huanoco forests, north of Lima (A. Erdmann, Ann. Ch. Pharm. c. 341). The bark is repeatedly exhausted with water containing hydrochloric acid, and the base, precipitated by caustic soda, is purified by repeated solution in acid, and reprecipitation, till it becomes white, and finally by crystallisation from alcohol.

Huanokine crystallises in small colourless prisms, very similar in form to cinchonine. According to H. Hahn (Jahresber. 1858, p. 372), they are monoclinic prisms, exhibiting the faces ∞P . $\infty P \infty$. ∞P . Angle ∞P : ∞P in the clinodiagonal principal section = 71° ; ∞P : $\infty P \infty$ = 110° . Cleavable parallel to ∞P ; less distinctly parallel to $\infty P \infty$. It is tasteless; but has a slight alkaline reaction, stronger in the alcoholic solution, which is also slightly bitter. It melts without decomposition, and solidifies in the crystalline form on cooling: at a stronger heat it sublimes. It is nearly insoluble in water, dissolves in 400 pts. alcohol of 80 per cent. at 17° ; and in 110 pts. at the boiling heat; in 600 pts. ether at 17° ; and in 470 pts. at the boiling heat. It is said to be a strong febrifuge.

The salts of huanokine are precipitated white by alkalis and alkaline carbonates, yellowish white by tincture of galls, white by mercuric chloride, yellow by chloride of gold.

The *sulphate* is nearly insoluble in water; but dissolves easily in excess of acid; the solution is not fluorescent.—The *hydrochlorate* is very soluble, and crystallises in large colourless prisms having an extremely bitter taste; not fluorescent. According to Hahn (*loc. cit.*) the crystals are rhombic prisms, with the faces $\infty P \infty$. $\bar{P} \infty$. \bar{P} . Angle ∞P : ∞P = 30° .—The *chloroplatinate* also forms rhombic crystals, ∞P . $\infty P \infty$. \bar{P} . Angle ∞P : ∞P = 75° ; angle between the macrodiagonal terminal edges and the principal axis = 132° .—The *tartrate* forms hemihedral rhombic crystals, ∞P . $\infty P \infty$. \bar{P} . Angle ∞P : ∞P = 138° ; $\frac{\bar{P}}{2}$: $\frac{\bar{P}}{2}$ = 70° .

(Hahn.)

According to De Vry (J. Pharm. [3] xxxii. 328), huanokine is identical with cinchonine, the differences observed by Erdmann between it and cinchonine having been probably due to admixture of quinine or cinchonidine. He found that hydriodate of cinchonine agreed perfectly, in external character and in its relations to polarised light, with the hydriodate obtained from huanokine prepared by Erdmann himself.

HUDSONITE. A black mineral from Cornwall, Orange County, New York, near the Hudson River. Specific gravity 3.43 to 3.5. It cleaves like Hedenbergite, and is regarded by Dana as a variety of augite, having a considerable portion of the silica replaced by alumina. The composition is, however, more like that of hornblende. Smith and Brush (Sill. Am. J. [2] xvi. 369) found in it:—

SiO ₂	Al ₂ O ₃	FeO	MnO	CaO	MgO	K ₂ O	Na ₂ O	Loss by ignition.
38.94	10.41	30.48	0.60	10.36	3.00	2.48	1.66	1.95 = 99.88

Kenngott found that a mineral from Monroe, designated as Hudsonite, was really a hornblende. (Rammelsberg's Mineralchemie, p. 996.)

HUMBOLDTILITE. Syn. with MELLILITE.

HUMBOLDTINE. Syn. with OXALITE.

HUMBOLDTITE. Syn. with DATHOLITE.

HUMIC ACID. See ULMIC ACID.

HUMITE. See CHONDRODITE (i. 930).

HUMOPIC ACID. $C^{10}H^{12}NO$ (?) (Wöhler, Ann. Ch. Pharm. l. 21).—An acid produced, with evolution of ammonia, by heating narcotine to about 220° .

It is purified by dissolving it in potash, precipitating with hydrochloric acid, re-dissolving in alcohol, and precipitating with water. It is an amorphous, dark-brown substance, insoluble in water and in dilute acids, but dissolves in alcohol with yellowish-red, and in alkalis with yellow colour, the latter solution forming brown gelatinous precipitates with barium- and lead-salts.

Wöhler's analysis of this acid gave 63.0 and 64.6 per cent. carbon, 5.3 and 5.0 hydrogen; whence he suggested the formulæ, $C^{10}H^{12}O^{11}$ and $C^{10}H^{10}O^{14}$. The formula above given (which requires 66.7 per cent. carbon and 5.3 hydrogen) is based upon the formula of narcotine recently established by Matthiessen and Foster (*Gmelin's Handbook*, v. 138). It is probable, however, that the acid has not been obtained pure,

and that the decomposition of narcotine by heat may be more complicated than that which is represented by the preceding equation.

HUMOURS OF THE EYE. See EYE (ii. 654).

HUMUS, or *Vegetable Mould*, is the product of the decay of vegetable matter. The fallen leaves, and all the parts of plants which are returned to the soil, either during the life of the plant or after its death, undergo peculiar alterations, the result of which is to transform them into a mass of compounds whose nature has not been exactly ascertained, but which are known to contain a large proportion of carbon. This decay is promoted by the action of air, by moisture, and by a certain degree of heat. It takes place most quickly in those constituents of the plant which are soluble in water, some of the insoluble matters, such as resins and fats, resisting decomposition for a long time, and remaining almost in their original state, so that they may be extracted from the humus by alcohol or ether. The decomposition is also greatly accelerated by the presence of putrifying nitrogenous matters; and this is doubtless one cause of the beneficial effect of animal manure.

Vegetable mould is in a continual state of slow combustion, whereby the organic compounds which it contains are gradually resolved into carbonic acid, water, and ammonia, which, as they are formed, are taken up by the roots and plants: hence the effect of vegetable mould in promoting the growth of plants, and partly also the advantage gained by frequently turning up and pulverising the soil, whereby the access of air and the decomposition of the organic matter are facilitated.

MUNTERITE. The name applied by S. Haughton (Phil. Mag. [4] xvii. 18; Jahresber. 1859, p. 289) to a hydrated silicate of aluminium, having a fatty lustre and the aspect of felspar, found in a coarsely crystalline granite in the neighbourhood of Nagpur in Central India. Specific gravity = 2.319. According to Haughton's analysis, it contains 65.93 per cent. SiO_2 , 20.97 Al_2O_3 , 0.30 CaO , 0.45 MgO and 11.61 water (= 99.26). This is very nearly the composition of cimolite (i. 984), with which also the mineral agrees nearly in lustre and specific gravity: hence Dana (Sill. Am. J. [2] xxviii. 133) regards it as identical with cimolite.

HUREAULITE. A phosphate of iron and manganese from Hureault, near Limoges, where it occurs in small veins in the granite. It forms translucent crystals belonging to the monoclinic system, having a yellowish- or reddish-brown colour and vitreous lustre. Specific gravity = 2.27. Somewhat softer than felspar; contains, according to the mean of Damour's analyses (Ann. Min. [5] v.), 38.00 per cent. P_2O_5 , 41.67 MnO , 7.86 FeO , 11.98 water, and 0.38 quartz &c.; whence the formula $\frac{2}{3}\text{MnO} \left\{ \begin{array}{l} \cdot 2\text{P}_2\text{O}_5 + 6\text{H}_2\text{O}; \text{ or it may be a double salt consisting of a pyro- and ortho-phosphate, of the form } \text{M}^2\text{P}_2\text{O}_5 \cdot 2\text{M}^2\text{PO}_4 \cdot 5\text{H}_2\text{O}. \end{array} \right.$ (Rammelsberg's Mineralchemie, p. 330.)

HURIN. An acid crystalline substance obtained from the juice of *Hura crepitans*. (Boussingault and Rivero, Ann. Ch. Phys. [2] xxviii. 430.)

HURONITE. A mineral from Lake Huron, containing 45.80 SiO_2 , 33.92 Al_2O_3 , 8.04 CaO , 4.32 FeO , 1.72 MgO and 4.16 water. It forms imperfectly laminated masses, having a light greenish yellow colour and waxy lustre, translucent on the edges. (Handw. d. Chem. iii. 942.)

EVERSALT. Native iron-alum from Iceland. (See SULPHATES.)

HYACINTH. See ZIRCON.

HYDRANCHIS GLOBOSA. (Lamb).—A euphorbiaceous plant, the pericarp of which contains a very acid poisonous substance, resembling strychnine and the allied poisons in its action. The poisonous substance is uncrystallisable, easily soluble in water and in alcohol; it has neither basic nor acid properties, but cannot be classed among the resins, on account of its solubility in water. The husk of the fruit contains 9.40 per cent. water, 5.36 gypsum, lime, potash, and chlorine; 2.52 wax and chlorophyll; 9.64 tannic acid; 6.64 resin; 15.15 starch, gum, and sugar; 3.99 varnish-like substance, soluble in water and in alcohol; 36.00 cellulose; and lastly, oxalic acid, and substances which can be extracted by strong hydrochloric acid and potash-ley. The seeds give up to ether, 41.06 per cent. of a green-yellow fat oil, then to alcohol 24.13 per cent. of a nearly black, brittle resin, resembling kino; they contain 10.7 per cent. of inorganic matters. (J. B. Henkel, Arch. Pharm. [2] xciv. 16; Jahresber. 1858, p. 532.)

HYALITE. See OPAL.

HYALOMELANE. Syn. with TRACHYLITE.

HYALOPHANE. A barytic felspar resembling adularia, discovered by Sartorius v. Waltershausen (Pogg. Ann. xciv. 134; c. 547) in the dolomite of the Binnenthal in the Valais. It is transparent and colourless when pure, but often milk-white from admixture of sulphate of barium. Hardness between 6 and 7. Specific

gravity = 2.77 to 2.83. It forms monoclinic crystals resembling those of adularia, $\infty P : \infty P = P_{\infty}$, often with (∞P_{∞}). Angle $\infty P : (\infty P_{\infty}) = 120^{\circ} 36'$; $\infty P : \infty P = 112^{\circ} 0'$; $\infty P : P_{\infty} = 130^{\circ} 36'$. Cleavage perfect parallel to P_{∞} (Waltershausen). The analysis of a perfect limpid specimen by Stockar-Escher (*Kennigolt's Uebersicht*, 1856-57, p. 107) gave:

SiO_2	Al_2O_3	BaO	CaO	MgO	K ₂ O	Na ₂ O	H ₂ O
62.67	21.12	16.05	0.46	0.04	7.82	2.14	0.58 = 99.88;

whence the formula $\frac{1}{2}BaO \left\{ \begin{matrix} SiO_2 + Al_2O_3.3SiO_2 = \frac{BaK}{Al'''} \left\{ Si_2O_6 = \left(\frac{BaK}{Al'''} \right) \right\} O_8; \end{matrix} \right.$

which is similar to that of andesin (see FELSPAR, ii. 618). (*Rammelsberg's Mineralchemie*, p. 609.)

HYALOSIDERITE. A variety of chrysolite from the Kaiserstuhl mountain in the Breisgau, where it occurs in yellowish and brownish-red crystals. It contains 31.63 SiO_2 , 32.40 MgO , 28.49 FeO , 0.48 Fe_2O_3 , 2.21 Al_2O_3 , 2.79 K_2O , and a trace of chromium. To bring it under the formula of chrysolite, $2M^2O.SiO_2$ or M^4SiO_4 , it is necessary to suppose that part of the silica is isomorphously replaced by alumina.

HYBLITE. See PALAGONITE.

HYDANTOIC ACID. $C^4H^4N^2O^4$ (?)—An acid produced by the action of potash on allantoin. On supersaturating the solution with acetic acid, precipitating with acetate of lead, decomposing the lead-salt with sulphuretted hydrogen, and evaporating the filtered liquid, the acid is obtained as an uncrystallisable syrup, deliquescent and insoluble in alcohol. It probably contains the elements of allantoin plus 1 at. water ($C^4H^4N^2O^5.H^2O$). (Schlieper.)

The name hydantonic acid is also applied by Baeyer to an acid formed from hydantoin by addition of the elements of water: no description of it has yet been given.

HYDANTOIN. $C^4H^4N^2O^2$. (A. Baeyer. *Ann. Ch. Pharm.* cxvii. 179.)—A compound belonging to the parabanic acid group, produced from allantoin by the reducing action of hydriodic acid:

Also, together with a small quantity of allanturic acid, by the action of hydriodic acid on alloxanic acid:

It crystallises with great facility in colourless crystals easily soluble in water; tastes slightly sweet, and grates a little between the teeth. It is converted by oxidation into allanturic acid:

With water it forms Baeyer's hydantonic acid.

HYDRACIDS. A term formerly applied to hydrochloric, hydrobromic, hydriodic, hydrofluoric, and hydrocyanic acids, to distinguish them from acids containing oxygen. The distinction is, however, no longer maintained, all acids being now regarded as salts of hydrogen. (See ACIDS.)

HYDRACRYLIC ACID. $C^4H^4O^4$.—An acid produced by the decomposition of iodopropionic acid, when a solution of a salt of that acid is heated to boiling:

It is most easily prepared by digesting iodopropionic acid with excess of silver-oxide, decomposing the resulting silver-salt with sulphydric acid, and evaporating the filtrate. Hydracrylic acid then remains in the form of a syrup, mixed with slender needles. It is tribasic; nearly all its salts are easily soluble in water, and many of them are decomposed by heat, with formation of acrylic acid:

The cupric salt is a blue-green varnish. The lead-salt, $C^4H^4(Pb^2)O^4$, forms a white, crystalline, deliquescent mass, perfectly insoluble in alcohol, and decomposing when heated to between 150° and 200° . The silver-salt, $C^4H^4Ag^2O^4$, is a flocculent mass, becoming dark-coloured and amorphous when dry, easily soluble in water, sparingly in alcohol, insoluble in ether; decomposing below 100° . (Beilstein, *Ann. Ch. Pharm.* cxvii. 366.)

HYDRAMIDES. A group of tertiary diamides (i. 172), formed by the action

1½ per cent., together with berberine: it appears also to have been previously noticed in 1851 by Durand (Amer. J. Pharm. xxiii. 112). It is very soluble in dilute mineral acids, which, on the other hand, dissolve berberine but sparingly: it may therefore be conveniently obtained from the alcoholic mother-liquors remaining after the separation of berberine (i. 379). For this purpose, the alcohol is distilled off, and the liquid, largely diluted with water, is cautiously mixed with ammonia till the resulting precipitate, consisting of a dark-coloured resin, no longer disappears on stirring. If the filtrate be then mixed with a slight excess of ammonia, hydrastine is precipitated as a brownish-yellow powder, appearing like starch under the microscope, and gradually becoming crystalline. By repeated crystallisation from alcohol, with help of animal charcoal, it is obtained in colourless, shining, four-sided prisms, becoming dull when dry.

Hydrastine is nearly insoluble in water, but dissolves easily in alcohol, ether, chloroform and benzene, and may be extracted directly from the pulverised root by heating it in a percolator with either of these solvents, neither of which will dissolve berberine.

Hydrastine melts at a temperature a little above 100°; it has a sharp bitter taste, but does not appear to be poisonous. Strong nitric acid colours it yellowish-brown; with sulphuric acid and chromate of potassium, or peroxide of lead, it assumes a brick-red to carmine-red colour. Its solutions mixed with chlorine-water acquire a blue fluorescence.

The salts of hydrastine are for the most part soluble.

HYDRATES. This term is applied to compounds containing oxygen and hydrogen, the whole or part of which exists, or may be supposed to exist, in the form of water; *c. g.*

Hydrate of chlorine	Cl.5H ² O	Hydrate of sodium	Na ² O.H ² O
Hydrated chloride of barium	BaCl ² .2H ² O	Sulphuric acid	SO ³ .H ² O
Crystallised sulpharsenate		Crystallised alum	Al ³ KS ² O ⁸ .6H ² O
of sodium	2Na ² AsS ⁴ .15H ² O	Crystallised glucose	C ⁶ H ¹² O ⁶ .H ² O
Hydrate of turpentine	C ¹⁰ H ¹⁶ .2H ² O		

Hydrated oxides may be regarded either as compounds of water with anhydrous oxides, as in the formulæ of hydrate of sodium and sulphuric acid above given, the water playing the part of an acid in the one case and of a base in the other; or as compounds formed from a simple or complex molecule of water, nH^2O , by the replacement of part (mostly half) of the typic hydrogen by a radicle either positive or negative: thus,

	Basic. Hydrate of sodium.	Acid. Nitric acid.	Alcoholic. Ethylie alcohol.
Water. H ² O	Na } O H }	NO ³ } O H }	C ² H ⁵ } O H }
H ² } O ² H ² }	Calcic hydrate. Ca ²⁺ } O ² H ² }	Sulphuric acid. (SO ⁴) ²⁺ } O ² H ² }	Glycol. (C ² H ⁴) ²⁺ } O ² H ² }
H ² } O ³ H ² }	Hydrate of aluminium. Al ³⁺ } O ³ H ² }	Orthophosphoric acid. (PO ⁴) ³⁺ } O ³ H ² }	Glycerin. (C ³ H ⁵) ³⁺ } O ³ H ² }
H ² } O ⁴ H ² }	Stannic hydrate Sn ⁴⁺ } O ⁴ H ² }	Glycero-sulphuric acid. (SO ³) ²⁺ } O ⁴ (C ³ H ⁵) ²⁺ } O ⁴ H ² }	Triethylenic alcohol. (C ³ H ⁵) ³⁺ } O ⁴ H ² }
H ² } O ⁵ H ² }		Pyrophosphoric acid. (P ² O ⁷) ²⁺ } O ⁵ H ² }	Tetraethylenic alcohol. (C ⁴ H ⁶) ⁴⁺ } O ⁵ H ² }
H ² } O ⁶ H ² }	Ferric hydrate. (Fe ³⁺) ³⁺ } O ⁶ H ² }	Glycerotartaric acid. (C ⁴ H ² O ⁷) ²⁺ } O ⁶ (C ³ H ⁵) ³⁺ } O ⁶ H ² }	Pentaethylenic alcohol. (C ⁵ H ⁷) ⁵⁺ } O ⁶ H ² }
H ² } O ⁷ H ² }			Triglycerin. (C ⁶ H ⁹) ⁶⁺ } O ⁷ H ² }

The last three compounds in the third column and the last four in the fourth, afford examples of hydrates in which more than half the typic hydrogen is replaced by an

acid or alcoholic radicle: other examples of such hydrates (which may also be regarded as anhydrides, inasmuch as they are formed by dehydration of normal hydrates) will be found under ETHYLENE, HYDRATES of (ii. 576), GLYCERYL, HYDRATES of (ii. 894), GLYCROTARTARIC ACIDS (ii. 893).

GLYCHOTARTARIC ACID (H. 888).
Metallic hydrates retain the elements of water with various degrees of force. Hydrate of copper parts with its water at a very moderate heat; hydrate of calcium, at a strong red heat; while the hydrates of potassium and sodium are not decomposed by the strongest heat that can be applied to them. Hydrated acids likewise exhibit various degrees of stability. Tribasic phosphoric acid, $\text{P}^2\text{O}_5 \cdot 3\text{H}^2\text{O}$ or PH^2O_4 , gives off part of its water at a red heat, being converted first into the dibasic acid, $\text{P}^2\text{O}_5 \cdot 2\text{H}^2\text{O}$, and ultimately into the monobasic acid, $\text{P}^2\text{O}_5 \cdot \text{H}^2\text{O}$, which resists further decomposition. The hydrates of volatile acids exhibit remarkable relations to heat. Under given circumstances of pressure and temperatures, there is for each acid a certain proportion of water which forms a stable compound, a weaker acid under that pressure and temperature giving off water, and a stronger acid giving off acid, till the most stable compound remains behind (Roscoe, Chem. Soc. Qu. J. xlii. 146). See **SULPHURIC ACID**, **NITRIC ACID**, **CHLORHYDRIC ACID**, &c.

The hydrates of the stronger acids and bases may be formed by direct combination of the anhydrous base or acid (anhydride) with water, the combination being sometimes attended with great evolution of heat, as in the case of sulphuric acid, baryta, and lime. In other cases, the hydrate cannot be formed directly, and in others again the union takes place but slowly. Acetic anhydride may be left in contact with water for several days without dissolving in it; but on the application of heat, it gradually dissolves. Among organic acids, it is found that dibasic acids are formed by the direct union of the anhydride and water, and that the hydrate may be decomposed by heat: this is the case with succinic and tartaric acids; whereas the hydrates of monobasic acids, such as acetic acid, cannot be thus decomposed by heat alone. This difference is probably related to the fact, that the molecule of a dibasic acid, like succinic acid, $(C^4H^4O^4)^{H^2}$ } O^2 , contains a sufficient number of atoms of basic hydrogen to form water ;

whereas the molecule of a monobasic acid, such as acetic acid, $\begin{matrix} \text{C}^2\text{H}^3\text{O} \\ \text{H} \end{matrix} \left. \vphantom{\begin{matrix} \text{C}^2\text{H}^3\text{O} \\ \text{H} \end{matrix}} \right\} \text{O}$, does not.

The hydrates of lithium, sodium, potassium, barium, strontium, and thallium, are easily soluble in water, forming strongly alkaline solutions; hydrate of calcium is moderately soluble; the other metallic hydrates are insoluble or nearly so; those of magnesium, mercury, lead, and silver are, however, sparingly soluble. The hydrates of the more acid or chlorous radicles are all more or less soluble in water, with the exception of certain organic acids of high atomic weight, such as the higher members of the fatty acid series, palmitic, stearic, cerotic acid, &c.: these bodies dissolve readily in alcohol and in ether. Similar remarks apply to the alcoholic hydrates.

In many hydrated compounds, part or the whole of the oxygen and hydrogen appears actually to exist as water, as in bases, salts, &c., containing water of crystallisation: e.g. crystallised hydrate of barium, $\text{Ba} \cdot \text{H}_2\text{O} \cdot 8\text{H}_2\text{O}$, crystallised alum $(\text{SO}_4)_2\text{Al} \cdot \text{K} \cdot 12\text{H}_2\text{O}$. Water can unite in this manner with salts and other bodies in the most various proportions, sometimes one molecule of the salt being united with several molecules of water, as in the instances above given, and sometimes, though less frequently, one molecule of water with two or more molecules of the salt; sometimes in more complex proportions, as in crystallised nitrate of strontium, $\text{Sr} \cdot (\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$.

Water thus united with a salt or other body is for the most part expelled at 100°C. : some salts, however, retain part of their water with greater tenacity than the rest; thus crystallised sulphate of zinc, $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, gives off 6 at water at 100° , but retains the seventh atom till heated to 238° ; sulphate of magnesium, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, exhibits a similar deportment. Moreover, this last atom of water, which is its greater stability appears to be more intimately united with the salt than the rest, may be replaced by a molecule of another salt, as sulphate of potassium or ammonium:

Crystallised sulphate of zinc	.	.	.	$\text{Zn}''\text{SO}^4 \cdot \text{H}^2\text{O}$	+ 6 aq.
Sulphate of zinc and potassium	.	.	.	$\left\{ \begin{array}{l} \text{Zn}''\text{SO}^4 \cdot \text{K}'\text{SO}^4 + 6 \text{ aq.} \\ \text{or } \text{Zn}''\text{K}'(\text{SO}^4)_2 + 6 \text{ aq.} \end{array} \right.$	

Water united with a salt in this manner is called by Graham *constitutional water*, to distinguish it from water of crystallisation. Liebig distinguishes these hydrated compounds, e.g. $\text{Zn}^{\text{II}}\text{SO}_4 \cdot \text{H}_2\text{O}$, by the term *halhydrates*.

HYDRAULIC LIMESTONE. See LIMESTONE.

HYDRIDES. This term is applied chiefly to the compounds of hydrogen with metals, alcohol-radicles, and organic acid-radicles, *e.g.* hydride of copper, Cu^2H^2 ; hydride of ethyl, $\text{C}^2\text{H}^5\text{H}$; hydride of benzoyl, $\text{C}^7\text{H}^5\text{O.H}$.

Metallic Hydrides. A few only of these compounds are known. The most important are the gaseous hydrides of *arsenic* and *antimony*, AsH^3 and SbH^3 (i. 322, 371), formed on the ammonia type. *Phosphoretted hydrogen*, or *phosphamine*, PH^3 , belongs to the same class. There is also a solid hydride of arsenic, supposed to have the composition AsH^2 , produced when water is electrolysed by a strong current, with metallic arsenic for the negative pole. It is doubtful whether a hydride of *bismuth* exists, analogous to the gaseous arsenides of arsenic and antimony. Hydride of *copper*, Cu^2H^2 , produced by the action of hypophosphorous acid on aqueous cupric sulphate, is remarkable for its reaction with hydrochloric acid, the products of which are cuprous chloride, Cu^2Cl^2 , and free hydrogen (ii. 66). A hydride of *iron* has been obtained by Wanklyn and Carius (Ann. Ch. Pharm. cxx. 69) by acting on ferrous iodide with zinc-ethyl. It is a black metallic powder, which gives off hydrogen when immersed in water.

Hydrides of Alcohol-radicles.—1. Of the radicles C^nH^{2n+1} . These hydrides are the homologues of marsh-gas, or hydride of *methyl*, CH^3H , the lowest term of the series. The hydrides of *ethyl*, *trityl*, and *tetryl* are gaseous at ordinary temperatures; the rest, up to $C^{12}H^{25}$, the highest yet obtained, are liquids of more or less disagreeable odour, burning with a slightly smoky flame, and regularly increasing in specific gravity, vapour-density, and boiling-point, as their atomic weights become greater. The highest terms of the series will doubtless be found to be solid waxes and paraffins.

Hydride of *methyl* (marsh-gas) is produced by the putrefaction and dry distillation of organic bodies, and by distilling acetic acid or acetone with excess of potash (i. 124). Hydride of *ethyl* is obtained by the decomposition of ethyl itself, which under certain circumstances splits up into this compound and ethylene (ii. 585):

also when iodide of ethyl is decomposed by zinc in presence of water:

Hydride of *tetryl*, $C^{10}H^{21}H$, is produced by heating tetrylic alcohol with chloride of zinc, and hydride of *amyl*, $C^5H^{11}H$, together with several of its higher homologues, by similar treatment of amyllic alcohol (p. 147).

Hydride of *amyl* and some of its homologues are also contained, together with other hydrocarbons, in the light oils resulting from the distillation of Boghead coal (Gr. Williams, Phil. Trans. 1857, p. 727; Jahresber. 1857, p. 437.—Chem. Soc. J. xv. 130), and of Wigan canal coal (Schorlemmer, Chem. Soc. J. xv. 419): for the mode of separating them, see p. 146. Many of these alcoholic hydrides are also contained in American petroleum or earth-oil (which indeed appears to consist almost entirely of them), hydride of *hexyl*, C^6H^{13} , constituting the principal portion (Pelouze and Cahours, Ann. Ch. Pharm. cxxiv. 289; cxxvii. 196; cxxix. 87). They are separated by fractional distillation, and purified by successive treatment with sulphuric acid and carbonate of sodium, desiccation with anhydrous chloride of calcium, distillation over sodium, and final rectification. In this manner, Pelouze and Cahours have obtained twelve of these hydrides, included under the general formula C^nH^{2n+2} , from hydride

Specific Gravities and Boiling Points of Alcoholic Hydrides, C^nH^{2n+2} .

	Specific gravities.			Boiling points.		
	Pelouze and Cahours.	Schorlemmer.	Wurtz.	Pelouze and Cahours.	Schorlemmer.	Wurtz.
Hydrides of						
Tetryl $C^{10}H^{21}$				little above 0°		
Amyl C^5H^{11}	0.628 at 17°	0.636 at 17°		30°	$39^\circ - 40^\circ$	$28^\circ - 30^\circ$
Hexyl C^6H^{13}	0.669 „ 16	0.678 „ 15.5		68	68 — 70	60 — 64

Tetradecetyl $C^{14}H^{29}$						
$C^{14}H^{29}$				236—240		
Pentadecetyl $C^{15}H^{31}$				255—260		

of tetryl, C^4H^{10} , boiling at a few degrees above 0° , to hydride of pentadecatyl, $C^{15}H^{32}$, boiling between 255° and 260° . The oil also yields a quantity of liquid boiling above 300° , and doubtless containing some of the higher terms of the same series. Moreover, in boring for it, large quantities of gas escape, exhibiting the characters of marsh-gas: hence it is probable that, in the great geological changes which have given rise to the separation of this remarkable liquid, the whole series of homologous alcohol-hydrides C^mH^{2m+2} has been produced, from marsh-gas up to the highest paraffins.

The preceding table (p. 181) exhibits the specific gravities and boiling-points of the alcoholic hydrides obtained from these several sources. The vapour-densities have also been determined in all cases, and found to agree nearly with those calculated from the respective formulae for a condensation to 2 volumes. Wurtz's determinations were made on the hydrides obtained by the decomposition of amyllic alcohol; Schorlemmer's, on those from cannel-naphtha; those of Pelouze and Cahours, on the hydrides from American petroleum.

These alcoholic hydrides are very stable compounds. They are little, if at all, acted upon by fuming nitric acid, strong sulphuric acid, or bromine; but chlorine converts them all into the corresponding alcoholic chlorides $C^mH^{2m+1}Cl$.

Each alcoholic hydride of the series $C^mH^{2m+1}H$ (except hydride of methyl) is identical in composition with a radicle, simple or mixed, belonging to the same series: thus—

Hydride of Ethyl	$C^2H^4.H$	=	Methyl	$CH^3.CH^3$
"	Trityl $C^3H^7.H$	=	Methyl-ethyl	$CH^3.C^2H^5$
"	Tetryl $C^4H^{10}.H$	=	Ethyl	$C^2H^5.C^2H^5$
"	Amyl $C^5H^{11}.H$	=	Ethyl-trityl	$C^2H^5.C^3H^7$
and generally :		=	Methyl-tetryl	$CH^3.C^4H^9$
	$C^{2m}H^{4m+1}.H$	=	$C^m H^{2m+1}. C^m H^{2m+1}$	
	$C^{2m+1}H^{4m+3}.H$	=	$C^m H^{2m+1}. C^{m+1}. H^{2m+2}$	

The question, therefore, arises: are the members of the two series, the alcohol-radicles and their hydrides, identical or only isomeric? Soon after the isolation of the alcohol-radicles by Frankland and Kolbe, in 1849, Laurent and Gerhardt pronounced the opinion that these compounds were the homologues of marsh-gas. This view has not been generally received as correct (see ALCOHOL-RADICLES i. 96); but recently, Schorlemmer (Chem. Soc. J. xv. 425) has endeavoured to solve the question by examining the products obtained by the action of chlorine on the radicles and their isomeric hydrides. He finds that ethyl-amyl, C^7H^{14} , treated with chlorine, yields a chloride, $C^7H^{13}Cl$, agreeing in composition, as well as in boiling point and other physical properties, with that which is produced by the action of chlorine on hydride of heptyl (p. 144). From amyl, C^5H^{12} , Schorlemmer obtained, in like manner, a chloride, $C^5H^{11}Cl$, boiling at about 200° , which he regards as identical with that which Wurtz obtained by the action of chlorine on hydride of decatyl, $C^{10}H^{22}.H$. From these results, Schorlemmer concludes that no chemical difference exists between the alcoholic hydrides and the radicles, at least among the higher members of the series.

2. *Hydrides of the Alcohol-radicles* C^mH^{2m+1} .—Two compounds of this series are known, viz:—

Hydride of Phenyl (Benzene)	C^6H^6	=	$C^6H^6.H$
Hydride of Benzyl (Toluene)	C^7H^8	=	$C^7H^8.H$

Both these hydrides are contained in the light oils obtained by the distillation of coal. When treated with strong nitric acid, they yield substitution-products, in the form of heavy oils, the formation of which affords the means of separating these hydrocarbons from those of other series with which they may be mixed (p. 146). The preparation and properties of these hydrides have already been fully described (p. 642, 673).

The hydrides of alcohol-radicles of other series have not yet been obtained.

Hydrides of Acid-radicles: The aldehydes, referred to the hydrogen-type HH , constitute this class of compounds, e.g. acetic aldehyde, $C^2H^4O = C^2H^3O.H$; benzoic aldehyde (bitter-almond oil), $C^7H^8O = C^7H^7O.H$ (see ALDEHYDES, i. 110).

HYDROALOETIC ACID. An acid formed from aloetic or chrysammic acid by the action of water and stannous chloride. A dark violet powder is then produced, which at 120° contains, according to Mulder, $SnO.C^11H^1N^2O^{11}$. This stannic salt, treated with potash, gives off ammonia and assumes a blue-violet colour; and when heated with strong nitric acid, gives off nitrous fumes, turns red, and yields, first aloetic acid, then, after longer boiling, chrysammic acid (Mulder, Ann. Ch. Pharm. lxxii. 265).

HYDROAPATITE. A hydrated phosphate of calcium, containing fluorine, found in milk-white, translucent, warty concretions, in clefts of a ferruginous-argillaceous rock, imbedded in a black slate, near St. Giron (Ariège) in the Pyrenees. It scratches fluor-spar, but is scratched by steel. Specific gravity = 3.16. It contains

40.00 per cent. P_2O_5 , 52.35 CaO, 3.36 F, and 5.30 water, together with 6.43 ferric phosphate, agreeing nearly with the formula $3Ca^2P_2O_5 \cdot CaF_2 \cdot 3H_2O$. (Damour, Ann. Min. [5] x. 65; Jahresber. 1856, p. 874.)

HYDROBENZAMIDE. $C^6H^5N^2$. *Tribenzylene-diamide, Hydride of Azo-benzoyl.* (Laurent, Ann. Ch. Phys. [2] lxii. 23; lxvi. 18; [3] i. 300.—Bertagnini, Ann. Ch. Pharm. lxxxviii. 127.)—This compound, which may be regarded as a tertiary

diamide, $N^2(C^6H^5)^2$, in which the hydrogen is completely replaced by the diatomic radicle benzylene, is produced by the action of ammonia on hydride of benzoyl (bitter almond oil). When rectified bitter almond oil (boiling at 180°) is left in contact with aqueous ammonia for a few days, or for only six or eight hours if the liquid be previously heated to the boiling point of the ammoniacal solution, a crystalline mass is formed, which must be broken up, washed rapidly with ether to remove adhering oil, and then dissolved in boiling alcohol, which leaves undissolved a number of secondary products resulting from the action of the ammonia on hydrocyanic acid contained in the bitter almond oil. According to Ekman (Ann. Ch. Pharm. cxii. 151), hydrobenzamide may be obtained in fine crystals by mixing bitter almond oil with an equal volume of ether and strong aqueous ammonia, and leaving the mixture at rest.

Hydrobenzamide separates from its alcoholic solution in colourless octahedrons with a rhombic base, truncated on their longer lateral edges. Angles of the terminal edges, 130° and 122° ; angles of the lateral edges, $84^\circ 50'$. It is insoluble in water, very soluble in alcohol and ether. The crystals are destitute of taste and odour, but the alcoholic solution has a taste of burnt almonds. The crystals melt at 110° , forming a thick oil, which has a sweet taste, and solidifies after a while to an opaque brown mass.

Decompositions.—1. Hydrobenzamide, when heated in the air, takes fire, and burns with a not unpleasant odour (Laurent).—2. Between 120° and 130° it changes in three or four hours into a marine (Bertagnini).—3. By dry distillation, it yields lophine and a strong-smelling volatile oil, leaving a small quantity of carbonaceous matter (Laurent).—4. When the alcoholic solution is continuously boiled, ammonia escapes, and on evaporating the alcohol, bitter almond oil remains (Laurent).—5. Boiled with aqueous chromic acid, it yields a large quantity of benzoic acid (Fownes, Phil. Trans. 1845, 263).—6. With acids, even at ordinary temperatures, it yields bitter almond oil and the ammoniac-salt of the acid (Laurent, Fownes).—7. Boiled with potash-ley, it changes gradually and without perceptible decrease of weight, into a marine, only a faint odour of bitter almond oil being evolved (Fownes). Boiled with alcoholic potash, it gives off a small quantity of ammonia and bitter almond oil (Laurent).—8. When it is fused with hydrate of potassium, the mass becomes first light yellow, then dark yellow, and ultimately brown and black; and if slowly heated, gives off nothing but ammonia: if the heat be continued, there is given off, besides ammonia, a mixture of about 4 vol. hydrogen gas to 1 vol. carburetted hydrogen. The black residue contains carbonate and cyanide of potassium, benzostilbin, benzolone, and a small quantity of a yellow oil, which thickens and becomes viscid on exposure to the air; the mass, which has then become dark yellow, contains nothing but benzostilbin and a considerable quantity of the yellow oil (Rochleder, Ann. Ch. Pharm. lxi. 89).—9. Heated with potassium, it yields a red fusible mass and a small quantity of charcoal (Laurent).—10. When sulphuric acid is passed through the alcoholic solution, sulphide of benzylene is produced (Cahours).—11. A solution of hydrobenzamide in absolute alcohol mixed with a solution of sulphurous anhydride in absolute alcohol, deposits, after a while, a white precipitate of sulphite of benzoyl and ammonium, $C^6H^5(NH^4)SO_3$, and the remaining solution yields by distillation, first alcohol, then diethyl-benzylene ether, $\{C^6H^5\}_2O$ (R. Otto, Ann. Ch. Pharm. cxii. 305).—12. When hydrobenzamide is saturated with hydrochloric acid gas, a compound free from nitrogen slowly volatilises, whilst a non-volatile azotised compound remains behind, which is not altered by ether, but is dissolved by alcohol, with separation of sal-ammoniac. This compound (hydrochlorate of hydrobenzamide) is resolved by water into sal-ammoniac and hydride of benzoyl:

and by absolute alcohol into sal-ammoniac and diethyl-benzylene ether:

(Ekman, Ann. Ch. Pharm. cxii. 151; Jahresber. 1859, p. 317.—Lieke, ibid. 318).

Hydrochlorate of hydrobenzamide, heated to 180° — 230° , yields, besides hydrochloric acid, an oily distillate, containing benzonitrile and chloride of benzyl, C^6H^5Cl (i. 573), and leaves a red-brown residue, which is separated, by digestion with alcohol at ordinary

temperatures, into a brown solution (A) and yellow flocks. The latter dissolve in a mixture of alcohol and chloroform, forming a solution which deposits two modifications of lophine, $C^{12}H^{14}N^2$; the one crystallising in needles which melt at 230° , the other in needles which melt at 170° (see Lophine). The brown solution (A) yields, first, the two modifications of lophine just mentioned; secondly, a base, probably amarine, melting at 90° ; thirdly, a base, $C^{12}H^{20}N^2$, which melts at 100° , forms an oxalate, $C^{12}H^{20}N^2 \cdot C^2H^2O^4$, crystallising from alcohol in nacreous laminae, and a platinum-salt, $C^{12}H^{20}N^2 \cdot HCl \cdot PtCl_2 \cdot 2H^2O$, in microscopic prisms; fourthly, another modification of the same base, whose platinum-salt is anhydrous; and fifthly, an oily base, $C^{14}H^{22}N^2$, forming a hydrochlorate, which melts at 220° , dissolves easily in water and alcohol, and crystallises in six-sided prisms. (Ekman, *loc. cit.*—Kühn, N. Jahrb. Pharm. xvi. 292; Jahresber. 1861, p. 404.)

13. Hydrobenzamide heated with 2 at. iodide of ethyl to 80° — 100° , yields a dark-brown viscid mass, which, after purification by solution in alcohol, precipitation by water, &c., is found to consist of di-iodide of tribenzylene-diethyl-diammonium $[(C^6H^5)^3(C^2H^5)^2N^2]^2I^2$; and the alcoholic solution of this iodide, treated with oxide of silver or hydrate of lead, yields the base $C^{12}H^{18}N^2O = [(C^6H^5)^3(C^2H^5)^2N^2]O$. This base, again treated with iodide of ethyl, does not yield any distinct compound. (Berodine, Ann. Ch. Pharm. cv. 257.)

Amarine, isomeric with hydrobenzamide, behaves differently with iodide of ethyl; yielding hydriodate of diethylamarine, $C^{12}H^{16}(C^2H^5)^2N^2 \cdot HI$, from which, by heating the potash, diethylamarine itself, $C^{12}H^{16}(C^2H^5)^2N^2$, may be obtained; and this base, again treated with iodide of ethyl, yields another base, which forms crystalline salts, and appears to contain a larger proportion of ethyl. This base is likewise acted upon by iodide of ethyl, yielding a hydriodate just like the former. Hence Berodine concludes that amarine contains at least 3 at. H, replaceable by ethyl, and represents it provisionally by the formula $N \begin{Bmatrix} N(C^6H^5)^3H \\ H^2 \end{Bmatrix}$.

Chloride of Hydrobenzamide, $C^{12}H^{18}N^2Cl^2$ (Th. Müller, Ann. Ch. Pharm. xxi. 144; Jahresber. 1859, p. 315), is produced by passing dry chlorine gas over hydrobenzamide, which then takes up 19.5 per cent. chlorine, and melts to a viscid yellow liquid. It is decomposed by water, yielding sal-ammoniac, hydrochloric acid, and an oily mixture of hydride of benzoyl and benzonitrile, boiling between 180° and 190° :

By anhydrous ether it is resolved into sal-ammoniac, and a mixture of benzonitrile with an oily body which boils at 183° , and has the composition of chlorohydrobenzamide (see below), but differs from that substance by its ready decomposibility by water into benzonitrile and hydride of benzoyl.

Chloride of hydrobenzamide heated to 180° — 200° is resolved into hydrochloric acid, chlorohydrobenzamide, $C^{12}H^{17}ClN^2$, which distils over as a colourless oil, and a residue which solidifies on cooling, and is resolved, by successive treatment with water, ether, and alcohol, into the following compounds:

The aqueous solution deposits on cooling a white powder, which separates from alcohol in hard granular crystals, consisting of $C^{12}H^{17}ClN^2 \cdot HCl$ or $C^{12}H^{17}N^2 \cdot Cl^2$; from water the same compound crystallises with 1 at. H^2O . Ammonia added to the solution throws down [? as a hydrate] the base $C^{12}H^{14}N^2 = N^2(C^6H^5)^4$, which may be called tetrabenzylene-diammonium. The chloroplatinate, $C^{12}H^{14}Cl^2N^2 \cdot PtCl_2$, is easily soluble.

The ethereal solution deposits crystalline needles insoluble in water, subliming at 300° , and having the composition $C^{12}H^{14}N^2$.

The alcoholic solution yields crystals insoluble in water and in ether, and containing, when dried over oil of vitriol, $C^{12}H^{14}N^2 \cdot HCl \cdot 2H^2O$. If the base is separated from this salt by ammonia, and redissolved in hydrochloric acid, the solution yields by evaporation a basic hydrochlorate, $2C^{12}H^{14}N^2 \cdot HCl \cdot 2H^2O$. The chloroplatinate, which is light yellow, contains $2(C^{12}H^{14}N^2 \cdot HCl) \cdot PtCl_2$ (platinum, by experiment, 17.4 per cent.; by calculation, 17.9).

Chlorohydrobenzamide. $C^{12}H^{17}ClN^2$. (Th. Müller, *loc. cit.*)—When chloride of hydrobenzamide is heated to 180° — 200° , this compound distils over as a colourless oil, heavier than water, and having a pungent odour of chlorine and benzonitrile together. It dissolves easily in alcohol and in ether, and is slowly decomposed by water, with formation of hydrochloric acid. When left in contact, for 24 hours, with a mixture of nitric and sulphuric acids, it forms a solution from which water throws down crystallisable nitrobenzonitrile, $C^6H^4(NO^2)N$.

Chlorenitro-hydrobenzamide. $C^3H^1Cl(NO_2)N$. (Müller, *loc. cit.*).—This compound is formed when chlorohydrobenzamide is left for 24 hours in contact with strong nitric acid, and is precipitated by water from the acid solution, as an oily very pungent liquid. It is soluble in alcohol, and the solution is decomposed by sulphide of ammonium, yielding benzonitrile and sulphobenzamide:

HYDROBENZILE. $C^{14}H^{12}O$. (Zinin, J. pr. Chem. xxxiii. 35.)—A product of the action of sulphide of ammonium on benzile ($C^{14}H^{10}O^2$). It is insoluble in water, soluble in alcohol and ether, and crystallises from these solutions in the shape of concavo-convex lenses. The crystals melt at 47° , forming a colourless liquid, which distills without alteration, and solidifies in a crystalline mass at 42° . They have the smell of bitter almonds, and a saccharine pungent taste. They dissolve readily in sulphuric acid, and are precipitated therefrom by water. They are slowly attacked by chlorine, and not sensibly altered by boiling potash.

HYDROBENZOLIN. $C^6H^4O^2$. (Zinin, Ann. Ch. Pharm. exxiii. 125.)—A compound produced by the action of nascent hydrogen on benzoyl-hydride (bitter almond oil), and containing the elements of 2 molecules of that compound ($C^6H^4O^2$), and 1 molecule of hydrogen, H^2 . To prepare it, 4 pts. of bitter almond oil free from prussic acid are dissolved in 6 pts. alcohol of 85 per cent.; the solution is mixed with 4 pts. alcohol previously saturated with hydrochloric acid gas; and one pt. of finely-granulated zinc is carefully added, so that it may dissolve without perceptible evolution of hydrogen. When the reaction is finished, the liquid is heated to the boiling point, mixed after cooling with a small quantity of ether (to remove a body which adheres to the zinc and retards the action) and with 1 pt. more of alcohol saturated with hydrochloric acid gas, then heated to complete the reaction, and mixed with a quantity of water three or four times as great as that of the bitter almond oil taken. Hydrobenzoin then separates as an oily body, which soon solidifies in a crystalline mass, and may be purified by washing in water, pressure between bibulous paper (to remove an acid oil), and recrystallisation from alcohol (or if somewhat impure, previously from ether). It is thus obtained in large rhombic plates, which melt at 130° , and boil above 300° . When gently heated with 2 pts. nitric acid of specific gravity 1.86, it is converted, without any evolution of red vapours or formation of secondary products, into pure benzoin; with stronger nitric acid, benzil is obtained. It is not attacked by potash, either aqueous or alcoholic, even at the boiling heat.

HYDROBERBERINE. $C^{20}H^{24}NO^4$. (Hlasiwetz and Gilm. Ann. Ch. Pharm. Suppl. ii. 191; Rép. Chim. pure, 1863, p. 426.)—A base produced by the action of nascent hydrogen on berberine, as first observed by Hlasiwetz (Rép. Chim. pure, 1862, p. 367). It is obtained by boiling in a flask, provided with a condensing tube to cause the vapours to flow back, a mixture of 6 pts. berberine, 100 pts. water, 10 pts. distilled sulphuric acid, 20 pts. glacial acetic acid, a quantity of granulated zinc, and a few pieces of platinum foil. The liquid gradually loses its colour, and as soon as the froth exhibits a wine-yellow colour, which it does after boiling for an hour or two, the action is stopped, the liquid filtered, any crystalline deposits that may have formed are dissolved in dilute sulphuric acid, and an excess of ammonia is added after cooling. Hydroberberine is then obtained as a bulky yellowish deposit, which must be collected on a filter, washed, dried at a gentle heat, then pulverised, boiled in alcohol, and purified by repeated crystallisation from alcohol. Instead of precipitating the base by ammonia, it may be advantageously obtained as a hydrochlorate, by adding common salt to the original solution. The hydrochlorate is then almost wholly deposited in the form of a crystalline powder.

Hydroberberine may also be prepared by acting on berberine with sodium-amalgam, but it is then yellow and more difficult to purify.

Hydroberberine is deposited from a hot alcoholic solution, in small shining granular crystals, or flattened needles, which are colourless or slightly yellowish, and appear to belong to the monoclinic system. It differs from berberine, $C^{20}H^{17}NO^4$ (the formula determined by Perrins, Chem. Soc. J. xv. 339), by four additional atoms of hydrogen, and may be reconverted into that compound by the action of nitric acid. On dissolving it in a mixture of equal volumes of hydrochloric acid and alcohol, and dropping in nitric acid diluted with alcohol, the liquid becomes coloured, and deposits crystals of hydrochlorate of berberine.

Hydrochlorate of Hydroberberine. $C^{27}H^{31}NO^4.HCl$.—Crystals of hydroberberine spread upon a watch-glass, under a bell-jar within which hydrochloric acid is evolved, are converted into a white powder, consisting of the hydrochlorate, soluble in warm water, and crystallising in laminae on cooling. The salt may also be obtained by

dissolving the base in hot hydrochloric acid; the solution on cooling forms a jelly, which is gradually transformed into crystals. It is more soluble in alcohol than in water. Its solutions yield copious precipitates with *chloride of platinum*; from a warm alcoholic solution, the platinum-salt is more gradually deposited in orange-yellow crystalline grains, consisting of $2(C^{20}H^{21}NO^4.HCl).PtCl^4$.

The *hydrobromate* and *hydriodate* are white, crystalline, and very slightly soluble.

The *nitrate*, which is also crystalline and very slightly soluble, is seldom obtained pure by dissolving the base in nitric acid, because the acid decomposes it; better by mixing a hot, very dilute solution of the sulphate with nitrate of sodium.—The *oxalate* crystallises in small rhombic plates, the *phosphate* in fine rhombic plates.

Sulphates of Hydroberberine. The neutral sulphate, $(C^{20}H^{21}NO^4)^2.H^2SO^4$, is obtained by dissolving an excess of the base in very dilute sulphuric acid. The liquid then deposits needles which fill it entirely, and after being expressed and purified by crystallisation, are very soluble in water, and contain a certain quantity of water, which they lose by exposure to the air; they likewise invariably contain a little free acid.

When the base is dissolved in a slight excess of acid, large transparent rhombohedrons are obtained, approaching nearly to the cube; they give off water when exposed to the air, and cannot be dissolved in water without decomposition. They appear to be a mixture of the neutral and acid sulphates, containing $4C^{20}H^{21}NO^4.3SH^2O^4.4H^2O$, or $(C^{20}H^{21}NO^4)^2.SH^2O^4\} .4H^2O$.

A moderately dilute solution of this salt mixed with excess of sulphuric acid becomes turbid and deposits small mammellated crystals, or a resinous mass, which gradually changes into crystals of the acid salt, $C^{20}H^{21}NO^4.SH^2O^4$, which may be purified by recrystallisation from alcohol.

Tartrate of Hydroberberine forms mammellated groups of needles.

Ethyl-hydroberberine. $C^{22}H^{23}NO^4 = C^{20}H^{20}(C^2H^3)NO^4$.—Hydroberberine heated for some hours in a water-bath with an excess of iodide of ethyl, yields a pasty mass, which when taken up by alcohol, forms tufts of yellow rhomboïdal prisms, consisting of hydriodate of ethyl-hydroberberine, $C^{22}H^{23}NO^4.HI$, very soluble in water, and containing water of crystallisation, which they give off entirely at 100° . The mother-liquors of the preparation still yield small quadrangular laminae of another substance, the admixture of which with the first crystals must be avoided.

HYDROBORACITE. *Hydrated Borate of Calcium and Magnesium.* $3CaO\} 8B^2O^3.18H^2O$.—Resembles fibrous and foliated gypsum. Colour white with spots of red, from iron. Translucent in thin plates. Melts before the blowpipe to a clear glass, tinging the flame slightly green and not becoming opaque. Heated in a tube it yields water. It is slightly soluble in water, the liquid having a faint alkaline reaction. It dissolves readily in nitric and hydrochloric acids. It was found by Hess (Pogg. Ann. xxxi. 49) in a collection of Caucasian minerals.

HYDROBOROCALCITE. Syn. with BOROCALCITE.

HYDROBROMIC ACID. See BROMIDE OF HYDROGEN (i. 672).

HYDROBRYOTIN. $C^{12}H^{14}O^{16}$.—An amorphous substance, insoluble in ether, but soluble in alcohol, produced by the decomposition of bryonin (i. 685).

HYDROBUCHOLZITE. See KYANITE (p. 449).

HYDROCALCITE. Hydrated carbonate of calcium, $CaCO^3.5H^2O$. Found in small rhombohedral crystals, forming an incrustation on wood under water. (See CARBONATES.)

HYDROCARBONS. Compounds consisting of carbon and hydrogen only. The number of bodies of this class at present known is very great, but the most important of them may be arranged in the following groups:

1. Alcohol-radicles $(C^nH^{2n+1})^2$ homologous with Methyl (CH^3)
2. Hydrides of alcohol-
radicles C^nH^{2n+2} " Marsh-gas (CH^4)
3. Olefines C^nH^{2n} " Ethylene or Olefant gas (C^2H^4)
4. Hydrocarbons C^nH^{2n-2} " Acetylene (C^2H^2)
5. Camphenes or Terebenes C^nH^{2n-4} isomeric with Turpentine, $C^{10}H^{16}$
6. Hydrocarbons C^nH^{2n-6} homologous with Benzene (C^6H^6)
7. Hydrocarbons C^nH^{2n-12} " Naphthalene, $C^{10}H^8$

The most fruitful source of hydrocarbons is the dry or destructive distillation of organic bodies, the nature of the products varying according to the temperature at which

the decomposition takes place. Thus, coal when distilled at a bright red, as for the production of illuminating gas, yields hydrocarbons belonging to the second, third, fourth and sixth of the above groups, together with a considerable quantity of naphthalene; but when distilled at the lowest temperature at which complete decomposition can take place it yields liquid hydrocarbons belonging chiefly to the second and third groups, together with a large quantity of paraffin, which probably also belongs to the second group. The slow decomposition of organic matters buried beneath the surface of the earth has also yielded large quantities of hydrocarbons belonging to the second group, as shown by the enormous quantities of petroleum found in certain parts of North America, which, as already observed (p. 181), consists almost wholly of alcoholic hydrides of the general formula C^nH^{n+2} .

The olefines, C^nH^{2n} , are produced by the dehydration of alcohols of the series $C^nH^{2n+2}O$, as by heating these alcohols with strong sulphuric acid or chloride of zinc, each alcohol then yielding the corresponding olefine, according to the equation $C^nH^{2n+2}O - H^2O = C^nH^{2n}$.

The reaction, however, at least in the case of some of the higher alcohols, is much more complicated than this equation would imply, resulting in the formation, not only of the olefine corresponding to the alcohol decomposed, but likewise of several of its homologues, and of the corresponding alcoholic hydrides; thus Wurtz, by distilling amyl alcohol with chloride of zinc, has obtained, not only amylene, C^5H^{10} , but likewise all its homologues up to decatylene or diamylene, $C^{10}H^{20}$, together with the corresponding alcoholic hydrides.

The lowest term of the olefine series, viz. methylene, CH^2 , is not known in the free state. Ethylene, C^2H^4 , tritylene or propylene, C^3H^6 , and tetrylene, C^4H^8 , are gaseous at ordinary temperatures; amylene, C^5H^{10} , and its higher homologues up to decatylene, $C^{10}H^{20}$, and cetylene, $C^{16}H^{32}$, are liquid at ordinary temperatures, their boiling points rising as their molecular weights increase. Cerotene, $C^{27}H^{54}$, and melissene, $C^{30}H^{60}$ are waxy solids, the former melting at 57° or 58° , the latter at 62° .

The more volatile olefines are remarkable for the facility with which they unite with chlorine, bromine, and iodine, forming compounds homologous with, or analogous to, Dutch liquid, $C^2H^4Cl^2$. This property affords an easy mode of separating these olefines from any gaseous mixture in which they may be present: for on passing the gaseous mixture through a bottle containing bromine, the olefines are absorbed and converted into heavy oily liquids (hence their name), while the other hydrocarbons in the mixture are unaffected.

The olefines unite very readily with sulphuric anhydride; and this property likewise affords an easy mode of separating them from gaseous mixtures: thus, if a ball of coke or pumice impregnated with Nordhausen sulphuric acid be passed up into a mixture of ethylene-gas with marsh-gas, hydrogen, carbonic oxide, &c., the ethylene will be absorbed, while the other gases will remain behind.

The volatile olefines also unite readily with strong sulphuric acid, forming compound acids of the form $C^nH^{2n}.SH^2O^4$, or $C^nH^{2n+1} \left\{ \begin{smallmatrix} SO^2 \\ H \end{smallmatrix} \right\} O^2$, homologous with ethyl-sulphuric or sul-

phovinic acid. This reaction is of especial importance, since it enables us to pass from an olefine to the corresponding alcohol: thus ethylene-gas shaken up with strong sulphuric acid yields ethyl-sulphuric acid, $C^2H^5.H \left\{ \begin{smallmatrix} SO^2 \\ H \end{smallmatrix} \right\} O^2$, whence, by distillation with water, ethylic alcohol is obtained (i. 72).

Olefines also combine with water, hydrochloric acid, hydrobromic acid, &c. Wurtz has shown (Ann. Ch. Pharm. cxxv. 114) that amylene combines with hydrobromic and hydriodic acid, forming compounds isomeric with iodide and bromide of amyl; and by treating the hydriodate, $C^5H^{10}.HI$, with moist oxide of silver, he has obtained a hydrate of amylene, $C^5H^{10}.H^2O$, isomeric with amyl alcohol. All these compounds are distinguished from the amyl-compounds, with which they are isomeric, by the facility with which they give up their amylene under the influence of various reagents. Thus hydrate of amylene quickly absorbs hydriodic acid gas, and is resolved into hydriodate of amylene and aqueous hydriodic acid; similarly with hydrochloric acid. Bromine also decomposes it rapidly into bromide of amylene and water; chlorine similarly but less quickly. With sodium it yields the compound $C^5H^{10}.NaHO$, which when treated with hydriodate of amylene, readily yields amylene, hydrate of amylene, and iodide of sodium:

Hydriodate of amylene is also rapidly decomposed by sodium, yielding iodide of sodium, amylene, and free hydrogen. With alcoholic potash, it yields amylene and iodide of potassium; with ammonia, the products are iodide of ammonium, amylene, and a small quantity of a base isomeric or perhaps identical with amylamine.

The amylene in all these compounds appears to be but loosely united with the water or the acid, and is set at liberty on the slightest disturbance; whereas in their isomers the amyl-compounds, the group C^5H^{11} , which is not capable of existing in the separate state, is easily transferred from one compound to another, and it is only with considerable difficulty that two molecules of it can be made to coalesce into one so as to form free amyl, C^5H^{12} .

Hexylene, C^6H^{12} , also unites with hydriodic acid, and the hydriodate, treated with water and oxide of silver, yields a hydrate, $C^6H^{12}.H^2O$, isomeric with hexylic alcohol, and possibly identical with the β hexylic alcohol discovered by Wanklyn and Erlenmeyer.

The formation and properties of the alcohol-radicles (i. 96) and their hydrides (iii. 180) have already been considered. Recent investigations seem to show that there is no essential difference between the alcohol-radicles in the free state, and their hydrides (pp. 144, 182).

Of the hydrocarbons, C^2H^{2n-2} , homologous with acetylene, only three have been obtained, viz. acetylene, C^2H^2 (i. 1111), allylene, C^3H^4 (i. 1112), and crotonylene, C^4H^6 (ii. 965).

Of the hydrocarbons, C^2H^{2n-6} , homologous with benzene, five are known, viz. benzene, C^6H^6 (i. 541), benzylene or toluene, C^7H^8 (i. 577), xylene, C^8H^{10} , cumene, C^9H^{12} (ii. 173), and cymene, $C^{10}H^{14}$ (ii. 206). They have all been specially considered, excepting xylene, which will be described in its place. These hydrocarbons, as already observed, are produced by the destructive distillation of coal and other organic substances at high temperatures; also in a great variety of chemical reactions (see BENZENE). They are distinguished by the facility with which they form substitution-compounds with concentrated nitric acid, e.g. nitrobenzene, $C^6H^5(NO^2)$. These nitro-compounds, being heavy oily liquids of rather high boiling point, afford the means of separating these hydrocarbons from others, such as the alcoholic hydrides, with which they may be mixed (p. 146). The same compounds subjected to the action of reducing agents, such as sulphydric acid or ferrous acetate, yield organic bases, which may be supposed to be derived from the nitro-compound by substitution of amidogen, NH^2 , for nitryl, NO^2 , e.g. aniline, $C^6H^5(H^2N)$, from nitrobenzene.

The camphenes, or terebenes, $C^{10}H^{16}$, isomeric with oil of turpentine, exist ready formed in a great number of plants. For their general properties see vol. i. p. 724.

The hydrocarbons are the simplest of all organic compounds, and may be regarded as the starting-points from which all others may be derived, by substitution or addition (see NUCLEUS-THEORY and RADICLES). Hence, of late years, the attention of chemists has been very much directed to the discovery of methods for producing these compounds directly from their inorganic elements; since, when this is accomplished, the formation of a great number of the more complex organic compounds, by the synthesis of their elements, becomes a comparatively easy matter. The most successful efforts in this direction have been made by Berthelot (Chem. Soc. J. xvii. 37), who has succeeded in producing certain hydrocarbons by direct combination of the elements carbon and hydrogen, and from these producing others of great complexity.

1. Acetylene, C^2H^2 , is produced when hydrogen is passed over carbon heated to bright redness by the electric arc. This gas, passed into a solution of cuprous chloride, forms cuprous acetylene, $C^2(Cu^2)H^2$; and this compound, subjected to the action of nascent hydrogen (evolved by the action of zinc on ammonia), yields ethylene:

Ethylene thus obtained may be converted into alcohol, and from this a host of other compounds, ethers, acetones, acids, amines, &c. may be derived.

2. Hydrocarbons may be formed from inorganic compounds containing their elements, such as water and sulphide of carbon, or carbonic anhydride. A mixture of sulphydric acid and sulphide of carbon, subjected to the action of copper at a red-heat, yields marsh-gas:

Marsh-gas may also be formed from carbonic anhydride, though by a less direct process, viz. by first converting the latter compound into carbonic oxide, this into formic acid ($CO + H^2O = CH^2O^2$, ii. 683), then subjecting a salt of this acid, the barium-salt, for example, to dry distillation:

Marsh-gas, mixed with an equal volume of chlorine, yields chloride of methyl, CH^3Cl ; and this ether distilled with potash, yields methylic alcohol, CH^3O , which is formed by the addition of 1 at. oxygen to marsh-gas, whereas ethylic alcohol is formed from ethylene by the addition of the elements of water. These two modes of formation of

alcohols from hydrocarbons are general, the former applying to all homologues of marsh-gas, the latter to all homologues of ethylene.

3. A hydrocarbon may be transformed into another of greater complexity: *a.* By *direct condensation*. Marsh-gas raised to a very high temperature, or subjected to the action of a series of induction-sparks, is converted into acetylene, which contains twice the quantity of carbon in the same volume: $2\text{CH}^4 = \text{C}^2\text{H}^2 + \text{H}^2$. The condensation of marsh gas may, however, be carried considerably further, and made to yield naphthalene, a hydrocarbon containing ten times as much carbon in the same volume: $10\text{CH}^4 = \text{C}^{10}\text{H}^8 + \text{H}^2$ viz. by enclosing the marsh-gas in a tube of very refractory glass, and keeping it for several hours at a temperature as near as possible to that at which Bohemian glass softens. The condensation may also be effected by subjecting the vapour of bromoform, CHBr^3 (tribrominated methylic hydride), to the action of copper at a red heat, so as to remove the bromine. The residue, CH , then suffers a six-fold condensation, yielding benzene, C^6H^6 .

b. By the union of two simple molecules into a more complex molecule. Thus, when a mixture of marsh-gas and carbonic oxide is slowly passed through a tube heated to low redness, tritylene, C^3H^4 , is produced:

This reaction may perhaps explain the formation of a small quantity of tritylene in the distillation of formate of barium; and it is doubtless to reactions of the same order that we may attribute the production of hydrocarbons of the same series, which has been experimentally demonstrated as high as amylene, in the distillation of acetates.

There are also other ways in which complex hydrocarbons may be built up by the union of those of more simple constitution. Wurtz has shown (Ann. Ch. Pharm. cxliii. 202; cxlvii. 56), that amylene, C^5H^{10} , may be produced by the union of the alcohol-radicles ethyl and allyl:

this combination being brought about by the mutual action of zinc-ethyl and iodide of allyl. A number of other hydrocarbons are, however, formed at the same time, the following having been isolated and analysed:

C^2H^4	C^3H^4	C^4H^{10}	C^5H^{12}	C^6H^{16}	C^8H^{20}
Ethylene.	Tritylene.	Amylene.	Hydride of amyl.	Allyl.	Decatylene.

The ethylene and tritylene are produced by the mutual action of the ethyl and allyl groups:

Decatylene, $\text{C}^{10}\text{H}^{20}$, results from the condensation of two molecules of amylene into one. Besides these compounds, there are also formed other hydrocarbons, boiling above 200° (decatylene, the least volatile of those above-mentioned, boils at 160°), and containing, like allyl, a smaller proportion of hydrogen than the olefines. The formation of these hydrocarbons explains that of hydride of amyl, in which the proportion of hydrogen is larger than in the olefines.

The hydrocarbon, C^4H^{10} , obtained in the reaction just described, possesses the principal physical and chemical properties of amylene produced from amylic alcohol by the action of chloride of zinc, and, therefore, is not merely an isomer (ethyl-allyl) of that compound. This formation of amylene from two hydrocarbons of lower molecular weight is analogous to that of chloride of heptyl, $\text{C}^7\text{H}^{15}\text{Cl}$, by the action of chlorine on ethyl-amyl, $\text{C}^2\text{H}^5\text{C}^3\text{H}^5$, and of chloride of decatyl, $\text{C}^{10}\text{H}^{20}\text{Cl}$, by that of chlorine on amyl itself, observed by Schorlemmer.

HYDROCARBOXYLIC ACIDS. (Lerch, Ann. Ch. Pharm. cxiv. 20; Rép. Chim. pure, 1863, p. 143; Jahresh. 1862, p. 276.)—This name is applied to three acids produced, together with others, by the decomposition of carboxide of potassium, the black amorphous substance formed in the preparation of potassium in the ordinary way, and likewise by the direct combination of potassium with carbonic oxide. This substance remains unaltered when kept in rock-oil or in a dry vacuum, but when exposed to the air, it absorbs moisture rapidly, acquiring a cherry-red and finally a yellow colour: it absorbs oxygen only when moist. When treated with water, alcohol or ether, out of contact with the air, it gives off gas, and leaves a black glutinous substance, which turns red on exposure to the air, and dissolves in water with red colour and without disengagement of gas. This mass yields, besides oxalic acid, three series of acids, including croconic acid (ii. 109).

Perfectly unaltered carboxide of potassium, to which Brodie assigns the formula $\text{C}^3\text{H}^4\text{K}$, yields, when treated with hydrochloric acid, an acid crystallising in white needles and having the composition $\text{C}^3\text{H}^4\text{O}^3$; this is trihydrocarboxylic acid.

If the carboxide of potassium be first treated with alcohol and then with hydrochloric acid, it yields black needles of dihydrocarboxylic acid, $\text{C}^3\text{H}^4\text{O}^2$ or $\text{C}^3\text{H}^4\text{O}^3$.

If the air has had access to the mass before or after the treatment with alcohol, it afterwards yields, with hydrochloric acid, dark garnet-red crystals of hydrocarboxylic acid, $C^{10}H^8O^{10}$.

Lastly, if the mass has been left in contact with the air till it has turned quite red, and it is then treated with hydrochloric acid, a fourth acid is obtained, called carboxylic acid, the potassium-salts of which are composed according to the formulæ $C^8HK^2O^{10}$ and $C^8K^2O^{10}$. On attempting to isolate this acid, fine colourless prisms of rhodizonic acid, $C^8H^4O^8$, are obtained, being derived from the preceding by fixation of water, and splitting up of the molecule :

In addition to these acids, croconic acid, $C^8H^2O^8$ (formed from carboxylic acid by division of the molecule), and oxalic acid, are obtained as final products of the oxidation.

The formation of dihydrocarboxylic, hydrocarboxylic, and carboxylic acids by oxidation of trihydrocarboxylic acid is represented by the following equations :

Trihydrocarboxylic acid. $C^{10}H^{10}O^{10} = \left. \begin{smallmatrix} C^{10}H^8O^8 \\ H^2 \end{smallmatrix} \right\} O^2$.—This acid is produced, as already observed, by the action of hydrochloric acid on carboxide of potassium which has not been exposed to the air; also by the reduction of dihydrocarboxylic acid. It forms white silky needles which, when exposed to moist air, quickly turn red, and are ultimately converted into dihydrocarboxylic acid. Its solution is acid, colourless, and very sensitive to the action of oxidising agents. By nitrate of potassium, it is converted into oxycarboxylic acid, with evolution of nitrogen. Of the 10 at. hydrogen contained in its molecule, 6 at. are easily removed by oxidation, giving rise to new radicles, viz. those of dihydrocarboxylic, hydrocarboxylic and carboxylic acids, whereas the remaining 4 at. are basic, and easily replaceable by metals, but not removable by oxidation. In the potassium-salt also, $C^{10}K^2O^{10}$, 6 at. K may be removed, two at a time, by oxidation, whereas the remaining 4 at. K appear to be irremovable: hence the rational formula of the acid above given. In like manner, dihydrocarboxylic acid contains 4 at., and hydrocarboxylic acid, 2 at. H, removable by oxidation.

The trihydrocarboxylates of the alkali-metals are soluble in water, the other salts are sparingly soluble or insoluble: they all become coloured by exposure to the air, yielding salts of the following acids :

Dihydrocarboxylic acid. $C^{10}H^8O^{10} = \left. \begin{smallmatrix} C^{10}H^6O^8 \\ H^2 \end{smallmatrix} \right\} O^2$.—This acid forms black metallic-shining monoclinic crystals, grouped in very thin tufts; the thinner crystals have a wood-yellow colour, and exhibit trichroism. They are permanent in the air, even at 100°, dissolve readily in water and alcohol, slowly in ether; the solutions are red by transmitted, violet by reflected light.

The salts of this acid are as unstable as those of the preceding. Those of the alkali-metals are black, soluble in water and crystallisable; the rest are blue or red precipitates; they are very easily converted by oxidation into rhodizonates or carboxylates.

Hydrocarboxylic acid, $C^{10}H^6O^{10} = \left. \begin{smallmatrix} C^{10}H^4O^8 \\ H^2 \end{smallmatrix} \right\} O^2$, was obtained accidentally in the preparation of the preceding acid from a black mass which had undergone partial alteration. It crystallises from alcohol in long brown needles, which in contact with water are immediately resolved into dihydrocarboxylic and rhodizonic acids :

HYDROCAROTIN. $C^{10}H^{10}O$. (Husemann, Ann. Ch. Pharm. cxvii. 200; Jahresber. 1861, p. 754).—A substance contained, together with carotin (i. 805), in the root of the carrot (*Daucus carota*). To obtain these substances, the crushed carrots are pressed, the residue is repeatedly washed out with water, and the united solutions are mixed with a little dilute sulphuric acid and tincture of galls (which facilitates the separation of the coagulum); the glutinous precipitate, freed by pressure from the enclosed liquid, is boiled six or seven times in the half-dry state with 5 or 6 vol. of alcohol of 80 per cent.; and the residue is treated with sulphide of carbon to extract the carotin. The alcoholic extract contains hydrocarotin together with mannite (if the carrots are a year old, but not if they are fresh), sugar, a fixed oil, and a small portion of carotin.

Hydrocarotin crystallises from the alcoholic extract, after long standing, in laminar crystals, which may be freed from mannite (if present) by recrystallisation from

hot alcohol, and finally by boiling with water. It is tasteless and inodorous, crystallises in large colourless silky laminae, from ether in flat rhombic prisms; is lighter than water (which does not wet it); melts at 126.8° ; dissolves in alcohol, and more easily in ether, sulphide of carbon, benzene, volatile oils, and chloroform. When heated above 100° , it turns yellow to yellowish red; after fusion it remains amorphous, and then dissolves less easily in benzene and sulphide of carbon.

Hydrocarotin is not precipitated from its alcoholic solution by metallic salts or tannic acid; it is not altered by the action of caustic alkalis, strong acids, or oxidising agents: with *fuming nitric acid*, it appears to form a nitro-compound. Strong sulphuric acid colours it red and dissolves it completely at a gentle heat, forming a solution from which it is precipitated by water apparently unaltered, but in the amorphous state. With *chlorine* it forms a resinous substitution-product, $C^{10}H^{12}Cl^2O$; with *bromine* a similar body, $C^{10}H^{12}Br^2O$, whose ethereal solution, when treated with alcoholic potash, gives up bromine, and forms a yellowish-red substance soluble with blood-red colour in sulphide of carbon. *Iodine* also, in sunshine, appears to form a substitution-product with hydrocarotin.

HYDROCERITE. See LANTHANITE.

HYDROCHINONE. See HYDROQUINONE.

HYDROCHLORE. See PYROCHLORE.

HYDROCHLORIC ACID. See CHLORHYDRIC ACID (i. 890).

HYDROCHRYSAMIDE. $C^7H^8N^2O^2$. (Schunck, Ann. Ch. Pharm. lxx. 231.)—A compound produced by the action of reducing agents on chrysammic acid (i. 965). It may be prepared by adding chrysammic acid to a boiling solution of sulphide of potassium containing excess of caustic potash; or to a boiling solution of protochloride of tin, afterwards removing the excess of acid, dissolving the residue in boiling potash, and leaving the solution to crystallise. It is difficult, however, by the latter method to obtain it free from oxide of tin.

Hydrochrysamide forms needle-shaped crystals, of a fine blue colour by transmitted, and metallic red by reflected light. Heated in a small tube, it gives off violet vapours, which condense in crystals on the cold parts of the tube; the greater part, however, is decomposed, giving off ammonia and leaving charcoal. It is insoluble in boiling water, and sparingly soluble in boiling alcohol, to which it imparts a faint blue tint. It is dissolved by strong sulphuric acid, and reprecipitated in blue flakes by water.—It is decomposed by boiling nitric acid, and by chlorine in presence of water. It dissolves in potash and in alkaline carbonates, forming solutions of the colour of sulphindigotic acid; acids precipitate it therefrom in blue flakes.

HYDROCINNAMIDE. $C^9H^9N^2 = N^2(C^8H^8)^2$. *Cinnhydramide*. *Hydride of Azocinnamyl*. (Laurent, Rev. scient. x. 119.)—Produced by the action of ammonia on hydride of cinnamyl:

When purified by recrystallisation from hot alcohol and ether, it forms colourless right prisms with rectangular base, but having their bases replaced by two triangular facets, meeting at a very obtuse angle. It is inodorous, insoluble in water, fusible, and solidifies on cooling to a transparent amorphous mass like gum. It is decomposed by distillation, yielding an oil and a solid substance. It is not decomposed by boiling hydrochloric acid, or by alcoholic potash; but boiling nitric acid decomposes it, yielding a product which melts in boiling water.

Dumas and Peligot, by treating oil of cinnamon with dry ammonia gas, obtained a product which crystallised from alcohol and ether in silky tufts, and to which they assigned the formula $C^9H^8O.NH^3$, but it probably consisted mainly of hydrocinnamide. (Gerhardt's *Traité*, iii. 385.)

HYDROCOTYLE ASIATICA. A plant used in India as a remedy against various cutaneous diseases. According to Leprie (J. Pharm. [3] xxviii. 47), it contains a peculiar principle, *vellarin* (from the Tamul name of the plant, *vallārai*), which he describes as a bitter, strong-smelling oil, soluble in weak alcohol and in ether, thickening on exposure to the air, soluble in aqueous ammonia, insoluble in potash.

HYDROCROCONIC ACID. $C^6H^4O^3 - \frac{C^6H^4O^3}{H^2} \cdot O^2$. (Lerch, Ann. Ch. Pharm. xxiv. 20.)—An acid produced by the action of hydriodic acid on croconate of potassium in closed vessels. On mixing the product of the reaction with alcoholic potash-solution, hydrocroconate of potassium, $C^6H^4K^2O^3$, separates as a dingy red precipitate, which crystallises from hot water in crimson needles. The blood-red solution of this

salt is converted into croconate (and a small quantity of oxalate) of potassium on exposure to the air, especially in presence of alkali.

Hydrocroconic acid is soluble in water, alcohol, and ether, and does not crystallise. The *barium-salt*, $C^2H^2Ba''O^2$, is a pæony-red precipitate, soluble in hydrochloric, insoluble in acetic acid. The *lead-salt*, $C^2H^2Pb''O^2$, is also a red precipitate.

HYDROCYANHARMALINE. See HARMALINE (p. 8).

HYDROCYANIC ACID. See CYANIDE OF HYDROGEN (ii. 214).

HYDRODOLOMITE. A hydromagnesite, having part of the magnesium replaced by calcium. Occurs on Somma in isolated, sinter-like, globular or stalactitic, earthy masses, having a white or yellowish white colour. According to Kobell (J. pr. Chem. xxxvi. 304), it contains 25.22 per cent. lime, 24.28 magnesia, 33.10 carbonic anhydride, and 17.40 water: whence the formula $3[(Mg; Ca)CO^3.H^2O] + Mg''H^2O^2$. (Ram-melsberg.)

HYDRO-ELECTRIC MACHINE. See ELECTRICITY (ii. 408).

HYDROFERRICYANIC ACID. See FERRICYANIDES (ii. 244).

HYDROFERROCYANIC ACID. See FERROCYANIDES (ii. 226).

HYDROFLUOBORATES. See BORON, FLUORIDE OF (i. 632).

HYDROFLUOSILICATES. See SILICON, FLUORIDE OF.

HYDROGALACTOMETER. An arrangement described by Zenneck (Jahrb. pr. Pharm. xx. 65; Jahresb. 1850, p. 619) for determining the amount of water added to normal milk. The milk is coagulated by a few drops of hydrochloric acid, and the volume of the curd, separated by filtration through flannel, is compared with that obtained in a similar manner from pure milk.

HYDROGEN. Atomic weight = 1. Symbol H. (*Inflammable air, Wasserstoff, Hydrogenium*).—The older alchemists do not appear to have been acquainted with this gas. The evolution of an air during the solution of iron in sulphuric acid was first noticed in the sixteenth century by Paracelsus. The inflammability of the air thus produced, was observed in the seventeenth century by Turquet de Mayerne, and afterwards (1672) by Boyle, in his "New Experiments touching the relation between Flame and Air." Lemery in 1700 observed the detonating property of this inflammable gas. But the first exact experiments on its nature were made in 1766 by Cavendish, who showed that it is a peculiar kind of air, which he called *inflammable air*; that it is produced when iron, zinc, or tin is dissolved in dilute sulphuric or hydrochloric acid; and that different metals evolve different quantities of the gas. He also estimated its specific gravity at $\frac{1}{5}$ of that of common air. (It is really about $\frac{1}{14}$.)

The inflammable air generated in these processes was, however, for some time confounded with other kinds of inflammable air, such as those produced by the destructive distillation of organic bodies, by the imperfect combustion of charcoal—with vapour of ether, &c., all of which were supposed to consist essentially of the same inflammable principle modified by the admixture of other substances. Moreover, it was supposed that the inflammable principle developed in the solution of metals in acids, proceeded from the metal, and that it was either phlogiston or intimately related thereto.

The production of moisture in the burning of hydrogen, appears to have been first noticed by Macquer and De la Metherie, in 1766; but no one at that time supposed that the only product of the combustion was water. Lavoisier supposed that hydrogen, like other combustible bodies, produced an acid in burning, and made several unsuccessful experiments to obtain this acid. But the grand discovery that water is the sole product of the combustion of hydrogen was made by Cavendish, in 1781, and published in 1783. Cavendish showed that 423 volumes of hydrogen required for combustion 1,000 volumes of air (which contain 210 volumes of oxygen) and will, therefore, burn exactly 420 volumes of hydrogen; and, moreover, that when hydrogen and oxygen gases are burnt together in certain proportions, nearly all the gas disappears, nothing but slight impurities remaining behind. These results were afterwards fully confirmed by the experiments of Lavoisier and Laplace (see GAS, ii. 780).

Sources.—Hydrogen is never found in the free state. The compound which contains it in the greatest abundance is marsh-gas, of which it forms one-fourth. Of water it forms one-ninth. It occurs in smaller quantities in combination with phosphorus, sulphur, iodine, bromine, carbon and nitrogen, and is an essential constituent of nearly all organic compounds.

Preparation.—Hydrogen is generally obtained by the decomposition of water, or of dilute acids.—1. It is produced in the state of greatest purity by electrolysis, as already explained in the article ANALYSIS OF GASES (i. 285).

2. By passing vapour of water over iron nails or wire contained in a gun-barrel, laid horizontally in a furnace, and heated to bright redness. The iron is thereby converted

into ferrous-ferrie oxide, $\text{Fe}^{\text{Fe}}\text{O}^{\text{Fe}}$, while hydrogen gas passes over, and may be collected over water.

3. By introducing potassium or sodium into an inverted tube or cylinder filled with water or alcohol, and standing in a vessel of the same liquid. It is best to wrap the metal in a piece of paper before plunging it under the mouth of the cylinder:

4. By dissolving zinc or iron in sulphuric acid diluted with an eight-fold quantity of water, or in hydrochloric acid diluted with twice its weight of water:

and

This is the most convenient method of obtaining the gas for general purposes.—5. By dissolving zinc, in contact with iron or platinum, in solution of caustic potash, zincate of potassium being then formed:

The use of the iron is to form an electric couple with the zinc, the latter then acting on the positive or active metal.

6. By acting on cuprous hydride with hydrochloric acid:

7. By heating formates or oxalates with excess of hydrate of potassium, sodium, or calcium:

8. By the action of hydrate of potassium on certain organic bodies having a tendency to form acids by oxidation:

Purification.—Hydrogen prepared by dissolving zinc or iron in sulphuric acid—which is the method most used—may contain the following impurities:—1. *Sulphurous acid*, if this acid is present in the sulphuric acid used.—2. *Nitrous oxide or nitric oxide gas*, if the sulphuric acid contains nitric oxide, nitrous acid, or nitric acid.—3. *Sulphydric acid*, if the zinc contains sulphide of zinc, or if the sulphuric acid contains sulphurous acid—or if a fresh quantity of strong sulphuric acid be added to the dilute acid already acting on the zinc, without mixing it well with the liquid.—4. *Phosphoretted hydrogen*, if the zinc contains phosphorus.—5. *Arsenetted hydrogen*, if the zinc contains arsenic, or if the sulphuric acid contains arsenious acid.—6. *Carbonic anhydride* has occasionally been observed in hydrogen prepared with peculiar kinds of zinc. These impurities, which give the gas an unpleasant odour, may be removed by passing it over substances which absorb or decompose the adventitious gases. Dumas passed the gas through two U-tubes, each about three feet long, and filled with broken glass, the glass in the first tube being moistened with nitrate of lead, which removes the sulphydric acid, and that in the second with sulphate of silver, by which the arsenetted hydrogen is separated; then through a third U-tube filled with fragments of pumice-stone saturated with strong potash; and, lastly, to render it anhydrous, first through a tube containing fragments of hydrate of potassium, then through another containing phosphoric anhydride or pumice-stone soaked in oil of vitriol. To avoid the presence of oxides of nitrogen, it is best to use sulphuric acid perfectly free from those oxides.

Hydrogen gas obtained by the use of iron may contain the same impurities as that prepared with zinc—and in addition:—1. *Ferruretted hydrogen*—to be removed by fuming nitric acid or solution of mercuric chloride; and 2. The vapour of an oily hydrocarbon, which is produced in larger quantity as the iron contains more carbon, and communicates a peculiarly repulsive odour to the gas. It may be removed by passing the gas through alcohol, and the alcohol may be afterwards separated by water.

According to Döbereiner (Schw. J. iii. 377), the gas obtained with either zinc or iron may be deprived of all odour by 24 hours' contact with moistened charcoal powder.

In whatever manner the gas may be prepared, it generally contains a small quantity of atmospheric air, proceeding from the liquids used in the preparation. The nitrogen cannot be removed; but the oxygen may be separated by leaving the gas for a while in contact with spongy platinum, which causes the oxygen to unite with a portion of the hydrogen and form water.

Properties.—Hydrogen is a colourless gas, of specific gravity 0.0693. It is the lightest of all known substances, being about $14\frac{1}{2}$ times as light as atmospheric air; it may therefore be used for inflating balloons. Soap-bubbles filled with it rise rapidly in the air. It escapes rapidly out of vessels with their mouths turned upwards; but a wide-mouthed vessel filled with it may be carried with its mouth downwards for a considerable distance without the gas escaping. For the same reason, it is easily collected by displacement, without the use of water, viz. by holding the vessel which is to receive it, over the extremity of a vertical tube attached to the mouth of the generating vessel.

Hydrogen is odourless when quite pure, but as usually prepared, it has a disagreeable odour, arising from impurities. Small animals introduced into the gas die instantly. In man, the pure gas excites, after two inspirations, disagreeable sensations and loss of muscular power; when mixed with air, it may be breathed for a longer time, but imparts a peculiar squeaking tone to the voice. It is not directly injurious, but so long as it is inhaled, oxygen gas, which is essential to life, is prevented from entering the lungs.

Hydrogen is very inflammable, and burns in the air with a pale blue flame. It does not support the combustion of those bodies which burn in the air: for instance, if a jar full of hydrogen be held with its mouth downwards, and a lighted taper plunged into it, the hydrogen will be set on fire at the mouth, but the taper will be extinguished. A jet of oxygen will, however, burn in hydrogen, as well as a jet of hydrogen in oxygen, though with a somewhat different appearance. The experiment may be made by setting fire to hydrogen-gas at the mouth of a bottle, and then directing a jet of oxygen through the flame into the body of the gas. A flame will then be formed at the orifice of the jet, and will continue to burn till the hydrogen is exhausted.

Hydrogen and oxygen unite to form water, in the proportion of 2 volumes of hydrogen to 1 volume of oxygen; and when the gases are mixed in these proportions, they may be made to unite, either slowly or rapidly, the entire volume of gas disappearing. On bringing a burning body in contact with the mixture, or passing an electric spark through it, combination instantly takes place throughout the whole mass, attended with great and sudden rise of temperature, whereby the mixed gases, or rather the watery vapour resulting from their union, are expended with a force sufficient to shatter the containing vessel, if not of great strength. If the vessel is entirely closed, and strong enough to resist the expansive force of the gas, no noise is heard; but if the mouth of the vessel be left open, or the gas be able to force for itself a passage into the air, a loud detonation is the result, arising from the concussion of the air by the escaping gases. The same effect is produced, though with much less intensity, when a mixture of 2 vol. hydrogen and 5 vol. atmospheric air (containing 1 vol. oxygen, the quantity required to unite with 2 vol. hydrogen) is exposed to the action of flame or the electric spark. Hence, in manipulating with hydrogen, great care must be taken to prevent accidental admixture of air, as, if such admixture takes place unknown to the operator, explosions of dangerous character may ensue when the gas comes in contact with flame. In collecting the gas, a considerable quantity should be suffered to escape before any of it is collected, so that the air in the apparatus may be completely eliminated.

The rapid combination of hydrogen and oxygen may be brought about, not only by the contact of flame, but also by the heat of a red-hot iron wire, or a coal hot enough to exhibit a visible glow by daylight. According to Biot (Gilb. Ann. xix. 99), the heat produced by suddenly compressing the detonating gas, is sufficient to cause the explosion.

The presence of certain metals causes the gases to unite, even at ordinary temperatures. This effect is exhibited most strikingly by platinum, in the form of platinum-sponge or platinum-black (see PLATINUM); but it is also produced by a plate of the metal rendered perfectly clean by rubbing it while hot with fused potash, then washing it with water, dipping it into hot oil of vitriol, and again washing with water. Similar effects are exhibited, though with less facility, by spongy iridium and osmium, finely divided palladium, gold in the form of leaves or dust, and silver leaf. This peculiar action of platinum and other metals appears to be due (in part at least) to the absorption of the gases by the metal, and their condensation within its pores. (See GASES, ABSORPTION OF, BY SOLIDS, ii. 804.)

The flame of hydrogen, though but feebly luminous, is intensely hot, and when a jet of oxygen is directed through it, as in the oxy-hydrogen blowpipe, the proportions of the two gases being properly adjusted so that neither of them is in excess, the heat

produced is the highest that can be obtained by chemical combination. (See *BLOW-PIPE, OXY-HYDROGEN*, i. 616.)

Hydrogen likewise unites very energetically with *chlorine*, forming hydrochloric acid. The gases, in equal volumes, may be mixed in the dark without uniting, but on exposure to diffused daylight, combination takes place gradually, and exposure to the direct rays of the sun, or to the light of the electric arc, or of lime ignited by the oxy-hydrogen flame, causes instant combination, attended with violent explosion. Explosion is also produced by contact with flame, or with a brick heated to 150°C . With *bromine-vapour*, hydrogen does not unite at ordinary temperatures, even in sunshine; but partial combination is effected by contact with a red-hot wire. With *iodine*, it unites when a mixture of hydrogen and iodine-vapour is passed through a red-hot tube, and, according to Blundell (Pogg. Ann. ii. 216), at ordinary temperatures under the influence of spongy platinum. With other elements hydrogen does not unite directly.

Hydrogen is an essential constituent of acids—properly so called—these bodies being in fact salts of hydrogen. (See *ACIDS*, i. 39.) It also forms basic compounds, viz. ammonia, arsenetted, antimonetted hydrogen, &c.; and unites with metals and organic radicals, forming compounds called hydrides (p. 180).

HYDROGEN, CHLORIDE OF. See CHLORHYDRIC ACID (i. 890).

HYDROGEN, FLUORIDE OF. See FLUORHYDRIC ACID (ii. 669).

HYDROGEN, IODIDE OF. See IODHYDRIC ACID.

HYDROGEN, OXIDES OF. Hydrogen forms two, or perhaps three, compounds with oxygen, viz. the *Protoxide* or water, H^1O ; the *dioxide* or *peroxide*, H^2O^2 , and perhaps *Ozone*, which according to Baumert is a *trioxide* of hydrogen, H^3O^3 .

Water. H^1O .—The properties of water will be described in a separate article; we shall here speak only of its composition. We have already stated that when pure oxygen and pure hydrogen are mixed in the proportion of 2 vol. H to 1 vol. O, and exploded, the entire volume of gas disappears and nothing is produced but water. Now the density of oxygen is 16 times as great as that of hydrogen: hence water is composed, by weight, of 8 pts. of oxygen to 1 pt. of hydrogen. This composition has hitherto been most generally represented by the formula HO , water being thus regarded as a compound of hydrogen and oxygen in equal numbers of atoms, and the atom of oxygen being supposed to weigh 8 times as much as that of hydrogen. But there are many reasons for supposing that a molecule of water contains 2 at. of hydrogen united with 1 at. of oxygen—a composition represented by the formula

H^2O or H^2O . These reasons have already been given in the article *ATOMIC WEIGHTS* (i. 461), and need not here be repeated. We will merely mention that, according to the formula H^2O , the atomic weights of oxygen and hydrogen are to one another as the densities of the two gases, which is the most simple supposition that can be made respecting them, and is in accordance with the conclusions deduced from the dynamical theory of heat (p. 132).

The composition of water by weight and volume may be ascertained in various other ways, besides the direct combination of the component gases. When water is decomposed by electrolysis, the gases are evolved very nearly in the proportion of 2 vol. H to 1 vol. O, but the volume of oxygen is always somewhat less than it should be on account of its greater absorbability in water. The composition might also be ascertained by passing vapour of water over red-hot iron, measuring the volume of the hydrogen evolved, and determining the increase in weight of the iron.

But the most exact method is that adopted by Berzelius and Dulong (Ann. Ch. Phys. [2] xv. 86) and by Dumas (Ann. Ch. Phys. [3] viii. 189), which consists in passing pure and dry hydrogen gas, obtained as described at p. 193, over red-hot oxide of copper. This oxide then gives up its oxygen to the hydrogen, and forms water, which is collected, partly in a small receiver attached to the end of the tube containing the oxide of copper, partly in a tube containing dry chloride of calcium. The quantity of water thus produced is weighed, and the loss of weight which the oxide of copper sustains by parting with its oxygen, is likewise determined. These experiments show that water is composed exactly in the proportion of 8 pts. by weight of oxygen to 1 pt. of hydrogen:

Calculation.				Dumas.		Berzelius and Dulong	
H^2	2	11.11		11.11		11.1	
O	16	88.89		88.89		88.9	
H^2O	18	100.00		100.00		100.0	

For the compounds of water, see *HYDRATES* (p. 179).

Dioxide, or Peroxide of Hydrogen. HO or H^2O^2 .—This remarkable compound was discovered by Thénard (*Traité de Chimie*, 4^{me} éd. iv. 2, 41).—It is produced when peroxide of potassium, sodium, barium, strontium, or calcium is digested in any acid which forms a soluble salt with the base resulting from the decomposition of the peroxide, the excess of oxygen not escaping as gas, but passing over to a portion of the water, and converting it into peroxide of hydrogen, e.g.:

Preparation.—Pure baryta is prepared by igniting, in a porcelain retort, nitrate of barium free from iron and manganese. The baryta, broken into pieces about the size of a nut, is then put into a coated glass tube and heated to low redness, while a current of oxygen gas free from carbonic acid and dried by means of quicklime, is passed over it. For the first eight minutes the gas is eagerly absorbed by the baryta. After it has begun to escape from the farther end of the tube (to which a gas delivery-tube passing under water is fitted), the stream is still kept up for the space of ten or fifteen minutes. The peroxide of barium obtained by this process is, after cooling, preserved in a bottle. In the next place, 200 grms. of water are mixed with as much hydrochloric acid as will neutralise about 15 grms. of baryta. Into this liquid, contained in a cylinder, or better, in a dish of silver or platinum kept cool by surrounding it with ice, 12 grms. of peroxide of barium, slightly moistened and rubbed up in an agate mortar, are introduced by means of a wooden spatula: on agitating or stirring the liquid with the pestle, the whole dissolves completely and without effervescence. The baryta is next precipitated by sulphuric acid, added drop by drop till slightly in excess: the presence of an excess of the acid may be known by the sulphate of barium falling down more quickly than before. 12 grms. more of the peroxide are then dissolved in the same liquid, and likewise precipitated by sulphuric acid. The liquid, which now contains hydrochloric acid, sulphuric acid, a large quantity of water, and a small quantity of peroxide of hydrogen, is next separated by filtration from the sulphate of barium, the precipitate washed with a little water, and the last wash-water retained for future washings. The filtrate is again mixed, as above, twice with peroxide of barium, and twice with sulphuric acid. The filtration is then repeated, and the process continued in the same way, till 90 or 100 grms. of the peroxide are consumed. The liquid thus obtained would, on decomposition, yield from 25 to 30 measures of oxygen gas. To separate silica, alumina, sesquioxide of iron, sesquioxide of manganese, &c., which proceed from the porcelain retort in which the nitrate of baryta was ignited, the liquid is mixed with concentrated solution of phosphoric acid (2 or 3 pts. of phosphoric acid to 100 pts. of peroxide of barium)—then surrounded with ice, and supersaturated with pounded peroxide of barium: silica and the phosphates of iron, manganese, and aluminium then separate rapidly in flakes, and must be separated from the liquid by filtration through linen, and if necessary through paper. The presence of a large quantity of sulphate of barium renders the filtration difficult. (If no phosphoric acid were present, the sesquioxides of iron and manganese would fall down by themselves, and give rise to a rapid evolution of oxygen gas; but when they are mixed with phosphoric acid, they do not produce this effect.) Should the liquid still contain portions of these oxides, they must be separated by the addition of a slight excess of baryta-water; whereupon, the liquid must be immediately and rapidly filtered through several filters at once, and the filters squeezed between linen to get all out. The whole of the baryta must then be separated by carefully adding sulphuric acid in very slight excess, and filtering. The filtrate now contains nothing but water, peroxide of hydrogen, hydrochloric acid, and a very little sulphuric acid. To separate the hydrochloric acid, the liquid is surrounded with ice, and mixed with sulphate of silver. In the first place, sulphate of silver, obtained by heating nitrate of silver in contact with oil of vitriol in a platinum crucible, is introduced in the form of powder into the liquid—the whole being constantly stirred till the liquid becomes clear, a sign that the hydrochloric acid is wholly or nearly precipitated. Any hydrochloric acid that may still remain must be separated by cautiously adding more sulphate of silver. If the latter has been added in excess, it must be precipitated by carefully dropping in a dilute solution of chloride of barium. The liquid should contain neither hydrochloric acid nor silver, and should therefore give no precipitate either with solution of silver or with hydrochloric acid. The chloride of silver is separated by filtration and pressure, any portion of liquid which comes through turbid being filtered over again. To remove the sulphuric acid also, and obtain a pure mixture of water and peroxide of hydrogen, the liquid is placed in a glass mortar surrounded with ice, and rubbed up with slaked baryta previously pounded and diffused through water: the baryta is added till the sulphuric acid is very nearly saturated. The liquid is then filtered, the filter pressed between linen, and baryta-water added in slight excess. This often occasions the precipitation of oxide of iron and oxide of manganese, as well as sulphate of barium; hence the filtration

must be rapidly performed. The excess of baryta is removed by cautiously adding dilute sulphuric acid, so that there may be rather a very slight excess of the acid than of the baryta. The whole of the sulphuric acid may likewise be removed by means of carbonate of barium obtained in a finely-divided state by precipitation, instead of by slaked baryta and baryta-water. Finally, to separate the whole or nearly the whole of the water, the vessel containing the liquid is placed in a dish containing oil of vitriol, and the whole placed under a receiver of the air-pump; the water then evaporates before the peroxide of hydrogen. The fluid is agitated from time to time. If it should deposit flakes of silica, which give rise to the escape of oxygen gas, it must be decanted off from them by means of a siphon: if it should evolve oxygen—which it will do as soon as it is so far concentrated as to contain about 250 times its volume of oxygen—two or three drops of sulphuric acid must be added to it. The concentration must be stopped after a few days, when the liquid is brought to such a state that when decomposed it would evolve 475 volumes of oxygen gas; for this residue, if left longer in vacuo, would evaporate as a whole. The peroxide of hydrogen must be kept in long glass tubes closed with stoppers and surrounded with ice; but, even under these circumstances, it decomposes slowly and evolves oxygen gas. (Thénard.)

2. Peroxide of barium is decomposed by hydrated hydrofluoric acid or solution of hydrofluosilicic acid, the whole being kept constantly cool: in this case, insoluble fluoride of barium or double fluoride of silicium and barium separates at once. As soon as sufficient quantities of acid and peroxide of barium have been mixed, the peroxide of hydrogen, still containing a large quantity of water, is filtered from the precipitate and concentrated in vacuo over oil of vitriol. (Pelouze, *Berz. Lehrb.* i. 411.)

Properties.—Colourless transparent liquid, of specific gravity 1.462; it does not freeze at -30° ; evaporates in vacuo at ordinary temperatures without decomposition, though much less readily than water; does not redden litmus, but gradually bleaches both litmus and turmeric paper; has a harsh, bitter taste, similar to that of tartar-emetic; whitens the tongue and thickens the saliva; when placed upon the hand, it instantly turns the cuticle white, and after a time produces violent itching. (Thénard.)

Peroxide of hydrogen is miscible in all proportions with water, part of the water freezing out on exposure to cold. A solution containing eight times its own volume of oxygen gas begins to evolve gas at 50° , and subsequently gets into a state of violent ebullition, and when this has ceased, nothing is left but water. The peroxide likewise unites with acids, e.g. phosphoric, sulphuric, hydrochloric, nitric acid, &c., forming mixtures in which it is less easily decomposable than when alone.

It is doubtful whether peroxide of hydrogen has ever been obtained quite free from water. Thénard, however, found in a specimen prepared as above described, 6.02 per cent. hydrogen, and 93.98 oxygen, the formula HO requiring 5.88 H, and 94.12 O.

Decompositions.—The second atom of oxygen is retained by the hydrogen very loosely. Under various, and often enigmatical circumstances, it separates from the water in the form of gas, the volume of which at 14° and 0.76^m. bar. (29.8 inches) amounts to 475 times that of the liquid. The gas often escapes with such rapidity as to produce violent effervescence, and even explosion. Great heat is also developed, and when the experiment is made in the dark, even light is apparent.

The several modes of decomposition are as follows:—

1. In the circuit of the voltaic battery, peroxide of hydrogen, like water, is gradually resolved into hydrogen at the negative and oxygen at the positive pole—only that the proportion of oxygen is greater than in the decomposition of water. (Thénard.)

2. By a certain elevation of temperature. At freezing temperatures, peroxide of hydrogen is but very slowly decomposed; at ordinary temperatures, it merely evolves a bubble of oxygen now and then, the decomposition not being complete for months; at 20° the escape of gas becomes more perceptible. By suddenly raising the temperature to 100° , this gradual escape of gas may be converted into a kind of explosion. Finally, there remains behind nothing but pure water. Sunshine does not appear to accelerate the decomposition at ordinary temperatures. (Thénard.)

3. By contact with certain substances, which either remain unaltered, or take up part of the oxygen of the peroxide, or on the contrary themselves evolve oxygen.—The rapidity with which these substances induce the separation of oxygen from the peroxide depends partly on their chemical nature, partly on the minuteness of their mechanical division: the further this is carried, the more rapid is the action. (Thénard.)

a. Peroxide of hydrogen, whether pure or in aqueous solution, acts as a powerful oxidising agent. It converts arsenious acid into arsenic acid, sulphurous acid into sulphuric acid, sulphide of lead into sulphate of lead, and the hydrated protoxides of manganese, iron and cobalt, into the peroxide and sesquioxides respectively. The protoxides of barium, strontium, and calcium are transformed into the corresponding

peroxides, which, being insoluble, are precipitated. The concentrated solution of hydrogen acts with great violence upon certain of the elements, as arsenic, molybdenum, chromium, &c., converting them at once into their higher oxides.

b. Certain bodies, among which are included charcoal, many metals, and some metallic oxides, induce, by their mere contact, a more or less violent decomposition of the peroxide into water and oxygen, without themselves undergoing any change; gold, platinum, and silver, particularly when in the precipitated or spongy state, act most violently, and cause a great disengagement of heat. A slightly acid solution of the peroxide is less amenable to the action of these agents than is the pure aqueous solution; alkalis on the other hand facilitate the decomposition. The action of the above-mentioned bodies in causing the decomposition of the peroxide is termed catalytic. Its nature, however, is not at present understood.

c. But the most remarkable circumstance connected with peroxide of hydrogen is its property of acting as a reducing agent. When peroxide of hydrogen, or its analogue, peroxide of barium, is added to any one of the following substances, namely, the protoxides of silver or mercury, the peroxides of manganese or lead, the chromic, permanganic, and ferricyanic acids, or their salts, not only is oxygen evolved from the peroxide of hydrogen, but also from the other oxidised body. Several of these reactions were noticed by Thénard in 1818, but they were first minutely examined and explained by Brodie in 1850 (Phil. Trans. 1850, p. 759; Chem. Soc. Qu. J. iv. 194; further, Chem. Soc. Qu. J. vii. 304). In accordance with his views, it seems that the second atom of oxygen in the peroxides of hydrogen and barium is not merely retained in an unstable state of combination, but that it is, by association with the oxide of an electro-positive element, like hydrogen or barium, thrown into a polar state, opposite to the polar state of the oxygen in unstable protoxides, and to that of the loosely combined oxygen in the more or less chlorous peroxides. Hence when the peroxide of hydrogen or barium is brought into relation with one or other of these oxygenised compounds, the two oppositely polarised oxygens unite with one another, as indicated in the following formulæ:—

Brodie has shown that, in the third and fourth reactions, the amounts of oxygen set free correspond exactly with the above expressions. In the other two reactions, some additional oxygen is set free catalytically, from the decomposition of the peroxide *per se*. For finely-divided metallic silver has the property of decomposing peroxide of hydrogen catalytically, whence the oxygen liberated according to the second equation has not been found to constitute more than 49, instead of 50, per cent. of the total quantity of oxygen evolved. It is observable that in no case can the oxygen from the peroxide constitute less than one-half of the total oxygen liberated. The above reactions are perfectly comparable with admitted reactions showing the formation of hydrogen and the alcohol-radicles (see CHEMICAL AFFINITY i. 857), for example:—

Schönbein, apparently unaware of Brodie's researches, has recently drawn attention to the phenomena of deoxidation effected by the peroxides of hydrogen and barium, and has shown that ozone is rendered inactive by them. He regards ozone as permanently negative oxygen, $\overset{-}{\text{O}}$, which can form ozonides of silver, of manganous oxide, &c., and, in the above reaction, is neutralised by the permanently positive oxygen, $\overset{+}{\text{O}}$, of the peroxide of hydrogen; whereas, according to Brodie, the polarity of the oxygen depends upon the nature of the body with which it is associated, and is manifested only at the instant of its disassociation. (Schönbein, Verhandl. d. naturf. Gesellsch. in Basel. ii. 113, 463, 472; Ann. Ch. Pharm. cviii. 157; J. pr. Chem. lxxvii. 257, 263; lxxx. 266, 275; lxxxi. 1; lxxxiii. 86; Jahresber. 1858, p. 58; 1859, p. 66; 1860, p. 54; 1862, p. 96.)

Schönbein has confirmed the observations of Meidinger and others, that peroxide of hydrogen may sometimes be detected in water which has undergone electrolysis. He seems also to have shown that traces of peroxide of hydrogen are produced in man-

the oxidation occurring in the presence of moisture; for example, those of iron, copper, zinc, &c. This production of peroxide of hydrogen he considers to be representative of the other oxidation. Thus when moist zinc-filings are oxidised by exposure to air, a quantity of peroxide of hydrogen, which may be dissolved out by water and submitted to chemical tests, is formed, according to the following equation:

Peroxide of hydrogen, even in a very dilute state, may be recognised either by its oxidising or by its reducing properties. Thus it decolorises a solution of indigo, especially in the presence of sulphate of iron, which apparently serves to convey the oxygen from the peroxide to the indigo; and similarly it liberates iodine from a solution of iodide of potassium, starch, and sulphate of iron. On the other hand, it decolorises a solution of permanganate of potassium by reduction, and causes a blue precipitate in a solution containing sesquichloride of iron and ferrieyanide of potassium. It eventually reduces chromic acid to the state of chromic hydrate, but its first action is to produce, by oxidation, a very unstable perchromic acid. This compound, which has a deep blue colour, is readily soluble in ether, and its ethereal solution has a certain degree of stability; so that the presence of peroxide of hydrogen in any liquid may be ascertained by mixing it with ether, and then adding a few drops of a solution of chromic acid, whereby the ether assumes a bright blue colour.

The compound radicle, peroxide of hydrogen H_2O_2 , is equivalent to the simple radicle chlorine Cl , and in a great number of reactions is exchangeable for chlorine and its congeners. One of the most generally useful modes of oxygenating different compounds consists in first substituting a halogen in exchange for hydrogen, and then, by means of water, substituting peroxide of hydrogen in exchange for the halogen. Thus, by the action of bromine upon acetic acid, we obtain bromoacetic acid:—

Then, by the action of water upon bromacetic acid, we obtain glycollic, or oxyacetic acid:—

(Odling's Manual of Chemistry, p. 124.)

Trioxide of Hydrogen. $\text{H}^{\circ}\text{O}^{\circ}_3$.—This, according to Baumert (Pogg. Ann. lxxxix. 38), is the composition of OZONE (*q. v.*)

HYDROGEN, PHOSPHIDES OF. Three of these compounds are known, viz. phosphoretted hydrogen gas, PH_3 , liquid phosphide of hydrogen, PH_2 , and the solid phosphide, P^{H} .

1. **Phosphoretted Hydrogen or Phosphamine.** PH³.—This gas, the analogue of ammonia, is produced by the spontaneous decomposition of phosphorised organic bodies, decaying fish for example. Its natural evolution appears to be the cause of *ignis fati* and similar luminous appearances. The gas is also liberated in many chemical reactions, but it is very difficult to obtain pure, being always mixed with a greater or lesser proportion of free hydrogen, and frequently with the vapour of liquid phosphide of hydrogen, which renders it spontaneously inflammable, a property which it does not possess when free from the liquid phosphide. The spontaneously inflammable gas was discovered in 1789 by Gengembre (Crell. Ann. i. 450), and the non-spontaneously inflammable gas by Davy some years later.

Production of the spontaneously inflammable gas. 1. The compounds of phosphorus with the alkali-metals are resolved, in contact with water, into an alkaline hypophosphite and phosphoretted hydrogen. An impure phosphide of calcium is generally used for the purpose, prepared by heating phosphorus with lime (i. 719). When it is thrown into water, spontaneously inflammable phosphoretted hydrogen is slowly liberated, and the bubbles of gas, as they reach the surface, take fire, burn with a highly luminous flame, and produce thick clouds of white smoke, which, in a quiet atmosphere, ascend in the form of successive gradually expanding rings.

2. Phosphide of zinc, tin, or iron, with aqueous sulphuric or hydrochloric acid, yields metallic sulphate or chloride and phosphoretted hydrogen gas.

3. Phosphorus heated in an aqueous solution of a fixed alkali, yields phosphoretted hydrogen gas, together with a hypophosphite and phosphate of the alkali-metal. Such an action is exerted by potash, soda, lithia, baryta, strontia, and lime, and, according to Raymond, by oxide of zinc and protoxide of iron. The primary decomposition yields phosphoretted hydrogen and hypophosphite; thus with lime-water:—

But from the very beginning of the action, the phosphoretted hydrogen gas is mixed with more or less free hydrogen, and there is likewise a certain quantity of phosphate produced; and as the boiling is continued and the solution becomes more concentrated, the quantity of hydrogen gas continually increases, because a greater and greater quantity of the alkaline hypophosphite is resolved, by boiling in the alkaline liquid, into hydrogen and an alkaline phosphate, e.g.:

This secondary decomposition takes place especially with the hypophosphites of the true alkali-metals; hence solutions of the alkaline earths are best adapted for the preparation of pure phosphoretted hydrogen.

4. When hypophosphites are heated, phosphoretted hydrogen is evolved, generally of the more inflammable, more rarely of the less inflammable variety, mixed with a certain quantity of vapour of phosphorus and free hydrogen gas. (H. Rose.)

The non-spontaneously inflammable gas is produced—1. When hypophosphorous or phosphorous acid is heated, these acids being then resolved into phosphoric acid and phosphoretted hydrogen, which may be collected over water:

According to Dumas and H. Rose, the first portions of gas evolved by this process are pure, but the later portions contain a considerable quantity of free hydrogen. The phosphorous acid should be gently heated in a flask of hard glass, as when softer glass is used, a phosphite of alkali-metal is frequently formed, which is decomposed by the heat and yields free hydrogen. The mixture of phosphorous and phosphoric acids, sometimes called *phosphatic acid*, which is produced when phosphorus is left to oxidise slowly in moist air, may be used for the purpose. By the application of a stronger heat, hypophosphites, as well as hypophosphorus itself, yield phosphoretted hydrogen, but the gas produced from the salts is usually spontaneously inflammable and mixed with free hydrogen.—2. When zinc or iron is dissolved in aqueous phosphorous acid, or zinc in a mixture of aqueous phosphorous acid and sulphuric acid, or when phosphoric acid is deoxidised by potassium or sodium (Wöhler).—3. When phosphorus is boiled with hydrate of potassium and alcohol, the non-inflammable gas is evolved, mixed with hydrogen gas and alcohol vapour, and there remains hypophosphite of potassium and a small quantity of phosphate, together with excess of potash (H. Rose).—4. When phosphide of calcium is decomposed by concentrated hydrochloric acid (Dumas).—5. Phosphorus, under the influence of light, decomposes water, producing phosphoric oxide [? red phosphorus] and phosphoretted hydrogen gas, which remains dissolved in the water.

Spontaneously inflammable phosphoretted hydrogen may be freed from the compound PH^{P} , and rendered non-inflammable, by passing it through a freezing mixture of ice and salt; but according to Graham, the addition of a minute quantity of nitric oxide gas will confer on it the property of spontaneous inflammability [? by oxidising a small quantity of it to PH^{P}]. It is also deprived of its spontaneous inflammability by exposure to sunlight, by contact with charcoal and other pulverulent bodies, and by admixture with the vapours of ethylic chloride, ethylic oxide, alcohol, turpentine, &c.

Properties. Phosphoretted hydrogen is a colourless gas of specific gravity 1.214 referred to air, or 17.26 referred to hydrogen (Dumas); by calculation for a condensation to 2 volumes it is $\frac{31 + 3}{2} = 17$. It is liquefiable, but has not yet been solidified

(p. 98). It smells like stinking fish, or rather the fish in a state of decomposition have the odour of the gas, since they evolve it. It is sparingly soluble in water, more so in alcohol, ether, and volatile oils. Neither the gas nor its solutions have any action upon blue or red litmus paper.

Decompositions.—1. When a series of electric sparks is passed through the gas, two volumes of it are converted, with deposition of phosphorus, into three volumes of hydrogen.—2. Most metals heated in the gas combine with the phosphorus, and liberate the hydrogen.—3. Phosphoretted hydrogen is very inflammable, burning with a brilliant flame and evolving a white smoke of phosphoric acid. A mixture of the non-spontaneously inflammable gas and oxygen standing over water is gradually absorbed, with production of phosphorous acid. The mixture of the two gases, though changing very gradually at ordinary pressures, undergoes, when suddenly rarefied, an instantaneous decomposition, attended with violent explosion.—4. Phosphoretted hydrogen

quickly reduces many oxidised bodies, *e.g.* nitric oxide, nitric acid, sulphureous anhydride and sulphuric acid. It is completely absorbed by solutions of hypochlorous acid and the alkaline hypochlorites.—5. It precipitates the solutions of many metallic salts those of lead very slowly, those of copper more quickly, and those of the noble metals most quickly of all. The precipitates, save those produced with mercury-salts, are black or dark-coloured. They consist of metallic phosphide, as in the case of copper; of mixed phosphide and metallic salt, as in the case of mercury; or of reduced metal, as in the case of silver and gold. Solution of sulphate of copper is often used for estimating the proportion of free hydrogen in ordinary phosphoretted hydrogen, by observing the quantity of gas which it leaves unabsorbed.

6. Chlorine, bromine, and iodine decompose phosphoretted hydrogen, abstracting its hydrogen. If in excess, they also combine with its phosphorus to form the respective chlorides, bromides, and iodides, or their products of decomposition with water. When bubbles of phosphoretted hydrogen are introduced into a receiver of chlorine, they inflame with a sharp explosion, producing hydrochloric acid and pentachloride of phosphorus. Many metallic chlorides also, when gently heated in phosphoretted hydrogen, produce hydrochloric acid gas—the volume of which is three times as great as that of the phosphoretted hydrogen—and a metallic phosphide; or else hydrochloric acid, free phosphorus and free metal.—6. Sulphur heated in phosphoretted hydrogen forms sulphide of hydrogen and sulphide of phosphorus.

Phosphoretted hydrogen, though devoid of any alkaline reaction, is in other respects closely analogous to ammonia; hence it is called phosphamine. Thus it unites directly with hydriodic acid to form the hydriodate of phosphamine, $\text{PH}^3\cdot\text{HI}$, or iodide of phosphonium, PH^4I , and a corresponding compound with hydrobromic acid. Moreover, like ammonia, phosphamine unites with the perchlorides of many metals, forming white saline bodies of similar constitution to the ammonio-chlorides.

Hydriodate of Phosphamine may be obtained by the direct combination of the two gases, or by adding a little water to equal atomic proportions of iodine, ground up with pounded glass, and phosphorus cut up into small pieces. Vapours of hydriodate of phosphamine mixed with hydriodic acid are immediately given off, the former condensing as a crystalline deposit. A better mode of preparation is, however, that given by Hofmann, which consists in gently heating iodine in a current of dry phosphoretted hydrogen gas:

The salt crystallises in cubes, which fuse when moderately heated, and out of access of air, may be sublimed without change. They are deliquescent and are decomposed by water into hydriodic acid and phosphamine.

Hydrobromate of Phosphamine, $\text{PH}^3\cdot\text{HBr}$ or PH^4Br , is also obtained by direct combination, or it may be prepared by introducing bromide of silicon, together with a little water, into a jar of phosphoretted hydrogen (Serullas). It crystallises in cubes, sometimes transparent, sometimes opaque; boils at about 30° . Vapour-density, obs. = 1.906; calc. (2 vol.) = 3.98; hence this compound affords an example of anomalous vapour-density, probably arising from disassociation (i. 469; ii. 816).

Derivatives of Phosphamine.—The three atoms of hydrogen, like those of ammonia, in phosphamine, may be replaced by metals or organic radicles, *e.g.* *tricupric phosphide*, $\text{P}^3(\text{Cu})^2$; *tricuprous phosphide*, $\text{P}^3(\text{Cu})^2$; *triethylphosphine*, $\text{P}(\text{C}^2\text{H}^5)^3$. The metallic phosphamines are obtained by passing phosphoretted hydrogen gas over the heated metals or their oxides, or into solutions of the respective salts, or by treating the metals directly with phosphorus. (See PHOSPHIDES.)

The organic derivatives of phosphamine constitute a more important class of compounds, exactly analogous to the tertiary monamines (i. 176). Phosphorus-bases analogous to the primary and secondary monamines have not yet been obtained. The tertiary phosphines are obtained by decomposing the zinc-compounds of the alcohol-radicles with trichloride of phosphorus, *e.g.*:

They are volatile strongly basic compounds, which unite readily with acids, forming crystalline salts, analogous to those of triethylamine, &c. Triethylphosphine (like triethylamine) unites directly with iodide of ethyl, forming the iodide of tetraethylphosphonium, $\text{P}(\text{C}^2\text{H}^5)^4\text{I}$, from which, by the action of moist oxide of silver, the hydrate of tetraethylphosphonium, $\text{P}(\text{C}^2\text{H}^5)^4\text{HO}$, may be obtained. (See PHOSPHORUS-BASES.)

Liquid Phosphide of Hydrogen. This compound, which communicates spontaneous inflammability to phosphoretted hydrogen gas, was discovered by Paul Thénard (Ann. Ch. Phys. [3] xiv. 6), and regarded by him as PH^3 . By some chemists, however, it is supposed to contain oxygen as well as hydrogen, and to

constitute the hydrogen representative of oxychloride of phosphorus, namely, H^*PO . It is produced, together with spontaneously inflammable phosphoretted hydrogen gas, by the action of water on phosphide of calcium (i. 719):

and may be separated by passing the gas through a U-tube cooled by a freezing mixture.

Into the middle tubulure of a three-necked Woulfe's bottle, holding about a pint, is inserted a glass tube 12 inches long and half an inch wide, so as to reach nearly to the bottom. To the second tubulure is adapted a tube twice bent at right angles; this tube dips into water and serves for a safety-tube. Into the third is fitted a U-tube of $\frac{1}{4}$ inch diameter, immersed to the depth of 5 or 6 inches in a freezing mixture. The part which projects above the freezing mixture is bent at a not very acute angle, and drawn out at two points not far from each other and near the end, so that, at the conclusion of the operation, the liquid may be introduced into the intermediate part of the tube, and the parts which have been drawn out closed by the blowpipe. The apparatus being thus arranged, the bottle is three parts filled with water and placed in a water-bath heated to between 60° and 70° ; the last-mentioned tube is closed; and a few drops of phosphide of calcium are thrown through the middle one into the bottle. The gas evolved takes fire, and drives out the air through the safety-tube. The U-tube is now to be opened, and from 400 to 600 grains of phosphide of calcium gradually introduced into the bottle: in a few minutes, oily drops of liquid are seen to collect in the part of the tube nearest to the bottle. The process must be stopped after 15 or 20 minutes, because water condenses in the tube, together with the phosphide of hydrogen, and often stops it. The tube is now to be sealed at the narrowed neck nearest to its extremity, then removed from the bottle, and held by the finger (covered with caoutchouc to save the operator from being burnt) in such a position that any remaining gas may escape; it is then warmed by the hand to cause the portions of liquid which have been separated by particles of ice to run together, and again placed in the freezing mixture to solidify the water, and prevent it running back. This being effected, the liquid is made to flow towards the sealed end of the tube, and the other neck of the tube is closed by the blow-pipe. A well-conducted operation yields about 30 grains of liquid.

Liquid phosphide of hydrogen is colourless and does not solidify at -20° ; at 30° or 40° , it appears to volatilise and to be decomposed at the same time; refracts light strongly. It is insoluble in water. Alcohol and oil of turpentine appear to dissolve it, but it quickly decomposes in the solution. It burns spontaneously in the air, with an intensely bright white flame, and produces dense white fumes. It communicates spontaneous inflammability to 500 times its weight of phosphoretted hydrogen gas. All combustible gases are rendered spontaneously inflammable by admixture with liquid phosphide of hydrogen.

By the action of light it is resolved into solid and gaseous phosphide of hydrogen, $5\text{PH}^2 = \text{P}^2\text{H} + 3\text{PH}^2$. It is also decomposed, like peroxide of hydrogen, by contact with various substances. An indefinite quantity of liquid phosphide of hydrogen may be decomposed by a cubic centimetre of hydrochloric acid gas.

Solid Phosphide of Hydrogen. P^2H ?—When spontaneously inflammable phosphoretted hydrogen is exposed to sunshine, a solid yellowish compound is deposited on the sides of the glass, the gas at the same time losing its property of spontaneous inflammability (Leverrier, *Ann. Ch. Phys.* lx. 176). The same solid compound is obtained in larger quantity by treating liquid phosphide of hydrogen with hydrochloric acid, or by dissolving phosphide of calcium in strong hydrochloric acid, the liquid phosphide being then resolved into the solid and gaseous phosphides (see above). Hence spontaneously inflammable phosphoretted hydrogen, passed through aqueous hydrochloric acid loses its spontaneous inflammability and yields a deposit of solid phosphide.

This compound is insoluble in water and in alcohol. It dissolves in warm potash, with liberation of non-spontaneously inflammable phosphoretted hydrogen. It takes fire at about 150° . (P. Thénard, *loc. cit.*)

HYDROGEN, SELENIDE OF. H^*Se . *Selenhydric* or *Hydroselenic acid*. *Seleniatted Hydrogen*.—A gaseous compound analogous to sulphydric acid, produced by the action of dilute hydrochloric or sulphuric acid on selenide of potassium, iron, or other metals. It is colourless and inflammable, soluble in water, and cannot long be preserved over mercury. It has a most offensive, acrid odour, impairing or even destroying the sense of smell for several hours, and producing inflammation of the eyes. Its aqueous solution absorbs oxygen from the air, and deposits selenium. It has a hepatic taste, a slight acid reaction, and gives with the solutions of most metals, precipitates consisting of metallic selenides, those of manganese, zinc, and cerium being flesh-coloured, the remainder brown or black. (Berzelius.)

HYDROGEN, SULPHIDES OF. Sulphur unites with hydrogen in two proportions, forming the protosulphide, H^2S ; and the persulphide, probably HS or H^2S^2 .

Protosulphide of Hydrogen. H^2S . *Sulphydric acid. Hydrosulphuric acid. Hydrothionic acid. Sulphuretted hydrogen.*—This compound may be formed in small quantity by burning sulphur-vapour in hydrogen gas, or hydrogen gas in sulphur-vapour, precisely as its analogue, water, is produced under similar circumstances from oxygen and hydrogen.

The gas is ordinarily prepared by the action of an acid—sulphuric or hydrochloric for instance—upon a metallic sulphide, usually that of iron or antimony. Dilute sulphuric acid acts readily upon sulphide of iron, producing, even in the cold, a rapid effervescence of sulphydric acid:

Inasmuch as sulphide of iron is an artificial product, nearly always containing an excess of metallic iron in admixture, the sulphydric acid obtained from it is generally contaminated with free hydrogen; but the native crystalline trisulphide of antimony, being a normal sulphide, when acted upon by boiling hydrochloric acid, yields the gas in question in a very pure state, thus:

The sulphydric acid obtained from either of these sources may be passed through a small quantity of water to wash it, and over chloride of calcium to render it dry. It may be collected in the gaseous state over mercury, or absorbed at once into water, in which it is very soluble.

Sulphydric acid, more frequently sulphydrate of ammonia, results from the spontaneous decomposition of sulphuretted organic compounds; also from treating non-sulphuretted organic compounds with sulphur. Reinsch recommends a laboratory process for obtaining pure sulphydric acid, by heating in a glass flask a mixture of equal parts of sulphur and suet.

Sulphydric acid occurs naturally, and is not unfrequently evolved from fumaroles and volcanoes. It exists to a considerable extent in certain mineral waters known as hepatic waters, those of Harrogate, for instance. It is also produced spontaneously in many waters charged with organic matter and sulphates, usually sulphate of calcium.

Properties.—At ordinary temperatures and pressures, sulphydric acid is gaseous. It may be obtained in the liquid state by generating it in one limb of a sealed tube, from sulphuric acid and sulphide of iron freed from metallic iron, and condensing it in the other limb, which should be immersed in a freezing mixture, that of ice and salt being sufficient for the purpose; or liquid persulphide of hydrogen may be gently heated in one limb of a bent sealed tube, when it breaks up into sulphur, which remains, and sulphydric acid, which may be condensed in the other limb kept cool for the purpose. By the powerful refrigeration resulting from the evaporation *in vacuo* of a mixture of solid carbonic anhydride and ether, it may be solidified. Solid sulphydric acid, or sulphur-ice, is a white transparent mass which melts at -85° . Liquid sulphydric acid is a colourless transparent fluid, remarkable for its extreme thinness or mobility. Its specific gravity is 0.9 compared with that of water as 1. Sulphydric acid gas is transparent and colourless. Its density is somewhat greater than that of atmospheric air, being 1.1781 referred to air, or 17 referred to hydrogen, as unity. It is characterised by an offensive odour resembling that of rotten eggs, the smell of which indeed is due to the evolution of this gas, or of its compound with ammonia. In the concentrated state it cannot be breathed with impunity, and even when much diluted it frequently gives rise to nausea and vertigo. An atmosphere containing $\frac{1}{10}$ per cent. of this gas proves fatal to the lower animals.

Sulphydric acid is readily inflammable. It burns with a bluish flame, forming sulphurous acid, and frequently deposits free sulphur from the imperfect access of oxygen. Most metals when heated in the gas absorb the sulphur and leave the hydrogen. Cadmium or tin is generally used for the purpose: $\text{Cd}^2 + \text{H}^2\text{S} = \text{Cd}^2\text{S} + \text{H}^2$. The bulk of the resulting hydrogen is equal to that of the original sulphydric acid; or, in other words, two volumes of sulphydric acid, H^2S , when acted on by metal, leave two volumes of hydrogen. Sulphydric acid in the gaseous state, or dissolved in water, is decomposed by chlorine, bromine, and iodine, with liberation of sulphur and formation of hydrochloric, hydrobromic, and hydriodic acids respectively. In a similar manner it is decomposed, with liberation of sulphur, by nearly all oxidising agents; and even sulphurous acid, which usually acts as a deoxygenant by absorbing oxygen, acts in this case as an oxygenant by affording oxygen:

In some cases, however, a peculiar sulphur-acid, the pentathionic, is formed in addition, thus:

A saturated aqueous solution of sulphydric acid contains about three times its volume of the gas. It is a clear colourless liquid, having a slight acid reaction, and the smell and taste of the gas. It is gradually decomposed by exposure to air, its hydrogen being oxidised into water and its sulphur set free. Sulphydic acid when burnt yields sulphurous acid, as we have seen; but moist sulphydric acid, mixed with air or oxygen, and exposed to a moderately warm temperature, from 40° to 90° , is converted into sulphuric acid.

Sulphydic acid, like water, is capable of giving up the half or the whole of its hydrogen in exchange for a metal, the resulting compound being a sulphhydrate or a sulphide, according as 1 or 2 at. H are thus replaced; *e.g.* *sulphhydrate of barium*, BaHS ; *sulphide of barium*, Ba^2S . It is only the alkali-metals and alkaline-earth-metals that appear to be capable of forming definite sulphhydrates, all of which are soluble in water and crystallisable. The heavy metals form insoluble sulphides, which may be derived from a single or a multiple molecule of sulphydric acid, just as the corresponding oxides are derived from a single or multiple molecule of water; *e.g.* *sulphide of silver*, Ag^2S ; *mercuric sulphide*, Hg^2S or Hhg^2S ; *trisulphide of antimony*, Sb^3S_3 , &c. (See SULPHIDES AND SULPHHYDRATES.)

The sulphides of the heavy metals are precipitated from solution of metallic salts by sulphydric acid or an alkaline sulphide or sulphhydrate:

Some metals are precipitated in this manner from their acidified solutions by sulphydric acid gas or its aqueous solution; others only from neutral or nearly neutral solutions, by an alkaline sulphide or sulphhydrate, in some cases as sulphides (nickel, cobalt, manganese, zinc, uranium), in others as hydrates (chromium, and the metals of the earths proper); and, lastly, there are some metals, namely those of the alkalis and alkaline earths, which are not precipitated either by sulphydric acid or an alkaline sulphhydrate. On these reactions is founded a division of the metals into groups, which forms the basis of the mode of separating them usually adopted in analysis. (See ANALYSIS, INORGANIC, i. 217.)

Sulphydic acid is recognised by the black discoloration it produces on paper moistened with solutions of lead or bismuth, and by the black tarnish it gives to silver-foil.

Persulphide of Hydrogen. H^2S^2 ?—This compound seems to be the sulphur-representative of peroxide of hydrogen, which it much resembles in its properties. It is made by gradually adding the solution of a persulphide of alkaline earth- or alkali-metal to an excess of hydrochloric acid diluted with twice its bulk of water:

The persulphide of hydrogen is formed without any evolution of gas, and separates as a yellowish oily fluid; heavier than water. It has the property of dissolving sulphur to a considerable extent, owing to which circumstance its composition has not been satisfactorily established. Persulphide of hydrogen has a peculiar, sulphurous, disagreeable odour. It produces superficial white eschars on the skin and mouth. It is insoluble in water, but soluble in ether, forming a solution which soon decomposes and deposits crystals of sulphur. It is readily inflammable, and burns with a blue flame. It is possessed of bleaching properties analogous to those of peroxide of hydrogen.

Persulphide of hydrogen is a very unstable substance, and, especially at increased temperatures, undergoes spontaneous decomposition into sulphydric acid and sulphur. By effecting this decomposition in a sealed tube, liquid sulphydric acid may be obtained (p. 203). The stability of the persulphide is increased by the presence of moderately strong acids. Alkalis, on the other hand, promote its decomposition. Hence if, in its preparation, the hydrochloric acid be added to the alkaline persulphide, instead of the persulphide to the acid, no persulphide of hydrogen, but only sulphydric acid and sulphur will be obtained. Under the influence of catalytic agents, such as finely-divided platinum, gold, iridium, and charcoal, which effect the similar decomposition of peroxide of hydrogen into oxygen and water, persulphide of hydrogen undergoes an instantaneous decomposition into sulphur and sulphydric acid. It reduces peroxide of manganese and the oxides of silver and gold, the last two with great violence, and frequently even with ignition. (*Odling's Manual of Chemistry.*)

HYDROGEN, TELLURIDE OF. H^2Te . *Tellurhydric* or *Hydrotelluric acid*. *Telluretted hydrogen*.—This compound is evolved as a gas, when certain metallic tellurides, the telluride of zinc being generally used, are treated with hydrochloric acid:

It closely resembles its analogues, sulphydric and selenhydric acids, smells very much like the former, burns with a blue flame, has a slight acid reaction, and dissolves in

water, forming a colourless liquid which deposits tellurium when exposed to the air. It precipitates most metals from their solutions in the form of tellurides (q. v.)

HYDROHALITE. A native hydrated chloride of sodium, $\text{NaCl} \cdot 2\text{H}_2\text{O}$. (Dana, ii. 506.)

HYDROKINONE. See HYDROQUINONE.

HYDROLIC ACID. See OLEIC ACID.

HYDROLITE. Syn. with GIBBLINITE (ii. 924).

HYDROMAGNESITE. Hydrated carbonate of magnesium, $4\text{MgO} \cdot 3\text{CO}_2 \cdot 4\text{H}_2\text{O} = 3(\text{MgCO}_3 \cdot \text{H}_2\text{O}) \cdot \text{MgH}^+\text{O}^+ \text{ or } 3(\text{MgH}^+\text{CO}_3) \cdot \text{MgH}^+\text{O}^+$.—It occurs native in small monoclinic crystals, usually acicular or bladed and tufted, also amorphous or as a chalky crust. Specific gravity = 2.145. Hardness of crystals = 3.5. Lustre vitreous to silky or sub-pearly; also earthy. Colour and streak white. It is found in serpentine at Hrubchitz in Moravia; near Kumi in Negroponto; at Hoboken, New Jersey, and other localities in North America (Dana, ii. 457). A specimen from Texas, Lancaster county, Pennsylvania, analysed by Smith and Brush (Sill. Am. J. [2] xv. 207), gave 36.00 per cent. CO_2 , 43.96 MgO, 19.68 water, and 0.36 silica. Artificially prepared hydrocarbonate of magnesium has sometimes the same composition.

HYDROMAGNOCALCITE. Syn. with HYDRONOLMITE.

HYDROMARGARIC and HYDROMARGARITIC ACIDS. Acids of doubtful constitution, which Frémy obtained by treating olive-oil with strong sulphuric acid. (See MARGARIC ACID and PALMITIC ACID.)

HYDROMELLONE. See MELLONE.

HYDROMETER (*55wp*, water; *55wp*, measure). *Gravimeter, Pèse-liqueur*; on the Continent, most commonly called the *Arcometer* (*ἀράμετρον*, rare, subtle). An instrument which, on being placed in a liquid, shows its specific gravity, either by direct inspection, or by simple adjustment and calculation.

Its action depends on the simple principle of hydrostatics, that a floating body must displace its own weight of liquid. The truth of this principle is seen if we consider that any part of a mass of liquid at rest must be supported by the pressure of the surrounding liquid, and will certainly continue to be supported, so long as it has the same weight and volume: hence it may be conceived to become solid without altering the conditions of equilibrium. Now weight is mere downward pressure, and the solid immersed in a liquid need not weigh so much as an equal volume of liquid, provided that the difference is exactly made up by downward pressure, or weight communicated from another part of the solid, above the surface of the liquid.

Thus, in *fig. 557*, suppose the solid AB to have the same weight as a volume of water equal to the volume of the part AC. When placed in water, the solid will sink up to the point C: for the upward pressure of the water, which usually supports a volume of water equal to AC, will then be exactly sufficient to support the weight of the solid AB. If we now place AB in a liquid of less specific gravity, the weight of AB will be greater than the weight of the volume AC of the liquid, and equal, for instance, to the weight of the volume AC_1 . Then by similar reasoning, AB will sink into this lighter liquid up to the point C_1 . Again, if AB sink in a third liquid only up to the point C_2 , it is obvious as before, that the volume of liquid AC_2 is equal in weight to the solid AB.

Now the specific gravities of bodies are, by definition, in the proportion of the weights of equal volumes of the bodies, or, which is the same, in the inverse proportion of the volumes of equal weights. In other words, the specific gravity is less, as it requires a larger volume to make a given weight. Now the volumes AC, AC_1 , AC_2 , of the respective liquids are all of one weight, that of the solid AB: hence the specific gravities have the inverse proportion of AC, AC_1 , AC_2 , or if we assume the first (water) to have the specific gravity 1.00, the

specific gravities of the others are $\frac{\text{AC}}{\text{AC}_1}$, $\frac{\text{AC}}{\text{AC}_2}$.

The hydrometers commonly used do not differ from the solid body AB above described, except that the part which meets and cuts the surface of the liquid is usually of very narrow section, in order that slight differences in the density of the liquid may cause the hydrometer to rise or sink through a considerable space. The form of those parts of the hydrometer below the liquid has no effect upon the accuracy of the result, but for convenience the lower parts are usually much expanded, in order that they may be proportionally shorter. Several different forms of the hydrometer are shown in *figs. 558, 559, 560*. The hydrometer in *fig. 558* would indicate specific gravities differing through a considerable range, but without much accuracy. It is accompanied by a tube TB, which holds the liquid under examination. That in *fig. 559*, on the contrary, has

Fig. 557.

a very slender stem (SM), and would indicate with great accuracy any specific gravities within a certain narrow range. Hydrometers are usually made of light glass tubes and bulbs blown in a single piece. The chief part of the weight is given by small shots or mercury, carefully adjusted so that the instrument shall sink to a convenient depth in the required liquids, and then sealed up in a small bulb at the lowermost extremity. In other cases, the hydrometer is made of thin gilt brass or silver, as in *fig. 560*, but the weight is still placed below, in order that the instrument may float upright and stiffly.

Fig. 558. Fig. 559. Fig. 560.

Fig. 561.

Graduation.—We have yet to consider the nature of the graduation on the stem of any hydrometer which is to give by inspection the specific gravity of the liquid in which it floats. Reverting to *fig. 557*, let the distance AC to which the hydrometer sinks be successively x_0, x_1, x_2 , &c. when AB stands in liquids of the densities ρ_0, ρ_1, ρ_2 , &c.

Then $\frac{x_1}{x_0} = \frac{\rho_0}{\rho_1}$, $\frac{x_2}{x_0} = \frac{\rho_0}{\rho_2}$, &c. Of these quantities let ρ_0 be the density of distilled water at the temperature 62°F , which we assume as 1.00; call the corresponding length x_0 , the unit of length. Then $x_1 = \frac{1}{\rho_1}$, $x_2 = \frac{1}{\rho_2}$, &c., and $x_1 - x_0 = \frac{1}{\rho_1} - \frac{1}{\rho_0}$.

Thus we see that equal differences of specific gravity are indicated, not by any equal intervals on the scale, but by the differences of the reciprocals of those specific gravities, or by quantities proportional to them. The scale which must then be employed is to be obtained by calculation, and its character is shown with some accuracy in the divided line AB *fig. 561*.

Until recently, indeed, it was customary to graduate the stem of every hydrometer into some series of equal divisions arbitrarily chosen, and the indications were either used conventionally, without reference to specific gravity at all, or the corresponding specific gravity was ascertained by calculation or reference to a table. It is obviously desirable, however, to adopt the true scale of specific gravities, since this can always be constructed with facility and sufficient accuracy.

A mode of graduating hydrometers with accuracy, as practised by Mr. Ackland, is described in the Reports of the Jurors of the Exhibition of 1861 (p. 26). It consists of the following processes:

1. Ascertaining the exact position of three or more points of the scale, according as the stem of the hydrometer is more or less truly cylindrical.

2. Dividing with great accuracy a scale on boxwood, to show the specific gravities required to be indicated by the hydrometer.

3. Making a reduced copy of the boxwood scale, so as to form a scale, the points of which shall correspond with the ascertained points on the hydrometer-tube. The scale so formed on paper is ready to be engraved on the hydrometer.

For example, suppose it be required for a hydrometer to show specific gravities from 1.00 to 0.700. A bulb is chosen with a stem as uniform as possible, and three points—for instance, .700, .850, and 1.000—are ascertained as follows: Load the hydrometer till it sinks in distilled water of the temperature 62° to some marked point convenient for the degree 1.00; let the weight of the instrument then be x . To ascertain the point of the degree .85, alter the weight of the hydrometer until it is $\frac{1.00 \times x}{.85}$, and placing it in water, mark where it is cut by the surface. Lastly, alter the weight to $\frac{1.00 \times x}{.70}$,

and mark the point as before, which will correspond with the specific gravity .700. The original weight x of the hydrometer may then be restored and the tube sealed. This method, requiring the use of no liquid but water, is very convenient, and was suggested to Mr. Ackland by Dr. Clarke of Aberdeen.

The remainder of Mr. Ackland's processes are performed by calculating the reciprocals of the specific gravities required, forming them into a scale, and then reducing this scale and transferring it to the glass tube by a dividing engine of peculiar and ingenious construction.

We have formed the following table of the reciprocals, and their differences. Intermediate degrees can easily be interpolated when necessary.

Specific gravity.	Reciprocal.	Difference of Reciprocals.	Specific gravity.	Reciprocal.	Difference of Reciprocals.
2.00	.500		1.25	.800	
1.95	.513	.013	1.20	.833	.033
1.90	.526	.013	1.15	.870	.039
1.85	.541	.015	1.10	.909	.043
1.80	.556	.015	1.05	.952	.048
1.75	.571	.015	1.00	1.000	.053
1.70	.588	.017	.95	1.053	.058
1.65	.606	.018	.90	1.111	.066
1.60	.625	.019	.85	1.176	.074
1.55	.645	.020	.80	1.250	.083
1.50	.667	.022	.75	1.333	.090
1.45	.690	.023	.70	1.429	.109
1.40	.714	.024	.65	1.538	.129
1.35	.741	.027	.60	1.667	.151
1.30	.769	.028	.55	1.818	.182
		.031	.50	2.000	

We shall now describe a graphical method which the chemist can easily use as a substitute for Mr. Ackland's dividing engine, so as to graduate his own hydrometers with accuracy. Draw a line AB (*fig. 561*) on a sheet of good paper, and lay off upon it, with exactness, as many of the reciprocal numbers or differences, given in the table, as are likely to be required within the range of the hydrometers to be graduated: this may easily be done with the aid of a decimal or diagonal scale and a pair of compasses. The absolute size of this scale is of no importance, except that the larger it is the more accurate will the result probably be.

Now suppose the points on a hydrometer have been determined for the specific gravities .700, 1.00 and 1.30. Draw a line exactly parallel to AB, and measure off distances PQ, QR, equal to the absolute distances of the points on the hydrometric stem, placing the points P, Q, R, as nearly as possible opposite the specific gravities .700, 1.00, 1.30, on the scale AB. Draw lines through P and the degree .70, and through Q and the degree 1.00. If these lines never meet, the scale on PQ will be identical with that on AB. But suppose they meet in S: draw lines through S and the several degrees on AB between .70 and 1.00. Then the intersections of these lines and PQ give the required points for the scale PQ. Next draw a line through R and the degree 1.3. If this also pass through the point S it will indicate that the stem of the hydrometer is perfectly uniform. But wherever S', the point of intersection of Q—1.00 and R—1.30 may be, draw lines from S', through the degrees of AB, giving by their intersection with QR the required points of graduation.

If necessary, other points besides P, Q, R, might, for the sake of accuracy, be

determined on the stem of the hydrometer, and the graduation could still be performed, with but little extra trouble, from many successive points of intersection.

The hydrometer scale, when once obtained on paper, can be transferred to the glass stem of the instrument by the usual process of etching with hydrofluoric acid. The glass must be covered with bees'-wax, and firmly fixed, at a proper distance, in the same straight line with the divided scale, the degrees of which may then be easily and accurately transferred by a beam-compass. For fuller directions on the method of graduating glass tubes, the reader must consult Bunsen's *Gasometry* (p. 26), also the article *ANALYSIS OF GASES* in this Dictionary (i. 269). Were it desired often to graduate hydrometers, it would be best to engrave the scale AB (*fig. 561*) upon a glass plate, together with converging lines drawn through the degrees, and then to use it as Bunsen describes.

The smaller intervals of a hydrometer scale may always be subdivided into equal parts by estimation, or otherwise, without appreciable error.

The delicacy of the hydrometer may always be increased to an indefinite extent by lessening the diameter of the stem; but in the same proportion it becomes more limited in range, and troublesome to use. The adhesion of air-bubbles is a great source of discrepancy, especially in the metal instruments, and for this reason all hydrometers should be made with as smooth and small a surface as possible.

Again, the attraction of the glass or metal stem for the water causes the surface of water to rise up against the stem in a parabolic curve. This phenomenon alone, by preventing us from getting an exact reading, is almost enough to condemn the hydrometer as a standard instrument of measurement. Fortunately the hydrostatic balance and the specific gravity bottle are means of determining specific gravities with unlimited accuracy and considerable ease. The hydrometer takes a subordinate rank, and is chiefly employed in approximately determining the strength of solutions or mixtures of liquids. It often effects a wonderful saving of time or trouble, and any person frequently occupied with liquids of a variable strength or composition should have hydrometers suitably constructed in range and delicacy for testing them. To treat the instrument as suitable for exact scientific measurement, and to investigate and determine corrections for every little error which might arise, would be a mistake. We accordingly proceed to describe various well-known forms of the hydrometer, which are extensively used for practical purposes.

Sykes' Hydrometer is of importance because, by Act of Parliament (58 Geo. III. c. 28; see also 3 & 4 Will. IV. c. 52 § 123) it is employed in the collection of the excise revenue of the United Kingdom levied upon spirituous liquors,

Fig. 562.

of which of course the strength must be determined. It is made of brass (*fig. 562*) with a spherical bulb A, $1\frac{1}{2}$ inch in diameter, a weight (B) to sink it and maintain it upright in the liquor, and a flat uniform stem C, $3\frac{1}{2}$ inches long, divided into ten parts, each of which is again divided into two parts. A series of nine weights of the form D accompany the instrument, having the proportions 10, 20, 30, . . . 90. These weights are placed in succession at E, until the instrument is found to sink in the liquor up to some point of the divided scale. The numerical reading of the scale at the point where it is cut by the surface of the liquor, added to the number on the weight employed, gives the required result. But the temperature of the liquor must also be observed, and the proportion of spirit it contains ascertained by a table in which the variables are the degrees of the hydrometer and thermometer.

The supernumerary weight F may be placed on the summit of the stem, and then causes the hydrometer, loaded with the circular weight 60, to sink to the same point in pure water to which it would otherwise sink in proof spirits. Concerning the determination of the proportion of alcohol contained in a mixture with water, see *ALCOHOLOMETRY* (i. 81).

Jones' Hydrometer is an improvement on that of Sykes. It is accompanied by three detached weights, so that, according as these are used or not, the hydrometer may have four different degrees of weight.

Corresponding to these are four separate scales on the sides of the stem, which is made square for the purpose. A thermometer, also with four different scales, is included in the lower part of the instrument, and the whole is so contrived that the number of gallons in the 100 under or over *proof* may be read off.

The following formulæ apply to any hydrometer, as for instance Sykes' or Jones', in which weights are added below the liquid.

Let w = weight of hydrometer.

v = volume of hydrometer up to the bottom of the scale.

m = area of section of stem (supposed uniform).

HYDROMETER.

In liquid A let the hydrometer loaded with the weight w_1 sink to the degree x_1 (measured in inches from the bottom of scale), and in liquid B, when loaded with w_2 , let it sink to x_2 . Also let v_1 = volume of weight w_1 .

Then the volume of A displaced is $V + v_1 + x_1.m.$
 " B " $V + v_2 + x_2.m.$
 The weight of the volume of A displaced is $W + w_1.$
 " B " " $W + w_2.$

Then $(V + v_1 + x_1, m)$ and $(V + v_2 + x_2, m) \frac{W + w_1}{W + w_2}$ are the volumes of equal weights of A and B. And we have

$$\frac{\text{specific gravity of A}}{\text{specific gravity of B}} = \frac{(V + v_2 + x_2.m)(W + w_1)}{(V + v_1 + x_1.m)(W + w_2)}.$$

Hydrometers could easily be constructed in which weights might be added above the surface of the liquid, so that the volume of the lower parts of the instrument should not be altered. The above formula would then apply, after omission of v_1 and v_2 . A hydrometer of this kind, giving any specific gravity from '6 to 2.0, was shown in the Exhibition of 1851. (Jury Reports, p. 296.)

Baumé's *Hydrometer* is extensively employed on the Continent, and was originally described by Baumé in his *Éléments de Pharmacie*, p. 466. Separate instruments are usually constructed for liquids heavier and lighter than water, although it is obvious that this is not necessary. For liquids heavier than water, the graduation is as on the right-hand side of *fig. 563*, and is determined by marking as 0 the point to which the hydrometer sinks in pure water, and as 15 the point to which it sinks in a solution of 16 pts. by weight of salt in 85 pts. of water. The interval is divided into 15 equal parts, and a scale of similar equal parts is extended as far as desirable.

For liquids lighter than water, the graduation is as on the left-hand side of *fig. 563*. The degree 10 is now determined by pure water, while the degree 0 is the point to which the hydrometer sinks in a solution of 10 pts. of salt in 90 pts. of water. The interval is divided into 10 equal parts, and the scale is extended as in the former case.

The degrees of Baumé's hydrometers being entirely arbitrary, the following tables must be used to ascertain from their indications the specific gravities of liquids with respect to water as the standard:

Comparison of the Degrees of Baumé's Hydrometer with the real Specific Gravities of liquids heavier than water.

Degrees.	Specific gravity.	Degrees.	Specific gravity.	Degrees.	Specific gravity.	Degrees.	Specific gravity.
0	1.000	20	1.162	39	1.346	58	1.617
1	1.007	21	1.160	40	1.357	59	1.634
2	1.013	22	1.169	41	1.369	60	1.652
3	1.020	23	1.178	42	1.382	61	1.670
4	1.027	24	1.188	43	1.396	62	1.689

19	1.143						

Deparcieux's Hydrometer is an instrument with a large bulb and very narrow stem, used for determining the specific gravity of water from various springs or other sources. (*Prony's Architecture Hydraulique*, tom. i. § 614-627.)

The *Marine Hydrometer* is adapted to taking the specific gravity of sea-water. In fig. 561 is shown an accurate instrument of this kind made of gilt brass, the flat stem of which is divided into 40 parts, from 3 or more points experimentally determined. Each degree corresponds to a point in the third place of decimals; thus the degree 27 represents the specific gravity 1.027, and the whole range of the instrument is accordingly from 1.000 to 1.040.

The hydrometers supplied by Government to the navy and mercantile shipping are slender glass instruments, but their accuracy is secured by comparison and determination of the error, if any, just as in the case of barometers and thermometers. They are employed in daily or hourly observations on the water of the ocean.

The *Lactometer* is a hydrometer closely resembling Sykes's hydrometer, but adapted by Dicus of Liverpool for determining the quality of milk. By means of a series of eight weights, the scale has a range of 80 degrees, and a thermometer and an ivory sliding-rule accompany the instrument in order that the milk may be tested at any temperature, and the result reduced to the standard temperature of 55° without calculation (*Brewster's Edinburgh Cyclopædia*, or *Agric. Survey of Lancashire*). This instrument must not be confused with the other lactometer first described by Sir Joseph Banks (*Brande's Journal*, iii. pp. 393-4), and consisting of a simple graduated test-tube, in which the new milk is allowed to stand, until the cream rises to the top and its proportional amount may be directly measured off.

Wilson's *Beads* consist of a series of little balloon-shaped glass bubbles, adjusted to certain degrees of specific gravity. When a number of them are thrown into a liquid, those which are of greater specific gravity than the liquid sink into it, those which are of less specific gravity float, while only the single bead which corresponds in specific gravity with the liquid remains indifferently in any part of the liquid, or at least sinks or rises very slowly. Upon each bead is engraved the specific gravity which it indicates. These useful little instruments were much improved and patented by Mrs. Lovi.

Fahrenheit's *Hydrometer* differs somewhat from and is even simpler than the common hydrometer. In place of a scale, it has only a single mark on the stem, but at the top of the stem is a small scale-pan on which weights are to be placed until the hydrometer sinks up to the mark in the liquid which is being tested. By this means we measure the weight of a constant volume of the liquid displaced: for this weight, by the principles of hydrostatics, is equal to the whole weight of the loaded hydrometer supported by the liquid. Hence the ratio of this weight for any given liquid to the weight for pure water at 62° F., is the specific gravity required.

This hydrometer would admit of more accurate results than the common instrument, but would be inconvenient in common use.

Nicholson's *Hydrometer* (fig. 564), invented by the author of the "Chemical Dictionary," is an ingenious modification of Fahrenheit's hydrometer, by which it is rendered capable of determining specific gravities of solid bodies as well as of liquids. It has a single mark on the stem, and bears three scale-pans, one at the summit of the stem, above the surface of the liquid, and the other two, one of which is concave downwards, at the lower extremity of the instrument. When it is placed in water, the air must be allowed to escape from this lowest scale-pan.

In taking the specific gravities of liquids, this hydrometer is identical with that of Fahrenheit. The weight of the instrument is generally adjusted from the first so that 1,000 grains placed in the upper dish will cause it to sink in pure water, at 62° F., up to the mark on the stem. Let the weight, however, required for this purpose, whatever it may amount to, be called w_1 , the weight of the instrument itself being W . When placed in a liquid of which the specific gravity differs from that of water, and is required to be known, a weight w_2 less or greater than w_1 must be placed in the upper pan to sink it to the zero mark. Then $\frac{W + w_2}{W + w_1}$ is obviously the specific gravity required.

To take the specific gravity of any solid substance, a portion of it weighing less than w_1 is placed in the upper pan, with such additional weight, say w_3 , that the hydrometer will sink in pure water up to the zero mark, as it does when loaded with w_1 .

Fig. 564.

Then the weight of the substance is obviously $w_1 - w_3$. Now transfer the substance to one of the lower pans, that which is concave downwards being used when the substance is lighter than water, and has to be forced under. The instrument must again be adjusted so as to float in water at the usual level, and it will be found that some further weight has to be added for this purpose. Let the weight now in the pans be w_4 . Then the specific gravity of the substance is $\frac{w_1 - w_3}{w_4 - w_3}$.

This instrument becomes more and more delicate and accurate in its indications as the stem is of smaller diameter. As actually constructed by the inventor, the stem was a piece of hardened steel wire $\frac{1}{16}$ inch in diameter. But the more delicate, the more troublesome does the instrument become in use; the adherence of water to the parts above the surface, the adherence of air to those below, and the inevitable changes of temperature in the water, are sources of unavoidable error. The chemist, in his balance and specific gravity bottle, has always at hand the means of ascertaining specific gravities with any degree of accuracy, and is not likely to use Nicholson's hydrometer. But this instrument is a valuable companion to the scientific traveller; since, besides its use in taking specific gravities, it may be employed in place of a balance for ascertaining any small weight.

Having now given all that it is likely to be practically useful concerning the hydrometer, we think it quite needless to describe all the minute varieties of construction and arbitrary scales proposed by Homberg, Clarke, Gay-Lussac, Dica, Richter, Adie, Quin, Guyton, Speers, Charles, and others. Much information is given in the *Handwörterbuch der Chemie*, 2^e Aufl., &c., ii. 165-190.

The hydrometer is said to have been first invented by Hypatia, daughter of Theon Alexandrinus, who flourished about the end of the fourth century, but the discovery is sometimes ascribed to Archimedes. However this may be, the English philosopher Robert Boyle appears to have first brought it into use, having described it in *Phil. Trans.* for 1675 (x. 329), or *Boyle's works* (1772, iv. 204). His instrument was almost identical with Nicholson's hydrometer, and was especially intended to determine the fineness of gold alloys, being hence called a "*New Essay Instrument*."

Many references concerning the history and varieties of the hydrometer will be found in *Young's Lectures* [1845] i. 240.—*Benoit's Théorie Générale des Pèse-liqueurs* [1821], is a work we have not been able to meet with. Clarke's hydrometer (*Phil. Trans.* xxxvi. [1730], p. 277), Brewster's Capillary Hydrometer, Staktometer, or Drop-measurer, are described in the *Edinburgh Cyclopædia*, xi. pt. ii. p. 442.—W. S. J.

HYDRONICKELMAGNESITE, also called *Pennite*. A variety of hydrodolomite (p. 191) containing 2 per cent. or less of carbonate of nickel, with water. It forms pale-green or whitish incrustations, having a surface of minute spherules, and occurs together with emerald-nickel, into which it graduates, also with chromic iron, at Texas, Lancaster county, Pennsylvania, and according to Heddle, at Swinanes, in Unst, Shetland. Hermann found in it 44.54 CO₂, 20.10 CaO, 27.02 MgO, 1.26 Na₂O, 0.70 FeO, 0.40 MnO, 0.15 Al₂O₃, and 5.84 H₂O = 100. (Dana, ii. 457.)

HYDROPHANE. A variety of opal, which becomes transparent when immersed in water.

HYDROPHILITE. A name applied to chloride of calcium.

HYDROPHITE, also called *Jenkinsite*. A hydrated silicate of magnesium and iron, which occurs massive, and sometimes fibrous. Specific gravity 2.46—2.65. Hardness = 3.5. Lustre, feeble, subvitreous. Colour, mountain-green to blackish-green; streak pale; translucent to opaque.

	SiO ₂	FeO	MnO	MgO	Al ₂ O ₃	V ₂ O ₅	H ₂ O
a.	36.19	22.73	1.66	21.08	2.895	0.125	48.08 = 100.75
b.	38.97	19.30	4.36	22.87	0.53	.	48.36 = 99.38
c.	37.42	20.60	4.05	22.75	0.98	.	48.18 = 99.28

a. *Hydrophite* from Taberg, in Sweden (Svanberg, *Pogg. Ann.* li. 535).—b. *Jenkinsite* from O'Neil's mine, Orange county, New York (Smith and Brush, *Sill. Am. J.* ii. 369). These analyses lead to the formula $\frac{1}{2}\text{MgO} \cdot \frac{1}{2}\text{FeO} \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$; which, regarding 2 at. water as basic, may be reduced to the form of an orthosilicate, $3(2\text{M}^+\text{O} \cdot \text{SiO}_3) \cdot \text{H}_2\text{O}$, or $3\text{M}^+\text{SiO}_3 \cdot \text{H}_2\text{O}$.

HYDROPSITE. A silicate of manganese with excess of manganous oxide, containing, according to Du Menil's analysis, 54.37 per cent. SiO₂, 41.33 MnO, 0.92 FeO, and 1.26 CaO. (*Rammelsberg's Mineralchemie*, p. 459.)

HYDROPSIN. The name given by Garnal (*Schmidt's Jahrb. d. ges. Méd.* cvi. 8) to an albuminous substance which he obtained from a dropsical effusion.

HYDROQUINONE. *Hydrochinone, Hydrokinone* (Wöhler, Ann. Ch. Pharm. xlv. 354; li. 150; Hesse, *ibid.* cx. 194; cxiv. 292).—This name is applied to two substances, one colourless and the other green.

COLOURLESS HYDROQUINONE (Pyroquinole), $C^6H^4O^2$, isomeric with oxyphenic acid, is the chief product of the dry distillation of quinic, carbohydroquinonic, and oxysalicylic acids (*q. v.*), and is likewise produced by the action of reducing agents (stannous chloride or sulphurous acid) on quinone, from which it differs by 2 at. H; also, together with a brown crystalline body containing $C^6H^4N^2O^2$, by the action of phenylamine on quinone (A. W. Hofmann, Proc. Roy. Soc. xiii. 4):

Preparation.—1. The distillate, mixed with solid particles, which is obtained by the dry distillation of quinic acid, is filtered from tar, and again, after cooling, to separate benzoic acid; the yellow, heavy, oily mixture of benzene, phenic acid and salicylic acid, is distilled from the filtrate; the brown residue in the retort is evaporated and left to cool till benzoic acid crystallises out; the mother-liquor is diluted with water, which makes the liquid milky and separates tar; and the resulting filtrate is evaporated till the hydroquinone crystallises out.—2. Sulphurous acid gas is passed through warm water saturated with quinone, and having quinone also suspended in it, till all the quinone is dissolved, and the liquid appears colourless; the solution is then gently evaporated to the crystallising point, and the crystals are purified by pressure and recrystallisation.—It is not necessary previously to remove the sulphuric acid by carbonate of barium.—A saturated aqueous solution of quinone may also be mixed with aqueous hydriodic acid, and the watery liquid, after filtration from the iodine, evaporated to the crystallising point.

Properties.—Hydroquinone forms transparent, colourless, rhombic crystals exhibiting the combination, $\infty P \infty$. $\infty P \infty$. P. oP (Hesse). It sublimes, when heated, in shining laminae, like benzoic acid; melts at 177.5° and solidifies to a crystalline mass at 163° . It is inodorous, has a sweetish taste, and is neutral to vegetable colours. It dissolves easily in water, especially when hot, also in alcohol and in ether. From solutions of alkaline sulphites, it crystallises unaltered, sometimes however in sulphur-yellow rhombohedrons or long four-sided prisms, resembling the sulphhydrates of hydroquinone. (Hesse.)

Decompositions.—1. Hydroquinone, suddenly heated above the boiling point, is partially decomposed into quinone and green hydroquinone. When passed in the state of vapour through a glass tube at a low red heat, it is resolved into quinone and hydrogen (Hesse).—2. *Oxidising agents*, viz. chlorine, chromate of potassium, sesquichloride of iron, or nitrate of silver, convert hydroquinone dissolved in water into green hydroquinone, with formation of hydrochloric acid, chromic oxide, or protochloride of iron and hydrochloric acid, or with precipitation of silver.—3. Strong nitric acid converts it almost wholly into oxalic acid (Hesse).—With hydrochloric acid and chlorate of potassium it yields tetrachloroquinone (chloranil) (Hesse).—4. The aqueous solution of hydroquinone imparts a saffron-yellow colour to cupric acetate, and when heated throws down cuprous oxide, quinone volatilising at the same time.—5. Ammonia imparts to it a brown-red colour, and yields on evaporation a brown mass like ulmic acid. Potash acts in like manner. (Wöhler.)

Hydroquinone dissolves in a moderately concentrated hot solution of neutral acetate of lead, and the solution, on cooling, yields prisms containing $C^6H^4O^2 \cdot C^6H^4PbO^4 + \frac{1}{2} H^2O$. These crystals give off 5.23 per cent. of water (nearly $\frac{1}{2}$ at.) over sulphuric acid.

Sulphhydrates of Hydroquinone.—There are two of these salts. The first, containing $4C^6H^4O^2 \cdot H^2S$, is obtained in colourless prisms by passing sulphydric acid gas into a saturated solution of hydroquinone heated to 40° .—The second $3C^6H^4O^2 \cdot H^2S$, is obtained, by passing sulphydric acid into a cold saturated solution of hydroquinone, in small shining crystals, which redissolve when heated if the passage of the gas be continued, the solution, as it cools, yielding the compound in very regular colourless rhombohedrons. These crystals remain unaltered when dry, but water eliminates sulphydric acid from them, and on boiling the solution, hydroquinone is reproduced.

GREEN HYDROQUINONE OR QUINHYDRONE. $C^6H^4O^4 = C^6H^4O^2 \cdot C^6H^4O^2$.—This compound may be regarded either as a compound of quinone and colourless hydroquinone, or as a double molecule of the latter compound minus 2 at. H, or again as a double molecule of quinone ($C^6H^4O^2$) plus 2 at. H.

It is produced:—1. By mixing the aqueous solutions of quinone and hydroquinone, whereupon it is immediately precipitated in the crystalline form.—2. By combining aqueous quinone with a quantity of hydrogen not sufficient for the formation of the colourless hydroquinone; e. g. aqueous quinone mixed with sulphuric acid at the

negative pole of the galvanic circuit; quinone mixed with sulphuric acid in contact with zinc; aqueous solution of quinone with gradual addition of dichloride of tin or protosulphate of iron, or sulphurous acid, or alloxantin, the latter being converted into alloxan.—3. By the partial dehydrogenation of aqueous hydroquinone; e.g. when spongy platinum or animal charcoal moistened with the solution is exposed to the air; when chlorine gas is passed through aqueous hydroquinone, or that liquid is mixed with nitric acid, chromate of potassium, sesquichloride of iron, or nitrate of silver.—The mixtures prepared according to (2) or (3) with concentrated solutions, assume for a while a black-red colour, and then become filled with long, green, metallic-looking prisms of quinhydrone; but if the solutions are too dilute, the quinhydrone remains dissolved and is decomposed, emitting the odour of quinone.—The largest crystals are obtained by at once adding to a saturated aqueous solution of quinone (or even to its mother-liquor) a quantity of aqueous sulphurous acid just half sufficient for the formation of hydroquinone.

Properties.—Quinhydrone forms very long and thin green prisms, having a metallic lustre, like the wings of gold-beetles or humming birds, and brighter even than murexid; they appear red-brown by transmitted light when strongly magnified. It melts easily to a brown liquid, and sublimes partly undecomposed in green laminae. Smells slightly like quinone, and has a pungent taste.

It dissolves sparingly in cold water, abundantly and with red-brown colour in hot water, separating as it cools. *Alcohol* and *ether* dissolve it readily, forming yellow or red solutions. *Ammonia* dissolves it with green colour. The aqueous solution forms with *acetate of lead* a bright greenish-yellow precipitate, quickly changing to dirty grey.

Decompositions.—1. When quinhydrone is heated, it sublimes partly undecomposed, partly converted into yellow quinone.—2. When it is boiled with water, quinone distills over, and the remaining dark red-brown liquid contains, together with a large quantity of hydroquinone, a brown tar, which separates partly on cooling, partly on subsequent addition of water.—3. The green solution of quinhydrone in *ammonia* quickly assumes a dark red-brown colour on exposure to the air, and leaves a brown amorphous mass when evaporated.—4. Quinhydrone is converted into colourless hydroquinone by aqueous *sulphurous acid*, *stannous chloride*, or *zinc and sulphuric acid*, but not by hydriodic acid or tellurhydric acid.—5. The aqueous solution quickly reduces *nitrate of silver*, on addition of ammonia.

Derivatives of Hydroquinone.

Carbohydroquinonic acid. $C^*H^*O^* = C^*H^*O^*.CO^* = \left(\begin{smallmatrix} C^*H^*O^* \\ H^* \end{smallmatrix} \right)^m \left\{ O^* \right.$ (O. Hesse,

Ann. Ch. Pharm. cxii. 527, cxiv. 292; cxvii. 22; E. Lautemann, *ibid.* cxx. 315).—An acid produced:—1. By the action of bromine on aqueous quinic acid.—2. By heating quinic acid to above 200°.—3. Small quantities of it are likewise obtained by the action of chlorate of potassium and hydrochloric acid on dilute aqueous quinic acid, or of peroxide of manganese and sulphuric acid on aqueous quinate of calcium. (Hesse.)

Preparation.—Bromine is added to aqueous quinic acid by portions of 10 drops each, till a portion of it remains undissolved, even after the liquid has been frequently agitated and left to stand for 12 hours. The solution is then decanted from the undissolved bromine, diluted, filtered, and mixed with carbonate of lead, as long as a brisk evolution of gas is thereby set up, and bromide of lead produced. The filtrate, evaporated to a thick syrup on the water-bath, and shaken up with about 5 vol. ether, yields to this liquid carbohydroquinonic acid, which after the ether has been distilled off, remains as a brown crystalline residue. It is purified by recrystallisation from water containing hydrochloric acid, with help of animal charcoal. Or the solution, treated with bromine and filtered, is mixed with carbonate of lead, till this salt begins to take up organic substances; the filtrate is precipitated with solution of neutral acetate of lead, and then, after this precipitate has been collected, a further precipitate is obtained by addition of ammonia. By decomposing the precipitates suspended in water with sulphuric acid, then boiling up and diluting the filtrate, carbohydroquinonic acid is obtained from the first precipitate. The acid obtained from the second lead-precipitate still retains unaltered quinic acid, from which it may be separated by ether. (Hesse.)

Properties.—Carbohydroquinonic acid crystallises from its aqueous solution with 1 at. water ($C^*H^*O^*.H^*O$), in furcate groups of needles, also in rhombic laminae or granular crystals. It is dimorphous. The granular crystals are distorted twins, belonging to the monoclinic system. The needles are rhombic prisms, having the acute edges perpendicularly truncated, cleavable at right angles to the prismatic faces (Hesse).—The crystallised acid dissolves in 40 or 50 pts. of water at 17°, very easily

in boiling water and in alcohol, but is insoluble in ether. It has a sour and bitter taste and reddens litmus. Heated to 100° it gives off, on the average, 10.5 per cent. water, leaving the anhydrous acid, $C^6H^4O^4$, which melts at 207° (corrected) with partial decomposition, and solidifies in the radio-crystalline form between 160° and 170° (Hesse). When cautiously heated, it sublimes with partial decomposition. (Lautemann.)

Decompositions.—1. Carbohydroquinonic acid is resolved by fusion, and with great facility when heated to 240° , into carbonic anhydride and hydroquinone, $C^6H^4O^4 = C^6H^4O^2 + CO^2$ (Hesse). When it is heated with pumice, pyrocatechin is obtained instead of hydroquinone, the former being apparently capable of passing, under circumstances not exactly known, into hydroquinone (Lautemann).—2. It is not altered by boiling dilute nitric acid; the concentrated acid converts it, with rise of temperature and evolution of nitrous acid, into oxalic acid, together with a trace of a yellow substance.—3. Sulphuric anhydride dissolves it, without evolution of gas, forming a blue liquid, brownish by reflected light. No conjugated sulphuric acid can be obtained from this solution.—In oil of vitriol, carbohydroquinonic acid dissolves slowly, and chars when heated.—4. Bromine dissolves slowly in the aqueous acid, with evolution of gas.—5. Aqueous carbohydroquinonic acid, in contact with acid carbonate of calcium and air, acquires a dark, nearly black colour, and deposits a black precipitate, which effervesces with acids (Hesse).—6. From cupric hydrate and potassio-cupric tartrate aqueous carbohydroquinonic acid separates cuprous oxide; from mercuric and silver-salts it separates the metal. Dilute aqueous carbohydroquinonic acid, mixed at 8° or 10° with neutral solution of nitrate of silver, becomes dark-coloured in a quarter of an hour, even in the dark, and in three hours separates metallic silver (Hesse). According to Lautemann it reduces nitrate of silver when heated, but not in the cold.

The carbohydroquinonates are, for the most part, easily soluble in water, sparingly soluble or insoluble in alcohol. Hesse regards the acid as monobasic, and the ammonium-salt as a basic salt, in which 1 at. ammonia takes the place of water of crystallisation, $C^6H^3(NH^4)O^4.NH^4$. The formula $\left\{ \begin{smallmatrix} C^6H^4O^4 \\ H^+ \end{smallmatrix} \right\} O^3$ represents it as tri-

atomic but monobasic, like glyceric acid (ii. 875). Strecker (*Handwörterb.* ii. [2], 996), regards the acid as dibasic. Carbohydroquinonic acid decomposes the carbonates of the alkaline earths. Its salts turn brown in the air. In contact with a small quantity of sesquichloride of iron, they acquire a violet colour; with a larger quantity, a fine purple-violet to chrome-green colour especially in neutral solution. (Hesse.)

Ammonium-salts.—When dry ammonia-gas is passed over dry carbohydroquinonic acid, 100 pts. of the acid take up from 22.3 to 22.7 pts. of ammonia (2 at. = 22.08 NH^3), without giving off water. The resulting compound, freed from excess of ammonia by standing over oil of vitriol, contains 44.7 per cent. C, and 6.2 H, corresponding to the formula, $C^6H^3(NH^4)O^4.NH^4$ (calc. 44.68 per cent. C, and 6.38 H). When exposed to moist air, it quickly gives off ammonia, and dissolves, with alkaline reaction, in water and alcohol. The latter solution, when evaporated, deposits small acid crystals. Hydrated ether partially dissolves the ammonium-salt, leaving a portion, perhaps consisting of $C^6H^3(NH^4)O^4.H^2O$. An ether-alcoholic solution of carbohydroquinonic acid becomes turbid when ammonia gas is passed over it, and then clear, depositing concentric groups of prisms. Brown substances are formed at the same time. (Hesse.)

Lead-salt.—From aqueous carbohydroquinonic acid, an aqueous or alcoholic solution of neutral acetate of lead throws down an amorphous yellow precipitate, easily soluble in nitric acid, with difficulty in acetic acid. Part of the carbohydroquinonic acid dissolves at the same time in the acetic acid which is set free, so that the filtrate still gives a precipitate with ammonia. (Hesse.)

The potassium-salt is precipitated from its aqueous solution by alcohol in the form of a syrup.—The manganous salt forms small prisms, easily soluble in water.—The zinc-salt forms laminae.—Aqueous carbohydroquinonic acid yields a greyish-yellow precipitate with tartar emetic; and with ferric hydrochlorate, a dark green solution changing to violet on addition of acid carbonate of sodium, or of tartaric acid, ferric hydrochlorate, and ammonia. It does not precipitate gelatin.

The following acids give reactions very similar to those of carbohydroquinonic acid: 1. Morintannic acid and Morin, which, according to Hlasiwetz, are isomeric with carbohydroquinonic acid.—2. Deutero-catechuic acid, $C^6H^4O^4$, and Triccatechuic acid, $C^6H^4O^4$. These two acids are supposed by Strecker (*Ann. Ch. Pharm.* cxviii. 289) to exist in catechu, inasmuch as he regarded the pyrocatechin, first as the one, then as the other of these acids, and finally, as a mixture of the two.—3. Proto-catechuic acid. This acid, according to Lautemann (*Ann. Ch. Pharm.* cxx. 316), must be regarded as identical with carbohydroquinonic acid, since the latter acid, when

heated with pumice, is capable of yielding pyrocatechin. But according to Hesse (Ann. Ch. Pharm. cxvii. 221), the two acids react differently with cupric tartrate, and must therefore be regarded as only isomeric.—4. *Oxysalicylic acid*. With regard to this acid, Lautemann thinks it probable that it may be capable of passing into carbohydroquinonic acid (or the latter into oxysalicylic acid).—5. *Hypogallic acid*.

Ethyl-carbohydroquinonic acid, $C^6H^{10}O^4 = \left\{ \begin{array}{l} C^6H^8O^4 \\ H^2C^2H^2 \end{array} \right\} O^2$. *Carbohydroquinonic ether*.—To prepare this compound, carbohydroquinonic acid is dissolved in alcohol of 90 per cent.; the solution is saturated with hydrochloric acid gas; the alcohol is distilled off in the water-bath; the residue is shaken up with ether, as long as that liquid takes up a substance which colours ferric chloride; the ether is then distilled off; the brown crystalline residue is shaken up with boiling, very dilute alcohol, and a small quantity of carbonate of sodium; the solution is left to cool; and the acid is again exhausted with ether. The ethereal solution when evaporated leaves coloured crystals, which may be decolorized by again treating them with dilute alcohol, soda, and ether. It forms colourless prisms united in radiate groups, neutral, melting at 134° (corrected), and becoming crystalline again at 124.3° .

The ether melts in boiling water before dissolving; dissolves easily in alcohol, and especially in common ether. The aqueous solution, added to neutral acetate of lead, forms a white amorphous precipitate soluble in acetic acid; it colours ferric hydrochlorate violet, changing to purple-violet on addition of a larger quantity of the iron-salt, and finally to chrome-green. It reduces mercuric chloride, nitrate of silver, and potassio-cupric tartrate. (Hesse, loc. cit.)

Chlorinated Hydroquinones. (Wöhler, Ann. Ch. Pharm. li. 155.—Städeler, *ibid.* lxi. 132, 306, 321.)—These compounds are produced by the action of reducing agents on the corresponding chlorinated derivatives of quinone: they are most easily prepared by means of sulphurous acid. They bear a greater resemblance to hydroquinone in proportion as they contain less chlorine. They act like weak acids, their alcoholic solutions yielding white precipitates with acetate of lead, the quantity of the precipitate being increased by addition of ammonia. The chlorine in these compounds does not exhibit its usual reaction with nitrate of silver. By oxidising agents, viz. by nitric acid and sesquichloride of iron, they are converted either into the corresponding chlorinated quinones, or compounds of these with the chlorinated hydroquinones.

Monochlorinated Hydroquinone, $C^6H^5ClO^2$, forms tufts of colourless prisms, very soluble in water, alcohol and ether, and liquefying in contact with the vapour of ether. It melts easily, and sublimes in white laminae, with partial decomposition. Its aqueous solution reduces nitrate of silver. It dissolves in ammonia, forming a dark-blue solution, changing to green, yellow, and red-brown.

Dichlorinated Hydroquinone, $C^6H^4Cl^2O^2$, forms beautiful nacreous crystals, which melt at 164° , and begin to sublime at 120° . It reddens litmus; dissolves sparingly in cold water, easily in boiling water, also in alcohol, in ether, and in hot acetic acid; sparingly in boiling hydrochloric acid; it is soluble also in hot concentrated sulphuric acid, and separates on cooling. With dilute potash it forms a colourless solution, which on exposure to the air turns green, then red, and deposits a violet powder. With ammonia, it forms a yellow solution, which reddens in contact with the air, and deposits a brownish precipitate.

Trichlorinated Hydroquinone, $C^6H^3Cl^3O^2$, forms colourless laminae, or flattened prisms melting at a little above 130° , and subliming in iridescent scales. It dissolves readily in alcohol and in ether; the alcoholic solution reddens litmus. It dissolves in potash and in ammonia, forming green solutions, which turn first red, then brown, and yield copious precipitates with hydrochloric acid.

Tetrachlorinated Hydroquinone, $C^6H^2Cl^4O^2$, forms colourless, nacreous laminae, insoluble in water, very soluble in alcohol and ether; its solutions redden litmus. When heated, it begins to turn brown at 160° , the colour becoming stronger towards 220° ; it then sublimes rapidly, but does not melt till more strongly heated; the melted mass crystallises on cooling. It dissolves in potash and in ammonia. The potash solution, saturated hot, deposits on cooling, prismatic crystals, apparently consisting of a potassium-salt.

Octochlorinated Acetyl-dihydroquinone, $C^6H^2Cl^8O^2 = C^6H^2(C^2H^3O)Cl^8O^2$ (Hesse, Ann. Ch. Pharm. cxiv. 292).—Produced by passing sulphurous anhydride into a mixture of tetrachloroquinone and glacial acetic acid, then evaporating and subliming:

It forms colourless laminae, which melt at 230° , dissolve easily in ether, alcohol, hot benzene, and strong acetic acid, but are nearly insoluble in water.

Octochlorinated Ethyl-dihydroquinone, $C^8H^2Cl^6O^4 = C^8H^2(C^2H^3)Cl^6O^4$ (Hesse, *loc. cit.*).—Obtained by passing sulphurous anhydride for some time through a heated mixture of tetrachloroquinone with 20 pts. alcohol of 92 per cent. The tetrachloroquinone then dissolves, and the solution mixed with water yields the octochlorinated ethyl-hydroquinone, which crystallises from benzene in colourless rhombic laminae, often an inch long, and exhibiting the combination $\infty P\infty . \infty P . mP\infty$. The compound melts at 236° , sublimes almost unaltered at 210° ; is nearly insoluble in water and in solutions of sulphites, but dissolves easily in alcohol, ether, hot benzene, and acetic acid. The alcoholic solution after a while becomes acid and brown-coloured, and ultimately deposits black prisms having a metallic lustre; on addition of hypochlorite of sodium, the solution yields green crystals, and then tetrachloroquinone. Octochlorinated ethyl-hydroquinone mixed with quicklime, and moistened with a few drops of water, exhibits a fine green colour.

Chlorinated Quinhydrone.—The chlorinated hydroquinones combine with the chlorinated quinones, forming compounds which may be regarded as chlorinated quinhydrones (p. 213). These compounds are produced by mixing the aqueous solutions of their components, or by the action of oxidising agents on the chlorinated hydroquinones, or of reducing agents on the chlorinated quinones. The *dichlorinated* compound, $C^6H^4ClO^2 . C^6H^2Cl^2O^2$, sublimes in brown needles, which colour the skin purple, and redden litmus.—The *tetrachlorinated* compound, $C^6H^4Cl^2O^2 . C^6H^2Cl^4O^2$, in the anhydrous state, forms yellow crystals; in the hydrated state, with $2H^2O$, it forms violet crystals.—The *hexachlorinated* compound, $C^6H^4Cl^3O^2 . C^6H^2Cl^5O^2$, appears to be formed by treating trichloroquinone with a quantity of sulphurous acid not sufficient to convert it completely into trichlorinated hydroquinone; and the *octochlorinated* compound, $C^6H^2Cl^4O^2 . C^6Cl^4O^2$, by the action of nitrate of silver on perchlorinated hydroquinone.

Phosphohydroquinonic acid, $C^6H^2PO^3 = C^6H^2O^2 . PHO^3$ (Hesse, *Ann. Ch. Pharm.* cxiv. 292).—Quinic acid dissolves in cold dilute aqueous phosphoric acid without decomposition; but on evaporating the solution, a copious evolution of gas takes place at a certain degree of concentration, and the remaining brown solution contains an acid, whose calcium-salt, which separates partly crystalline, partly amorphous, has the composition $C^6H^2CaPO^3$. The formation of the acid is represented by the equation:

Sulphite of Hydroquinone, $C^6H^2SO^3 = 3C^6H^2O^2 . SO^2$ (A. Clemm, *Ann. Ch. Pharm.* cx. 345).—When sulphurous anhydride is passed through a solution of quinone till that compound is completely converted into colourless hydroquinone, and the passage of the gas is then further continued, the liquid again turns yellow, and deposits, after concentration, yellow rhombohedral crystals having the above composition. This compound is very easily decomposable, and gives off sulphurous anhydride when heated, leaving colourless hydroquinone.

Sulphohydroquinonic acids. Acids containing the elements of hydroquinone and sulphuric anhydride; produced by the action of sulphuric acid or anhydride on quinic acid and hydroquinone. (O. Hesse, *Ann. Ch. Pharm.* cx. 194; cxiv. 292.)

1. **Disulpho-hydroquinonic acid**, $C^6H^2S^2O^3 = C^6H^2O^2 . 2SO^2$.—*Preparation of the barium-salt*.—Fuming sulphuric acid is poured into fused or finely pulverised quinic acid, till a fresh addition no longer causes any considerable evolution of gas; the liquid is gently warmed towards the end of the operation, diluted after cooling with a large quantity of water, neutralised with carbonate of barium, and evaporated to the crystallising point. The crystals which first separate take up a large quantity of colouring matter, so that the mother-liquor yields a less coloured salt.

The aqueous acid, obtained by decomposing the barium-salt with the exactly equivalent quantity of sulphuric acid, or the lead-salt with sulphydric acid, forms an acid syrup, easily soluble in alcohol, insoluble in ether.

The acid is *dibasic*, but only the dimetallic salts have been obtained. The salts and the aqueous acid produce with ferric hydrochlorate a fine blue colour, which disappears on heating, and reappears with a dingy tint on cooling. The blue colour is also destroyed, slowly by access of air, or by addition of nitric or acetic acid, quickly by addition of hydrochloric, sulphuric, or tartaric acid. A similar action is exerted by sal-ammoniac, chloride of barium, chloride of calcium, sulphate of magnesium, phosphate of sodium, neutral acetate of lead, and ferric hydrochlorate. The salts separate metallic silver from the nitrate.

The *ammonium-salt*, obtained by decomposing the barium-salt with carbonate of ammonia, separates from the concentrated solution in large crystals.

The *barium-salt*, $C^6H^4Ba^2SO^4.4H^2O$, forms beautiful monoclinic prisms, with angles of $113^\circ 4'$. When heated, it gives off suffocating vapours, hydroquinone, quinihydrone, and water, leaving a residue of charcoal. The salt dried in the air, or over oil of vitriol, gives off at 90° from 10.8 to 11.5 per cent. water (3 at. = 11.31 per cent. H^2O), then between 120° and 160° an additional 3.8 per cent. (1 at. = 3.77 per cent. H^2O), corresponding in all to 4 at. The salt dissolves readily in boiling water, with difficulty in cold water, and in alcohol either cold or boiling, but is insoluble in ether.

The *calcium-salt* resembles the barium-salt.

The *lead-salt*, $C^6H^4Pb^2SO^4.Pb^2H^2O^2$, is separated from the concentrated solution of the barium-salt by neutral acetate of lead, as a bulky precipitate, which quickly changes into yellowish microscopic crystals having a silky lustre. When heated, it assumes a lemon-yellow colour, and becomes carbonised. It is nearly insoluble in water and acetic acid, easily soluble in nitric acid, precipitable by ammonia.

The *potassium-salt*, $2C^6H^4K^2SO^4.3H^2O$, is obtained by neutralising the aqueous acid with carbonate of potassium, and separates with the same composition, even from solutions containing 2 at. acid to 1 at. potash. It forms colourless prisms having a saline taste, easily soluble in water, sparingly in alcohol. They retain 6.9 per cent. water over oil of vitriol, give off the whole at 160° , and decompose when melted.

2. *Sulphodihydroquinonic acid*, $C^{12}H^{16}SO^6 = 2C^6H^4O^2.SO^4.2H^2O$.—Produced by the action of fuming sulphuric acid on hydroquinone. The solution, which is formed without evolution of gas, yields, when saturated with carbonate of barium, a barium-salt, which crystallises in concentrically grouped needles containing $C^{12}H^{16}Ba^2SO^{10}$. This salt is easily soluble in water and in aqueous alcohol, sparingly soluble in absolute alcohol, and is precipitated therefrom in flocks by ether.

3. *Disulphodihydroquinonic acid*, $C^{12}H^{16}S^2O^{11} = 2C^6H^4O^2.2SO^4.H^2O$.—Hydroquinone exposed to the vapour of sulphuric anhydride deliquesces and yields this acid. The *potassium-salt*, $C^{12}H^{16}KS^2O^{11}$, crystallises in colourless monoclinic prisms or in flattened, sharp-pointed needles, easily soluble in water and in alcohol. The solution treated with ferric hydrochlorate acquires a transient dark-blue colour; it forms a white precipitate with ammoniacal acetate of lead, and reduces silver from the nitrate.

HYDROSALICYLAMIDE. $C^6H^4N^2O^3 = N^2(C^6H^4O^2)^2$. *Salhydramide. Salicylimide. Hydride of Azosalicyl* (Ettling, Ann. Ch. Pharm. xxxv. 261).—This compound is produced by the action of ammonia on hydride of salicyl (salicylous acid):

The hydride of salicyl is dissolved in 3 or 4 times its volume of cold alcohol, and a quantity of ammonia is added equal to that of the hydride of salicyl employed. The solution then immediately yields yellowish-white needles, and soon solidifies in a mass. On applying a gentle heat, the product dissolves completely, and the liquid, on cooling, deposits crystals of hydrosalicylamide.

Hydrosalicylamide crystallises in triclinic prisms, without modification. Angle $\infty P : \infty P' = 117^\circ 30'$; $oP : \infty P = 103^\circ 30'$; $oP : \infty P' = 93^\circ 30'$. It appears to be insoluble in water, and dissolves but sparingly in cold alcohol, but quickly in about 50 pts. of boiling alcohol. At 300° it melts to a yellow and brownish mass, yielding a white, very light sublimate. At a higher temperature it carbonises. It is not decomposed by weak *potash-ley* in the cold, but on boiling it gives off ammonia and forms salicylide of potassium. Dilute acids also do not decompose it in the cold, but on heating, ammonia is produced, and hydride of salicyl is set free. With an alcoholic solution of *sulphydric acid*, it yields hydride of sulphosalicyl:

Hydrosalicylamide forms several salts in which part of the hydrogen is replaced by metallic radicles.

The *cupro-cuprammonic salt*, $C^{12}H^{16}Cu^2(N^2H^4Cu)^2N^2O^6$, is obtained by mixing a very dilute and slightly cooled alcoholic solution of hydrosalicylamide with ammoniacal acetate of copper (acetate of cuprammonium). The liquid immediately acquires a fine emerald-green colour, and gradually deposits brilliant laminæ of the same colour, the solution being at the same time decolorised. The crystals are insoluble in water and in alcohol; they dissolve in cold dilute acids, but are reprecipitated on saturating the solution with an alkali. Strong mineral acids decompose them completely, liberating hydride of salicyl. Dilute potash does not decompose them without the aid of heat, and even then but slowly. They melt when heated, and yield by distillation an oil which solidifies on cooling, in a crystalline mass having the odour of gum-benzoin:

Ferrico-ferric ammoniac salt, $C^{12}H^{16}.2(NH^4Fe)N^2O^6$.—To prepare this salt, an aqueous

HYDROSILICITE—HYDROUS ANTHOPHYLLITE. 219

solution of ferric chloride is mixed with a quantity of tartaric acid sufficient to prevent its precipitation by a large excess of ammonia; a saturated alcoholic solution of hydrosalicylamide is then mixed with a quantity of ammonia sufficient to enable it to be treated with 30 or 40 times its volume of cold water without becoming turbid; and the two solutions are mixed. The mixture immediately acquires a deep blood-red colour, and after some time deposits a yellowish-red flocculent precipitate which gradually becomes darker coloured and granular. This precipitate is partially soluble in alcohol. It is not decomposed by cold dilute hydrochloric acid, but the hot concentrated acid decomposes it, with separation of hydride of salicyl.

Lead-salts.—Two of these salts appear to exist. One of them is obtained by mixing a solution of acetate of lead with ten times its volume of alcohol, heating the mixture, pouring in a little ammonia, and adding an alcoholic solution of hydrosalicylamide containing a small quantity of ammonia till the precipitate which forms at first no longer redissolves in the hot liquid; this liquid on cooling deposits a yellow granular powder.—The other lead-salt of hydrosalicylamide is obtained by mixing a solution of the hydramide with aqueous ammonia, and adding in the cold a solution of acetate of lead. Light yellow flocks are then formed, which become strongly electric by friction.

Hydrobromosalicylamide. $C^{21}H^{15}Br^2N^2O^3 = N^2(C^{21}H^{15}BrO)^2$. *Hydride of Bromosalicyl. Bromosamide.*—Obtained by the action of ammonia on hydride of bromosalicyl (bromosalicylous acid). Its properties and reactions are precisely analogous to those of the following compound. (Piria.)

Hydrochlorosalicylamide. $C^{21}H^{15}Cl^2N^2O^3 = N^2(C^{21}H^{15}ClO)^2$. *Hydride of Chlorosalicyl. Chlorosamide* (Piria, Ann. Ch. Phys. [2] lxi. 309).—Produced by the action of ammonia-gas on hydride of chlorosalicyl (chlorosalicylous acid):

On passing a current of dry ammonia gas over dry chlorosalicylous acid, the gas is absorbed and a yellow resinous mass is formed. To complete the reaction, it is necessary to withdraw the mass from time to time, pulverise it, and again submit it to the action of the gas. The product is then crystallised from absolute alcohol, or better from hot anhydrous ether.

Hydrochlorosalicylamide crystallises in small yellow scales, tasteless, nearly insoluble in water, but soluble in alcohol and ether, especially with aid of heat. Absolute alcohol dissolves it without alteration; but hot aqueous alcohol decomposes it, eliminating ammonia, especially in presence of acid or alkaline liquids.

HYDROSILICITE. A hydrous variety of augite, occurring in amorphous masses or as a crust on the palagonite tufa at Palagonia and Aci Castello in Sicily, associated or mixed with hercynite, phillipsite and calcite. According to v. Waltershausen, it contains 42.02 SiO₂, 4.94 Al₂O₃, 27.19 CaO, 3.41 MgO, 2.51 Na₂O, 2.67 K₂O, 15.08 water and carbonic acid, and 2.19 insoluble matter. (Rammelsberg's *Mineralchemie*, p. 861.)

HYDROSTEAHITE. A steatite from Göpfersgrün, in which Klaproth found 59.5 per cent. silica.

HYDROTALCITE. A talc-like mineral, translucent in thin folia, from Snarum in Norway, where it occurs imbedded in serpentine. Hardness = 2.0 (Hochstetter). Specific gravity = 2.091 (Rammelsberg). It dissolves easily and with effervescence in acids, retaining its solubility after ignition. Hermann examined a mineral (which he called *Völknerite*) evidently identical with this, from Scheschemskaja Gora in the Ural, where it occurs in the mica slate, together with chloraspinel, hydrargillite, and other minerals, and is said sometimes to form six-sided prisms cleaving perfectly parallel to the terminal faces. Specific gravity = 2.04.

Analyses. a. by Hochstetter (J. pr. Chem. xxvii. 376).—b.—c. by Rammelsberg (Mineralchemie, p. 166).—f. by Hermann (J. pr. Chem. xlii. 237).

Rammelsberg's and Hermann's analyses, abstracting the carbonic acid, lead to the formula $Al^2O^3.3H^2O + 5-6(Mg^2O.2H^2O)$ or $(Al^2)^{11}H^2O^5.5-6Mg^2H^2O^4$.

HYDROUS ANTHOPHYLLITE. An altered form of asbestiform tremolite (p. 169) found on New York Island and in Scotland.

HYDROZINCITE. See ZINC-BLOOM.

HYDURILIC ACID. $C^4H^4N^4O^4$.—An acid belonging to the uric acid group discovered by Schlieper (Ann. Ch. Pharm. cvi. 11), and further investigated by Baeyer (*ibid.* cxvii. 11). Schlieper, who assigned to it the formula $C^4H^4N^4O^4$, once obtained it accidentally in treating uric acid with dilute nitric acid, and concentrating the mother-liquor remaining after the alloxan (i. 135) had crystallised out; but he did not succeed in preparing it a second time. It was really produced by the decomposition of dialuric acid, which is one of the products of the action of nitric acid upon uric acid (ii. 965), and in Schlieper's experiment was decomposed by the heat of the sand-bath in which the syrupy liquid had been allowed to remain.

Baeyer obtains hydurilic acid by heating dialuric acid with glycerin (which acts merely as a solvent) to about 160° , the dialuric acid then splitting up into hydurilate of ammonium, formic acid, and carbonic anhydride:

Preparation from Uric acid.—The uric acid is first converted into alloxan by Schlieper's method of oxidation with hydrochloric acid and chlorate of potassium (i. 135); and the alloxan, after being dissolved in lukewarm water, filtered from the unaltered uric acid, and decolorised if necessary with pure animal charcoal, is converted into dialuric acid by reduction with stannous chloride. For this purpose, a quantity of tin equal to the weight of uric acid employed, is dissolved in excess of strong hydrochloric acid; the still hot liquid is added all at once to the alloxan solution; and more hydrochloric acid is added till the volume of the liquid amounts to 4 litres for a pound of uric acid decomposed. The preceding proportions must be carefully observed, for with a smaller proportion of tin, alloxantin is obtained instead of dialuric acid; and unless a large excess of hydrochloric acid is used, dialurate of tin separates in hard crusts, very difficult to decompose. On leaving the strongly acid solution to stand for a day, dialuric acid crystallises out in yellowish stellate groups of short four-sided prisms, which must be quickly washed, and dried in a vacuum. The quantity obtained amounts to about 50 per cent. of the uric acid employed.

To convert the dialuric acid into hydurilic acid, 9 pts. of the perfectly dry substance is mixed in a capacious flask with 5 pts. of concentrated glycerin (as it is obtained by evaporation in a basin till its temperature rises to 160°), and heated in an oil-bath to 140° — 150° . A brisk and regular evolution of carbonic anhydride then takes place, and as soon as this ceases and the contents of the flask have become solid, the temperature is raised for a short time to 160° , and the glycerin, after cooling, is removed by washing. A yellowish-white granular powder is then left, consisting of acid hydurilate of ammonium (p. 221). The glycerin takes no part in the reaction, but acts merely as a solvent.

To obtain the free acid, it is best to convert the acid ammonium-salt into a copper-salt and decompose this salt with hydrochloric acid. The crude ammonium-salt is dissolved in boiling water, ammonia is added in slight excess, and solution of cupric sulphate is added to the filtrate. The liquid then assumes a dark-green colour, and, if hot, deposits on cooling red watery crystals of neutral hydurilate of copper. This salt is then decomposed by hot hydrochloric acid, and the hydurilic acid which crystallises out is washed with dilute hydrochloric acid and dried over the water-bath.

Properties.—Hydurilic acid prepared as above forms a bulky white powder having a yellowish tinge; by once re-crystallising it from water, it may be obtained quite pure and colourless. It is very sparingly soluble in cold water, somewhat more in hot water, and crystallises therefrom on cooling in small four-sided prisms containing 4 at. water, $C^4H^4N^4O^4.4H^2O$. It is also but very slightly soluble in alcohol, which, however, does not precipitate it from the aqueous solution.—Sulphuric acid dissolves it without decomposition, and on adding water, part of the hydurilic acid separates out again. In hydrochloric acid it is even less soluble than in water, and is gradually precipitated by it from the aqueous solution. From a hot concentrated solution in hydrochloric acid, or from an ammoniacal solution decomposed by hydrochloric acid, it separates as a crystalline powder consisting of rhombic tablets containing 2 at. water of crystallisation: $C^4H^4N^4O^4.2H^2O$. The water, amounting to 6.86 per cent. (2 at. = 6.77) is given off at 140° .

Hydurilic acid bears a tolerably high temperature without decomposition; it likewise offers considerable resistance to the action of alkalis, being attacked but slowly and without blackening, by melting potash, with formation of oxalic acid. It is not attacked by reducing agents; but oxidising agents, such as chlorine, bromine, nitric acid, oxide of silver, peroxide of lead, and sesquichloride of iron, attack it very quickly, yielding various products. When heated with ferric chloride, it yields oxyhy-

durilic acid, an acid not yet examined, but characterised by the blood-red colour which it produces with ferric salts. With a mixture of *hydrochloric acid* and *chlorate of potassium*, hydrurilic acid yields dichloro-hydrurilic acid, $C^4H^4Cl^2N^2O^6$.—Fuming *nitric acid* converts it into alloxan without any other product; but with nitric acid of ordinary strength, it yields alloxan together with violuric acid, violantinn and dilituric acid (ii. 965). If the action be carried on to the end, with aid of heat, the only product is dilituric acid*; but if it be interrupted at an earlier stage, a mixture is obtained, varying in composition according to the duration of the action:

Dilituric acid may indeed be regarded as a product of the oxidation of violuric acid, $C^4H^4N^2O^3 = C^4H^4N^2O^4 + O$; and violantinn, $C^4H^4N^2O^3$, is a compound of the two. With *nitrous acid*, the same products are obtained. With nitrite of potassium and excess of nitrous acid, the products are violurate of potassium and alloxan:

Hydrurilic acid is most distinctly characterised by the splendid dark-green colour which the acid and its salts produce in a solution of *ferric chloride*. The colour is destroyed by strong acids and alkalis, also by heat, the hydrurilic acid then decomposing and the colour changing to red. Characteristic also are the chalk-white precipitates produced on adding hydrochloric acid to the alkaline solution, and the reactions with hydrochloric acid and chlorate of potassium and with nitric acid, just mentioned.

Hydrurilates. Hydrurilic acid is dibasic, yielding both acid and neutral salts. It dissolves easily in ammonia, potash, and soda, forming moderately soluble salts; the other hydrurilates are sparingly soluble or insoluble. These salts cannot, however, in general be obtained by double decomposition, since the acid has a great tendency to form double salts; they must therefore be prepared with the free acid. The acid decomposes most metallic chlorides, forming acid salts; also acetates, with formation of neutral salts, excepting in the case of the ammonium- and potassium-salts.

Hydrurilates of Ammonium.—The *acid salt*, $C^4H^4(NH^4)N^2O^6$, obtained by heating dialuric acid in glycerin (p. 220), is nearly pure, having only a faint yellowish colour. It is moderately soluble in boiling water, and separates, on cooling, in crystals and granules. By solution in hot dilute ammonia, and precipitation with acetic acid, it is obtained quite pure, in small octahedral crystals, which, however, soon lose their form. Strong acids remove only part of the ammonia. The crystals are anhydrous.

The *neutral salt*, $C^4H^4(NH^4)^2O^6$, is obtained by mixing the acid salt with ammonia, and separates from a hot saturated solution by rapid cooling in needles containing 2 at. water; it is also obtained in the same form by precipitation with sulphide of ammonium, in which it is insoluble. The solution when left to stand, or slowly evaporated, deposits large shining monoclinic prisms, with dihedral summits, containing 4 at. water, and efflorescing, with loss of water and ammonia, when exposed to the air. (For Rammelsberg's determination of the form of these crystals, see Ann. Ch. Pharm. cxxvii. 19.) The salt is moderately soluble in water, very easily in ammonia, and is completely precipitated therefrom by alcohol in amorphous flocks or in needles.

Hydrurate of Barium (neutral), $C^4H^4Ba^2N^2O^6 \cdot 2H^2O$, is obtained as an amorphous precipitate, which soon becomes crystalline, on adding a hot solution of hydrurilic acid to acetate of barium.

Hydrurilates of Calcium.—The *acid salt*, $C^4H^4Ca^2N^2O^6 \cdot 16H^2O$, separates, on adding hydrurilic acid to a solution of chloride of calcium, in small shining prisms, insoluble in water. The *neutral salt*, $C^4H^4Ca^2N^2O^6 \cdot 6H^2O$, is obtained by decomposing acetate of calcium with hydrurilic acid, as an amorphous precipitate, which becomes crystalline on standing. It gives off 2 at. water at 130° .

Hydrurilates of Copper.—The *acid salt*, $C^4H^4Cu^2N^2O^6 \cdot 16H^2O$, is obtained by adding cupric acetate to excess of hydrurilic acid, or by mixing the acid with cupric sulphate. From concentrated solutions it separates in green needles; from more dilute solutions, in thin prisms of a shining yellow colour. It is decomposed by excess of

* Schläpfer's "nitro-hydrurilic acid," obtained by the action of hot nitric acid on hydrurilic acid, was most probably dilituric acid containing potash, derived from the impure hydrurilic acid used. (Bayer, Ann. Ch. Pharm. cxxvii. 211.)

strong acids. When heated, it gives off the whole of its water, and is converted into a red powder of the anhydrous salt, which is also precipitated immediately from hot solutions.

The *neutral salt*, $C^6H^4Cu^2N^4O^8.8H^2O$, is obtained by adding hydurilic acid to excess of cupric acetate, or by mixing the neutral ammonium- or sodium-salt with cupric sulphate. Cold dilute solutions yield a red precipitate of the hydrated salt, consisting of short needles; warm concentrated solutions, a dark brown-red precipitate of the anhydrous salt. The red salt is converted by heat into the brown salt, giving off its water, but recovers it in contact in water. The salt is decomposed by excess of hydrochloric acid, yielding hydurilic acid and chloride of copper.

Hydurilates of Iron.—The ferric salt is a dark green, easily decomposable precipitate; the ferrous salt is a white precipitate which soon turns green.

Hydurilate of Lead is a white precipitate, insoluble in acetic acid, insoluble in water, soluble in nitric acid; obtained by adding hydurilic acid to neutral acetate of lead.

Hydurilate of Potassium has not been obtained in definite form. A solution of hydurilic acid in potash mixed with acetic acid, yields hydurilic acid containing variable quantities of potash; alcohol also throws down from the same solution a substance containing more potash than the neutral salt would contain.

Hydurilate of Silver.—Acetate of silver forms with hydurilic acid small shining prisms, which soon turn grey: with a cold solution of hydurilate of ammonium, it forms a white precipitate; with a warm solution, crystals which soon turn black. On boiling the silver-salt with water, silver is reduced, and the hydurilic acid is oxidised, forming oxyhydurilic acid (p. 221).

Hydurilate of Sodium, $C^6H^4Na^2N^4O^8.H^2O$, is obtained by acidulating a solution of hydurilic acid in strong soda-ley with acetic acid, and adding alcohol. The neutral salt then separates in small, colourless, shining prisms, which are moderately soluble in cold, easily in hot water. The acid-salt does not appear to exist.

Hydurilates of Zinc.—The *acid salt*, $C^6H^4Zn^2N^4O^{12}$, crystallises from a solution of zinc-chloride mixed with hydurilic acid, in beautiful feathery groups of needles having a strong lustre. The *neutral salt*, $C^6H^4Zn^2N^4O^8.4H^2O$, separates on mixing hydurilic acid with excess of zinc-solution, as a white amorphous precipitate, which soon becomes crystalline.

Dichlorohydurilic acid. $C^6H^4Cl^2N^4O^8$.—This compound is prepared on adding chlorate of potassium by small portions, and with constant stirring, to a pasty mixture of hydurilic and strong hydrochloric acid. A snow-white powder is thus obtained, which is very slightly soluble in water, either hot or cold, and is most easily purified by dissolving it in strong sulphuric acid, which exerts but little action on it, but thickens when heated with it over the water-bath, and, on gradual addition of water, deposits the chlorinated acid in small rhombic crystals, containing $C^6H^4Cl^2N^4O^8.4H^2O$. It is especially permanent in acid liquids, is not attacked by chlorine, and but slowly by warm nitric acid, with formation of dilituric acid, but is easily decomposed by alkalis.

Dichlorohydurilic acid is a strong dibasic acid, which dissolves in alkalis, especially with aid of heat, and is reprecipitated by hydrochloric acid. The solutions turn red on boiling, yielding a metallic chloride, and an acid not yet examined.

The *neutral potassium-salt*, $C^6H^4K^2Cl^2N^4O^8.4H^2O$, crystallises from a warm solution of potash saturated with the acid in small, beautiful six-sided tables. It dissolves sparingly in cold, more readily in hot water. It retains its water of crystallisation at 120° ; at a stronger heat it turns red and decomposes.

HYGRINE. (Wöhler and Lossen, Ann. Ch. Pharm. cxi. 374.—Lossen, *Dissertation*.)—An organic base occurring, together with cocaine, in coca-leaves (i. 1059). To extract the two bases, the leaves are exhausted with rain-water at a temperature of 60° to 80° ; the united extracts are precipitated with neutral acetate of lead and filtered; the filtrate is precipitated with a saturated aqueous solution of sulphate of sodium, again filtered and concentrated; and the concentrated liquid, after being rendered slightly alkaline by carbonate of sodium, is agitated four or six times with ether to extract the cocaine. The remaining liquid mixed with an additional quantity of carbonate of sodium, and again shaken with ether, yields hygrine and a neutral oil having the odour of tobacco. These substances remain when the ether is distilled off; and on further heating the residue, till it boils, the temperature quickly rises to above 280° , and a brown alkaline oil distils over, while a black resin is left behind. When the distillate is maintained at 140° , for some hours, in a stream of hydrogen, the greater part passes over of a yellow colour (a), while the remainder volatilises only at 140° to 230° , and condenses to a thick brown oil (b). Hygrine is contained in both portions; that in b, however, is contaminated with a neutral oil;

that in *a* with an easily volatilised substance. To remove a little ammonia present, *a* is converted into oxalate, the salt is dissolved in absolute alcohol, the solution evaporated, and the residue mixed with caustic potash, which separates the hygrine in the form of oil. The alkaline solution is heated to boiling in a stream of hydrogen, when the hygrine, dissolved in the water, passes over (by adding water to the residue and again distilling to dryness, a further quantity may be obtained), and is extracted from the distillate by ether; on again distilling the ethereal solution, the hygrine remains behind. The neutral oil in *b* is removed by dissolving *b* in water containing hydrochloric acid, shaking the solution with ether, and separating the ethereal layer; after which, the acid solution is supersaturated with caustic soda, and the hygrine taken up by ether, as in the treatment of *a*. (Lossen.)

Hygrine is a thick, pale-yellow oil, having a strong alkaline reaction, a burning taste, and an odour of trimethylamine. It produces white clouds with the volatile acids; distils very slowly with vapour of water. It does not appear to be poisonous.

Hygrine does not dissolve in water in all proportions. The aqueous solution forms a white precipitate with *dichloride of tin*, yellowish with *sulphate of iron*, light blue with *sulphate of copper*; on boiling the solution, the copper precipitate becomes granular, but not brown. Hygrine forms white precipitates with *chloride of mercury* and *nitrate of silver*; the silver precipitate quickly turns brown.

Hygrine combines with *hydrochloric acid*, forming deliquescent crystals. The aqueous hydrochlorate forms a brown flocculent precipitate with *di-iodide of potassium*, red-white with *dichloride of tin*, white with *corrosive sublimate*, partly flocculent and partly in oily drops. With *tetrachloride of platinum* it forms dirty white-yellow (or red) flakes, which are decomposed by heating the liquid, and do not appear in very dilute solutions. *Picric acid* throws down from hydrochlorate of hygrine a yellow powder; *gallo-tannic acid*, a white pœcceptitate.

Hygrine dissolves in *alcohol* and in *ether*.

HYGROMETER. HYGROMETRY. A Hygrometer (*ὕψος*, moist; *μέτρον*, measure) is any instrument which measures the amount or degree of moisture in the atmosphere. There are, however, several kinds of hygrometers which measure, or are said to measure moisture, by entirely different modes, and the problem itself—to estimate the degree of moistness of the air—is found on examination to be quite ambiguous. It is therefore necessary to attend to the principles of the subject.

Principles of Hygrometry.—Water, both liquid and solid, always tends to assume the gaseous form, and in so doing exerts an elastic force increasing as the temperature rises. In *fig. 565* the curve ABC is drawn so as to represent the law of the elastic force of aqueous vapour: if the divisions along the horizontal axis represent the tem-

Fig. 565.

perature of the water in degrees Fahr., the perpendicular lines drawn from them to the curve, being measured, will give the corresponding force of its vapour estimated in the height of the column of mercury which it would be able to sustain.

The elastic force obviously increases in a higher ratio than the temperature, and, in order that such increasing force may be exerted when water is confined in a given space, it is necessary that a larger and larger quantity of water should become vapour. It is true that if the weight of vapour be not increased, its elastic force will rise with its temperature, but in a much less ratio. For aqueous vapour, like any other gas, tends to expand by $\frac{1}{471}$ th part of its volume at 32° F. for every degree of increased temperature. Thus, if the vapour which rises from water at the temperature of 60° F. and has the elastic force of 518 inch be confined in the same space, but apart from water, and heated, its elastic force will rise in a manner represented by the straight line BE (*fig. 565*); but if more water be present to supply additional vapour, the elastic force of the whole vapour would rise, as shown by the curve BC.

and evaporations of dew in a manner fully described under the head of Regnault's Hygrometer.

The hygrometer of Daniell, however elegant and pleasing in theory, has many sources of inconvenience and inaccuracy. The expenditure of ether is considerable and costly, and in a hot and dry climate it is very difficult to obtain any deposition of dew, during the long-continued manipulation and close observation of the instrument which is always necessary. The warmth and moisture of the hand and body are sure to affect the indications of both thermometers. The cold ether vapour flowing from the upper bulb may also cause inaccuracy. The last and most important objection is that cold is produced only at the surface of the ether in the lower bulb, and there is no agitation of the liquid to ensure uniformity of temperature. Hence the internal thermometer may often indicate a temperature some degrees different from that at which dew is being deposited. This objection is partially remedied by making the lower bulb oblique, so that one part of it shall be nearly in contact with the thermometer-bulb within. Daniell, well aware of this objection, remarks that dew will first be deposited in a circle round the bulb near to the surface of the ether, and directs that the thermometer-bulb shall be placed so as to be cut by the surface of the ether.

Subsequent to Daniell's invention, several dew-point instruments were devised, in which the evaporation of ether was made to cool the bulb of a thermometer and cause a deposit of dew, either upon the bulb or a metallic capsule in a more simple manner. Such is that of Jones (Phil. Trans. [1826] cxvi. pt. ii. 53). Of a similar nature are the *hygromètre à capsule* and the *hygromètre à virole d'or* of Pouillet (Élém. de Phys. [7th ed. 1856] ii. 739). That of M. Belli (Ann. Ch. Phys. [3] xv. 506) is different and very ingenious, giving a continual indication of the dew-point.

Connell's *Hygrometer*, very lately proposed, and to some extent, we believe, brought into use, consists of a thermometer with its bulb immersed in ether, contained within a small metal globe. A common exhausting syringe is used to cause the evaporation of the ether, and the dew-point is then ascertained, exactly as in Daniell's or Regnault's hygrometer. This method presents some slight advantages over Daniell's, but retains all its worst causes of error and inconvenience. It is also an expensive instrument, and cannot compare with Regnault's Condenser Hygrometer either in theory or in practice. It is described in the Transactions of the Royal Society of Edinburgh xxi., and Phil. Mag. [4] viii. 81.

Dr. George Cumming's *Hygrometer* (Quar. Jour. of Sci. &c. 1828, Jan. to June, p. 403) seems first to have introduced a method now finally adopted as the best. It consisted (fig. 667) of a thin glass or metallic tube containing a delicate thermometer enveloped in sponge or other porous substance, upon which a little ether was to be poured. Almost any degree of artificial cold could then be produced by a stream of air from a pair of bellows, or other pneumatic contrivance. The only important objection to this instrument is the presence of a spongy or porous substance, which would prevent perfect uniformity of temperature within the tube.

Döbereiner further proposed a hygrometer in which a current of air from a forcing pump is made to traverse the ether, disposed as in Daniell's instrument, and thus produce cold by evaporation. (Pogg. Ann. lxx. 339.)

Regnault's *Condenser Hygrometer* (Ann. Ch. Phys. [3] xv. 129) may be described as a perfect instrument of its kind. In its complete form (fig. 668) it consists of a very thin and brightly polished silver thimble *a*, 45 mm. high and 20 mm. in diameter, fitted to the glass tube *b*, which again is fixed by the small lateral tube *c*, and the metallic tube *d*, to the stand. The upper end of the glass tube *b* is closed by a cork, bearing a thin glass tube *e*, descending nearly to the bottom of the silver thimble, and a very delicate and accurate thermometer, the pear-shaped bulb of which is in the centre of the thimble. A second exactly similar thermometer, similarly placed within a glass tube and silver thimble, is mounted on the other side of the stand, but the cork is not penetrated by any glass tube.

To make an observation, so much good ether is poured into the tube *b* as will rather

Fig. 667.

Fig. 668.

more than fill the thimble to the level *l*, and the cork being fitted in air tight, the instrument is put in connection, by means of the caoutchouc tube *g*, with a common aspirator, by which an exactly regulated flow of air through the instrument may be obtained. The aspirator, which may have a capacity of 3 or 4 litres (3 or 4 quarts) is placed close to the observer, and the hygrometer may be at some distance, for instance outside a window, being observed, if necessary, with a telescope.

Now when water is allowed to flow from the aspirator, air is drawn through the tube, and bubbling up through the ether, causes a more or less rapid evaporation. The temperature of the ether is thus slowly reduced, and from its constant agitation by the stream of air, the silver thimble and the thermometer-bulb are maintained at an exactly similar temperature. After a minute or two at the most, dew will begin to form on the thimble and will be very visible on its brightly polished surface. The thermometer is instantly to be read, and the stream from the aspirator to be stopped. Suppose that the reading observed is 48.1° F., the deposit of dew may increase for a few moments, but will soon begin to evaporate again, the thermometer rising. At the moment that the dew entirely disappears, read the thermometer again; let it be 49.3 . Considering that dew requires a short time to form or evaporate in a visible degree, it is obvious that the dew-point lies between 48.1 and 49.3 . Let an exceedingly slow current of air be now drawn through the ether, so that the thermometer is very gradually reduced to 49.2 , 49.1 , 49.0 , and so on. The point at which dew first appears may now be observed with much greater accuracy; let it be 48.8 . Still it is probable that 48.8 is somewhat below the exact dew-point. If, when the current is stopped, the small deposit of dew vanishes at 49.0 , we may consider the mean, or 48.9 , to be the true dew-point; but if necessary we may, by still slower procedure, approximate even more closely. "All these operations," observes M. Regnault, "take more time to describe than to execute; with a little practice, three or four minutes are sufficient for determining the dew-point almost within $\frac{1}{20}$ of a degree Centigrade."

At the same time, the second thermometer is to be read, to give the common temperature of the air. From its parallel circumstances and position, its indications would be exactly similar to those of the other; hence the difference of the two gives the depression of the dew-point free from almost all kinds of error. It is obvious that all the objectionable points in Daniell's hygrometer are avoided in this admirable instrument. The only remaining objection is the inconvenience of keeping or carrying about a large aspirator, and frequently filling it with water. In the Kew Observatory, the aspirator is in the form of a circular bellows, to the lower movable board of which a weight is attached. Mr. Welsh also proposed to expand the upper end of the tube *e* into a small funnel by which fresh ether may readily be introduced.

Lieut. Noble has obtained dew with this hygrometer, at all temperatures down to -35° , the limit of graduation of his thermometer, the only requisites when the dew-point is very low being patience and pure ether. (Phil. Mag. [4] xi. 305.)

Several London instrument-makers have rendered this instrument less expensive by omitting the second thermometer and its appendages. They have likewise substituted a closed tube of black glass for the polished silver thimble. This is, on the whole, an improvement, for the dew is even more visible on the black surface, and the difficulty of maintaining the silver bright is avoided; but on the other hand the uniformity of

Fig. 569.

temperature is not so rigorously ensured. As regards the temperature of the air, we think it is best learnt by an ordinary thermometer freely exposed, and that Regnault's parallel arrangement of the second thermometer, although beautiful in theory, is actually erroneous and undesirable in the ordinary use of the instrument.

Except, however, for refined researches or long continued series of observation, a much simpler apparatus will serve. The practical chemist has only to take a common test-tube, containing about $1\frac{1}{2}$ inch depth of ether, insert somewhat loosely a delicate tube-thermometer and glass tube, as shown in fig. 569, and gently blow with the mouth through the bent tube *a*, and the whole process of observation can be conducted almost as well as in Regnault's complete instrument. It is necessary to have the tube *a* of considerable length, that the moistness and warmth of the body and the breath may not affect the air surrounding the tube. The writer had used such an apparatus daily for many months before noticing that Regnault mentions its successful use.

Hygrometry by Evaporation.—Dr. Hutton of Edinburgh first suggested that the degree of cold produced by the evaporation of water in the air, would depend upon and therefore indicate the moistness of the air. Leslie again

very distinctly stated this principle (Leslie, *On the Relations of Air to Heat and Moisture*, 1813, p. 39), and reduced it to practice by covering one of the bulbs of his differential air-thermometer with wet muslin. The motion of the column of water towards the moist bulb, of course, shows the depression of the temperature of evaporation. This hygrometer might yet, we think, be often used in certain researches, and might be added to the common weather-glass.

The *Dry- and Wet-Bulb Hygrometer*, called on the Continent the *Psychrometer* ($\psi\chi\mu\rho\mu\epsilon\tau\epsilon\rho\varsigma$, cold; $\mu\epsilon\tau\rho\epsilon\sigma$, measure), is formed of two similar delicate thermometers placed in a gentle current of air, the bulb of one thermometer being covered with muslin and kept moist by a cotton thread leading from a small reservoir of rain or distilled water. The dry-bulb thermometer indicates the true temperature of the air; the other will be found to remain stationary at a temperature said to be that of evaporation, which is usually several degrees below that of the air. In saturated or moist air, the thermometers read alike; the difference increases in some proportion to the *dryness* of the air, and may be used as a sufficient measure of the dryness in many practical matters, such as the ventilation of dwelling-houses, halls, plant-houses and so on.

From observations of the dry- and wet-bulb thermometers, it is further possible, by means of tables previously determined by experiment, or by calculation from *a priori* principles, to determine the existing tension of aqueous vapour, and other hygrometric data. The most trustworthy table for such reductions is the following, which has been obtained by Mr. Glaisher from the combination of all the simultaneous observations of the dry- and wet-bulb thermometers with Daniell's hygrometer, taken at the Royal Observatory, Greenwich, from the year 1841 to 1854, with some observations taken at high temperatures in India, and others at Toronto.

TABLE I. To obtain the dew-point, multiply the difference of reading of the thermometers by the factor opposite the dry-bulb reading, and subtract the product from the dry-bulb reading.

Dry-bulb thermometer F.	Factor.	Dry-bulb thermometer F.	Factor.	Dry-bulb thermometer F.	Factor.	Dry-bulb thermometer F.	Factor.
10°	8.78	33°	3.01	56°	1.94	78°	1.69

28	5.12	51	2.04	74	1.73	96	1.59
29	4.63	52	2.02	75	1.72	97	1.59
30	4.15	53	2.00	76	1.71	98	1.58
31	3.70	54	1.98	77	1.70	99	1.58
32	3.32	55	1.96				

As an example, let the dry-bulb thermometer stand at 64.3° F., and the wet-bulb at 60.8°:

$$64.3 - 60.8 = 3.5 = \text{difference of readings.}$$

The factor to be used is 1.83 opposite 64°, the nearest degree to 64.3:

$$64.3 - 3.5 \times 1.83 = 57.9^\circ = \text{dew-point.}$$

In the Phil. Mag. [4] xi. 304, is a table for reduction of dry and wet-bulb readings from 51° F. down to -16°, giving also the probable error and measure of precision of the results determined by Lieut. Noble from observations at Toronto.

The dry- and wet-bulb thermometer having long become the ordinary working

hygrometer of the meteorological observer, Mr. Glaisher has paid much attention to the perfecting of the instrument in every detail. He has finally adopted a pair of very

Fig. 570.

delicate thermometers (see fig. 570) about one foot long, and with small spherical bulbs of thin glass of about $\frac{1}{4}$ inch diameter. They are mounted upon metal scales graduated from about -10° to $+130^{\circ}$ F. and fixed parallel to each other from 2 to 4 inches apart upon a metal cross piece. Care is taken that each pair of thermometers is as exactly similar as possible. The bulb of the wet thermometer is covered with thin muslin, round the neck of which is twisted a conducting thread of lamp-wick, common darning cotton, or floss silk; this passes into an adjacent vessel of water placed about three inches distant from the wet bulb, a little beneath it, and on the opposite side to the dry-bulb thermometer. It is a very objectionable practice to place a long glass cistern between the two thermometers; for the water will seldom be of exactly the same temperature as the surrounding air, and will tend slightly to vitiate the readings of both thermometers. The writer prefers for a cistern a short narrow-necked glass bottle, from which but little evaporation will take place. The water must be either rain or distilled water. Care must be taken never to record any readings when the bulb is not thoroughly moist all over. As dust and saline particles gradually settle on the wet muslin, it is well to re-cover the bulb and supply a fresh wick about every month. Before use, too, each wick

should be washed in a solution of carbonate of soda, and pressed whilst under water throughout its length. The supply of water to the bulb can be easily regulated by raising or lowering the cistern.

In taking an observation, the dry-bulb thermometer is first to be read, because it is most liable to change; the wet-bulb is then to be read, the two readings to be recorded, and a comparison with the thermometers made, to secure the correct number of whole degrees. The observer must follow the directions under the article THERMOMETER, as regards placing the instrument, correcting the thermometer-readings, &c.

The dry- and wet-bulb hygrometer continues to act even when the water is frozen, since evaporation still takes place; but especial care must be taken that the bulb really is covered with ice, and if not, water must be poured upon it, and the observation delayed till the water be frozen, and the thermometer sink to a constant reading. In frosty weather it is best to wet the bulb after every periodic observation, or at least ten minutes before the next.

Theory of the Psychrometer.—Although we may ascertain the dew-point from readings of the dry- and wet-bulb thermometers on purely experimental grounds, as in using Glaisher's factors, the subject also admits of mathematical investigation. Mr. Ivory first solved the problem (*Phil. Mag.* [3] lx. 80) with substantial correctness. August of Berlin, and Bohnenberger, showed the coincidence of the theory with experiment, and determined the constants with accuracy (August, *Ueber die Fortschritte der Hygrometrie in der Neuesten Zeit*, Berlin, 1830.—Bohnenberger, *Tubingen Nat. Hist. Soc. Memoirs*, vol. ii.). But the subject is best known in England from Dr. Apjohn's excellent results (*Phil. Mag.* [3] vi. 182; vii. 266, 470; xiii. 261).

We now give the investigation as it is stated by Regnault after the method of M. August.

The evaporation of a liquid involves the conversion of sensible into latent heat, and the supply of heat must be drawn from the liquid evaporated, from the remaining liquid, or from surrounding objects. When air is in contact with the moistened bulb of a thermometer, the evaporation of the water will reduce the temperature of the bulb, but the fall of temperature will be checked by heat communicated from the remainder of the air. At some point, the amounts of heat subtracted and communicated will be equal, and an invariable temperature of evaporation will be the result.

Let us suppose, with M. August, that the portions of air successively in contact with the moist thermometer-bulb become thereby perfectly saturated with moisture, and are reduced to the temperature of the bulb.

Let w = weight of stratum of dry air surrounding the bulb at 0° C., and under the pressure of 0.760.

A = height of barometer.

t = temperature of surrounding air given by the dry-bulb thermometer.

t' = temperature of evaporation, or the reading of the wet-bulb thermometer.

f and f' = the elastic forces of saturated aqueous vapour for the temperatures t and t' .

x = the actual elastic force of vapour in the air at the time.

In the stratum of air surrounding the bulb, the aqueous vapour exerts the elastic force f , and the air consequently exerts the elastic force $h-f$. The weight of dry air is then

$$w \cdot \frac{1}{1+\alpha t'} \cdot \frac{h-f}{30},$$

α being the coefficient of expansion of a gas for every degree of temperature. The weight of vapour already in this air is

$$w \delta \cdot \frac{1}{1+\alpha t'} \cdot \frac{x}{30};$$

in which δ represents the specific gravity of aqueous vapour in relation to air. The weight of vapour added by contact with wet bulb similarly is

$$w \delta \cdot \frac{1}{1+\alpha t'} \cdot \frac{f-x}{30}.$$

Now, if γ be the specific heat of air, the quantity of heat disengaged by the dry air in cooling from t to t' is

$$w \frac{1}{1+\alpha t'} \cdot \frac{h-f}{30} \cdot (t-t') \cdot \gamma.$$

Similarly k being the specific heat of aqueous vapour, the quantity of heat disengaged by the vapour previously in the air is

$$w \delta \frac{1}{1+\alpha t'} \cdot \frac{x}{30} (t-t') \cdot k.$$

Lastly, let λ be the latent heat absorbed by water, when becoming gaseous between the temperatures t and t' .

The quantity of heat absorbed will be

$$w \delta \frac{1}{1+\alpha t'} \cdot \frac{f-x}{30} \cdot \lambda.$$

Now when the temperature of evaporation is constant, this heat absorbed in evaporation must be equal to that given out by the air and the other portion of vapour;

or we have, by equating them and striking out the factor $w \cdot \frac{1}{1+\alpha t'} \cdot \frac{1}{30}$,

$$\gamma (h-f) (t-t') + \delta k x (t-t') = \delta \lambda (f-x);$$

whence

$$x = \frac{1 + \frac{\gamma}{\delta \lambda} (t-t')}{1 + \frac{k}{\lambda} (t-t')} f - \frac{\frac{\gamma}{\delta \lambda} (t-t')}{1 + \frac{k}{\lambda} (t-t')} \cdot h.$$

Inserting values of the known quantities, namely, for γ , 0.2669, for k , 0.2669 (the specific heat of aqueous vapour being assumed equal to that of air), for δ , the specific gravity of aqueous vapour, 0.6235, and for λ , the latent heat of aqueous vapour, 640- t' , according to the law of Watt, and neglecting some of the smaller terms, August obtains the formula $x = f - \frac{0.568 (t-t')}{640-t'} \cdot h$, the temperatures being expressed in centigrade degrees.

Regnault, using more accurate data, namely, for δ , 0.622, and for λ , 610- t' ($\gamma = k = 0.2669$ as before), modifies this to

$$x = f - \frac{0.429 (t-t')}{610-t'} \cdot h.$$

Experimentally, Regnault has found that the formula $x = f - \frac{0.480 (t-t')}{610-t'} \cdot h$ gives an almost perfect coincidence between the calculated and true results, when the air is not more than $\frac{1}{10}$ saturated. Otherwise the first coefficient 0.429 is to be preferred.

The formula which has been most used in the reduction of dry- and wet-bulb observations is that obtained by Dr. Apjohn. In the Greenwich observations it is given as follows:

$$F = f - \frac{d}{88} \cdot \frac{h}{30} \quad F = f - \frac{d}{96} \cdot \frac{h}{30}$$

The first formula is to be used when the reading of the wet-bulb is above 32° F., and the second when below. In the above, d is the difference of the dry- and wet-bulb readings, h the height of the barometer, f the elastic force of vapour for the temperature of the wet-bulb, to be taken from Table II., and F the elastic force of vapour at the dew-point, from which the dew-point may be found, if necessary, by the table.

32	.181	7	66	.639	22	100	1.918	
33	.188	8	67	.661	23			

be taken at once from the formula or table. In all other cases, however, since vapour above its dew-point expands like any other gas, we must have

$$\text{Actual weight of a cubic foot of vapour} \left\{ \begin{array}{l} \text{Weight of a cubic foot} \\ \text{of vapour at dew-point} \end{array} \right\} \times \frac{\text{Volume at dew-point}}{\text{volume at temperature of air.}}$$

The weight of a cubic foot of dry air is easily calculated from the following data of Regnault. Dry air expands by $\frac{1}{491.13}$ or .0020361 parts of its volume at 32° F. for

every increase of 1° of heat, and a cubic foot of dry air at 32° under a pressure of 30 inches of mercury weighs 566.85 grains. Thus are calculated, for a pressure of 30 inches of mercury, the numbers in column 3 of Table III.

If a cubic foot of dry air and a cubic foot of aqueous vapour of the same temperature be mixed together and compressed into a cubic foot of space, the elastic force of the mixture will be the sum of the elastic forces of the air and vapour. In order that the mixed or moist air may have the same elastic force as the dry air previously, it must be allowed to expand, in the proportion of the elastic force of the dry air to the sum of the elastic forces of the air and vapour.

Thus, if E_v = elastic force of vapour at temperature t ,

and p = elastic force of moist air—say the atmospheric pressure as shown by the barometer

we have $p - E_v$ = elastic force of dry air,

$$\text{and} \quad \frac{\text{volume of moist air}}{\text{volume of dry air}} = \frac{p}{p - E_v}.$$

Thus one cubic foot of dry air, after becoming saturated with moisture, expands into the volume $\frac{1}{1 - \frac{E_t}{p}}$ if it be confined under the same pressure as before.

We may now find the weight of a cubic foot of air saturated with aqueous vapour at any temperature: for it is obviously

$$(\text{Weight of cubic foot of dry air} + \text{weight of cubic foot of vapour}) \times \frac{p - E_t}{p}.$$

Thus are obtained the numbers in column 4 of Table III. When the dry- and wet-bulb thermometers read alike, we have at once the weight of a cubic foot of the atmosphere for the barometric pressure of 30 inches. For any other height of the barometer we must multiply by this height in inches and divide by 30. When the air is not saturated, we must subtract the following:

$$\left(\begin{array}{l} \text{Weight of cub.} \\ \text{ft. of dry air} \end{array} \right) - \left(\begin{array}{l} \text{weight of cub. ft.} \\ \text{of saturated air} \end{array} \right) \times \frac{\text{Weight of cubic foot of vapour at dew-point}}{\text{Weight of cubic foot of vapour at temperature of air:}}$$

from the weight of a cubic foot of dry air, and reduce the result as before to the barometric pressure at the time.

The Degree of Humidity represents the proportional saturation of the air with moisture, decimally expressed, so that saturated air has the degree 100, and perfectly dry air the degree 0. It is found by dividing the weight of vapour (Table III. column 2) at the dew-point by the weight which would be present at the temperature of the air, if it were saturated. Some writers use the corresponding elastic forces of the vapours at the dew-point and temperature of the air (Table II.) in place of the weights of vapour, but the results are nearly the same.

Chemical Method of Hygrometry. The chemist may always avoid the difficulties attending the use of hygrometers, by absorbing the aqueous vapour from

any given volume of air and actually weighing it upon the chemical balance. The necessary apparatus (fig. 571) consists of a common aspirator *a* and two U-shaped drying tubes *b*, *c*, containing fragments of pumice-stone soaked in strong sulphuric acid. The aspirator being full of water, the second tube *c* is detached, weighed accurately, and again attached on one side to the other drying tube *b*, on the other side to a long perfectly dry tube *d*, by means of which air from any required point, as for instance from the open atmosphere outside the laboratory window, may be drawn through the apparatus.

Fig. 571.

The fixed drying tube *b* is employed to prevent any vapour passing back from the aspirator. Regnault took great pains to ascertain the least necessary size of the weighed drying tube. He generally indeed employed two weighed tubes, each 0.18 metre in height, filled with large fragments of pumice-stone. But the second tube rarely gained 1 or 2 milligrammes in weight, and chiefly served to afford a proof that the absorption by the first tube was complete. It is probably best therefore to dispense with a second weighed tube, as the increased error in weighing the larger apparatus will probably be greater than the minute weight of vapour which may be lost. Additional accuracy may always be had by increasing the volume of air passed through the tube.

A determinate volume of water having been allowed to flow slowly and uniformly from the aspirator by the tap *c*, an equal volume of air, of course, passes through the tube *c*, and becomes desiccated. The weight of vapour absorbed is learnt by again weighing the tube *c*, but to determine the corresponding weight of air with accuracy, we must read the temperature at the end of the experiment by a thermometer placed in the centre of the aspirator, and likewise observe the barometer, then performing the calculation as directed on page 230.

This method may also be used to determine the amount of water suspended in the air in the form of mist or cloud. The weight of the watery particles is the excess of the whole weight absorbed over the maximum weight of vapour (saturated) as given in Table III. column 2.

The chemical determination of vapour has been fully considered by Brunner. (Ann. Ch. Phys. [3] iii. 309.)

The chemical method might obviously be used to determine the average amount of vapour in the air during any period of time. It is only necessary for this purpose that a perfectly uniform stream of air pass through the drying tube throughout the period. The total weight of vapour absorbed, divided by the total weight of air passed through, gives the required result. Such a process was proposed by Dr. Andrews (Brit. Assoc. 1861, Trans. of Sec. p. 29), who has also described an aspirator suitable for the purpose (Phil. Mag. [4] iv. 330), and we know not why it is not adopted, at least in some of the principal observatories.

Hygroscopic bodies. Most organised structures expand or contract according to their state of moisture or dryness, and many organic substances to such a degree that they afford very delicate indications of hygrometric changes. Thus a thin shaving of whalebone laid on the hand instantly curls up, and a slip of whalebone furnished with a multiplying index formed the hygrometer finally adopted by Deluc (Phil. Trans. [1791] lxxxi. 419). An ivory hygrometer was also constructed by Deluc (Phil. Trans. [1773] p. 404) and Leslie (Ann. Ch. Ph. i. 468). A hygroscope formed of pieces of deal-wood was designed in 1676 by John Coniers (Phil. Trans. xi. 715). Chimney ornaments are often seen in which certain figures are caused to move by the contraction or expansion of catgut, thus indicating the approach of rain or fine weather. The awn of the *Andropogon contortum* has been used for similar purposes by Capt. Kater; the awn of the *Avena sativa*, or wild oat, by Hooke; the internal membrane of the *Arundo Phragmites*, or common reed, by Adie; and the *Funaria hygrometrica*, or common cord-moss, the arista of the seed of the *Stipa pennita*, or common feather-grass, by others. The hygroscope usually placed at the top of the common barometer or weather-glass consists of an awn or vegetable filament which in twisting or untwisting moves a light index.

234 HYOCHOLALIC ACID—HYOGLYCOCHOLIC ACID.

Saussure's Hair Hygrometer is the only instrument of this class which has been supposed in late years to possess any scientific accuracy or importance. To construct it,

Fig. 572.

long, soft and straight human hairs must be prepared and boiled for half an hour in a litre of water containing 10 grammes of crystallised carbonate of soda. After being well washed in pure water and dried without heat, the best hair is chosen, of a length of about 24 centimetres. One end is fixed to the top of the instrument (fig. 572), and the other, being passed round a pulley of the diameter of 5 millimetres, is attached to a weight of about 0.2 gramme (3 grains). An index fixed to the pulley moves over a divided circle, the divisions of which are determined by placing the instrument first over water and then over sulphuric acid, that is in perfectly moist and perfectly dry air, and dividing the space which the index is thus caused to move over into 100 equal parts. When well and delicately constructed, such an instrument will promptly show the slightest changes of moisture in the air.

Regnault, in his "*Etudes de l'Hygrométrie*," has spent much labour and ingenuity in trying to render the Hair Hygrometer scientifically useful. He has only succeeded in showing that two of these instruments will give very different results, if there exists the slightest difference in the nature of the hairs, their preparation, or the weight by which they are extended; that the most carefully constructed instruments are but little accordant; and that, after all, the degrees are quite arbitrary, and can only be reduced to true degrees of humidity or force of aqueous vapour, by a table specially determined by experiment for each instrument. Such a table may be found in Pouillet's *Elements*

de Physique, 7th ed. ii. p. 742, having been prepared by Gay-Lussac, and supposed by him to apply to all Hair Hygrometers.

Regnault, indeed, has found that the zero of the Hair Hygrometer, at which it should stand in perfectly dry air, is quite illusory, for the hair will continue to shrink more or less even when it has been exposed for some months to the dry air. He therefore commences the graduation for air about $\frac{1}{2}$ saturated, or of 20 degrees of humidity.

Kæmtz (*Météorologie*, Paris, 1858, p. 74) compares the table of Gay-Lussac with others calculated for Saussure's Hygrometer by Prinsep, Melloni, and August. There is very little accordance.

A great number of experiments on hygrometers and hygroscopic substances are given in the three elaborate papers by Deluc in the *Philosophical Transactions* (1773 and 1791), and he says (*Ph. Trans.* [1791] lxxxi. 40), "I have concentrated in these pages an account of twenty years' assiduous labours in *hygrometry*, mostly occasioned by the anomalies of the *hygroscopic threads*."

There is a complete and learned history of hygrometry by Suerman, entitled "*Commentatio de definiendâ Quantitate Vaporis aëqui in Atmospherâ*," 4to. Lugd. Bat. 1831.

In Prof. Forbes' *Supplementary Report on Meteorology* (Brit. Assoc. Report, 1840. pp. 95-101) is an excellent *résumé* of the theory of the wet-bulb thermometer.

A general account of hygrometry, with examples of the calculations required in meteorology, is to be found in Dr. Drew's *Practical Meteorology*. W. S. J.

HYOCHOLALIC ACID. Syn. with HYOCHOLIC ACID.

HYOCHOLIC ACID. $C^3H^4O^4$.—An acid obtained, together with glycocine, by the action of potash on hyoglycocholic acid. It is insoluble in water, soluble in alcohol and ether, and crystallises in mammellated granules. Its *barium-salt* dried at 180° contains $C^3H^4Ba^2O^6$. (Strecker.)

HYOGLYCOCHOLIC ACID. $C^3H^4NO^4$. Formerly called *Hyocholic acid*. (Strecker and Gundelach, *Ann. Ch. Pharm.* lxii. 205.)—An acid which, in the form of a sodium-salt, constitutes the principal part of the bile of the pig: hence its name (from *ūs*, *ūs* a pig, and *χολή* bile).

To prepare the sodium-salt in the pure state, the fresh bile is completely saturated with sulphate of sodium; the mixture is heated for some hours on a sand-bath, and then left to cool; and the resulting precipitate, consisting of hyoglycocholate of sodium mixed with mucus and a small quantity of yellow colouring matter, is washed with a concentrated solution of sulphate of sodium, first by decantation and then on a filter, after which it is dried at 110° C. and treated with absolute alcohol, which dissolves the hyoglycocholate of sodium. The alcoholic solution is decolorised with animal charcoal, then precipitated by ether, and the precipitate is dried at 100° .

The free acid is obtained by precipitating the aqueous solution of the sodium-salt with dilute sulphuric acid, dissolving the precipitate in alcohol and precipitating with water. The liquid is milky at first, but becomes limpid after a while, and deposits

transparent drops. It must be left on the sand-bath for several days, because the precipitation is not complete till the last traces of alcohol are evaporated. By repeating this operation two or three times, the acid is obtained quite pure.

Hyoglycocholic acid is a white resinous body which melts in hot water, and then presents a silky aspect. It solidifies after remaining for a few days over the water-bath, and after it has lost all traces of water; does not melt even at 120° . It is but slightly soluble in water, imparting, however, an acid reaction; easily soluble in alcohol, but quite insoluble in ether. It dissolves readily in ammonia and in dilute solutions of the fixed alkalis or their carbonates. According to F. Hoppe (Jahresber. 1858, p. 568), the solutions of the free acid exhibit an optical rotatory power $= + 2^{\circ}$; that of the sodium-salt does not act on polarised light. It differs from the acid of ox-bile (glycocholic acid) by its sparing solubility in water, and by forming precipitates insoluble in water, with baryta, lime, &c.; in this respect it resembles cholonic and cholidic acids.

Hyoglycocholic acid is not altered by dilute sulphuric acid: the concentrated acid blackens it, with evolution of sulphurous acid. It is not oxidised by a mixture of sulphuric acid and peroxide of lead; but when the acid or any of its salts is heated with concentrated nitric acid, nitrous fumes are evolved, and a yellowish mass is formed, consisting chiefly of oxalic and cholesteric acids; at the same time volatile fatty acids are formed homologous with acetic acid. These volatile acids are also produced, together with hydrocyanic acid, when hyoglycocholic is oxidised by a mixture of chromate of potassium and sulphuric acid.

Hyoglycocholic acid, boiled for a long time with strong hydrochloric acid, is decomposed in the same manner as glycocholic acid (ii. 900), yielding first a resinous substance soluble in alkalis (hyocholoidic acid?), then hyodyslysin insoluble in alkalis, while glycocine remains in solution:

Potash induces a similar transformation, yielding hyocholoidic acid, which differs from hyodyslysin only by the elements of 1 at. water.

Hyoglycocholic acid is monobasic, the hyoglycocholates in the dry state containing $C^7H^{12}MNO^3$. The ammonium-salt is obtained by adding chloride, carbonate, or sulphide of ammonium to fresh pig's bile, or a solution of the sodium-salt. It dissolves very easily in water, but very sparingly in strong solutions of ammoniacal-salts. It is decomposed by boiling. The barium-salt, $C^7H^{12}Ba^2N^2O^{10}.2H^2O$, dissolves very sparingly in water, very readily in alcohol. The calcium-salt, $C^7H^{12}Ca^2N^2O^{10}.2H^2O$, resembles the barium-salt. The lead-salt is a white precipitate obtained by mixing a solution of the sodium-salt with neutral acetate of lead. This mother-liquor yields with the basic acetate another precipitate which appears to be a basic salt.

The potassium-salt, $2C^7H^{12}KNO^3.H^2O$, is prepared by dissolving the acid in caustic potash, and treating the solution with sulphate of potassium, &c., as in the preparation of the sodium salt. It is a white amorphous mass, which melts at the heat of the water-bath so long as it retains water or alcohol; when quite dry, it remains solid even at 120° .

The silver-salt, $C^7H^{12}AgNO^3$, is a gelatinous precipitate, which becomes flocculent when boiled.

The sodium-salt, $2C^7H^{12}NaNO^3.H^2O$, is a white powder which does not become moist by exposure to the air. Its alcoholic solution yields by evaporation a perfectly transparent varnish. It has a bitter and very persistent taste. Heated on platinum-foil, it melts, swells up, and burns with a smoky flame.

HYOCHOLOÏDIC ACID. The resinous substance formed previous to hyodyslysin, when hyoglycocholic acid is boiled with strong hydrochloric acid, is perhaps homologous with cholidic acid, $C^7H^{12}O^4$. According to Hoppe (Jahresber. 1868, p. 668), its solutions have a dextro-rotatory power $= 23.6^{\circ}$.

HYODYLSYIN. $C^5H^8O^3$.—A substance homologous with dyslysin, produced by the continued action of boiling hydrochloric acid on hyoglycocholic acid. It is insoluble in water, potash, and ammonia, sparingly soluble in boiling alcohol, moderately soluble in ether.

HYOSCYAMINE. (Geiger and Hesse, [1833] Ann. Ch. Pharm. vii. 270.)—An alkaloid contained in henbane (*Hyoscyamus niger*), and other species of *Hyoscyamus*. To prepare it, the bruised seeds of henbane are exhausted with hot alcohol containing 2 per cent. of sulphuric acid; the expressed juice is mixed with a quantity of slaked lime, sufficient to produce a strong alkaline reaction; the filtered liquid is slightly supersaturated with sulphuric acid, and again filtered; the alcohol is distilled off to one-fourth; the residue diluted with water; and the rest of the alcohol driven off at the lowest possible temperature. To the remaining liquid is then cautiously added a con-

centrated solution of carbonate of potassium, the liquid being again filtered if any turbidity is thereby produced; then a large excess of the same solution; and the whole is shaken with ether as long as that liquid takes anything up. The ethereal solution, separated from the watery liquid and evaporated, leaves impure hyoscyamine, which may be purified by mixing it with water till a clear solution is produced; adding to this solution twice its weight of ether-alcohol, digesting with animal charcoal, and evaporating off the ether-alcohol, first at a gentle heat, and afterwards in vacuo. If the residue is still coloured, it must be once more dissolved in dilute acid; the solution mixed with an equal quantity of alcohol, digested with animal charcoal, and decomposed by excess of carbonate of potassium; the hyoscyamine extracted by ether; and the whole process repeated if necessary.

Hyoscyamine may also be prepared, though less advantageously, from the herb of the plant, while in flower, by boiling the expressed juice, filtering, mixing with lime, treating the filtrate with excess of carbonate of potassium, and dissolving out the hyoscyamine by agitation with ether. The dried herb likewise yields it when treated with acidulated alcohol.

Hyoscyamine crystallises in stellate groups of silky needles, but is frequently also obtained as an amorphous sticky mass. When perfectly dry it is inodorous, but in the moist state, it has an unpleasant odour resembling that of tobacco. It is soluble in water, alcohol, and ether. The aqueous solution has an alkaline reaction. It melts when heated, and then volatilises with partial decomposition. It is decomposed when heated with acids. Strong nitric acid dissolves it without colour; strong sulphuric acid turns it brown. Iodine added to its aqueous solution forms a copious precipitate having the colour of kermes. Taken internally, even in small doses, it acts as a narcotic poison. Rubbed into the eye, even in minute quantity, it produces persistent dilatation of the pupil.

Hyoscyamine neutralises acids completely. Many of its salts crystallise and are permanent in the air. They have no odour, but an acrid, nauseous taste, and are very poisonous. Their solutions are not precipitated by dichloride of platinum; but yield whitish flocks with chloride of gold. With infusion of galls they form a white precipitate.

HYPARGYRITE. See MIARGYRITE.

HYPERSPIROÏLIC ACID. Syn. with SALICYLIC ACID.

HYPER, as a prefix, syn. with **PER**.

HYPERSTHENE (from *δύειν* and *σθένος*, strength, on account of the greater hardness and density of this mineral as compared with hornblende, with which it was formerly confounded). It is a sub-species of augite, containing, according to Muir's analyses (Pogg. Ann. lxiv. 162),

SiO ^a	Al ^a O ^a	CaO	MgO	FeO	MnO	H ² O
51.35	. .	1.83	11.09	33.92	. .	0.50 = 98.69

It is distinguished from common augite and diallage by its small proportion of calcium and large proportion of iron, and may be represented by the formula (Mg; Fe)²SiO².

Hypersthene has a density of 3.3—3.6, and a greyish or greenish-black colour, with a more or less distinct copper-red metallic iridescence on the most distinct cleavage-surface, arising from the presence of microscopic laminae of titaniferous iron imbedded in the mineral. It is remarkable that all the augitic rocks of Sweden contain titaniferous iron.

The name *Paulite* is given to hypersthene found in the island of St. Paul on the coast of Labrador. *Gedrite* is hypersthene in which the quantity of iron attains its maximum.

HYPERSTHENITE or *Hypersthene-rock* is a crystallo-granular mixture of hypersthene and labrador, with small quantities of titaniferous iron imbedded in the hypersthene, and occasional admixture of iron pyrites, mica, hornblende, olivine, garnet, opalite, &c. Labrador is usually the chief component. Quartz is never found in this rock. Hypersthene-rock belongs to the less frequently occurring crystalline, unstratified formations. It is found in the island of St. Paul, on the coast of Labrador, at Elfdalen in Sweden, at several localities in Norway, in the Isle of Skye, in Cornwall, in the Harz in Silesia, Bohemia, &c.

The following analyses of hypersthene are by Bunsen (Jahresb. 1861, p. 1070):
a. Coarse-grained, containing brown hypersthene and greyish-white labradorite, from a vein near Penig in Saxony.—*b.* Medium-grained, greenish-brown, containing greenish-white labradorite and dark green augite, from Tabor, near Getachin in Bohemia.—*c.* Somewhat finer-grained and browner, from Stransko near Liebetadl.—*d.* Greyish-green, crystalline, medium-grained, very slightly magnetic, containing triclinic felspar, from Hrabacow near Starkenbach.—*e.* From the railway cutting of the Woieschka valley, between Semil and Kostulow near Poric. It is finely crystalline, dark grey to greenish,

and effervesces with acids, in consequence of small masses of calcespar disseminated through it; scarcely magnetic, and with a weathered crust:

	SiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	K ² O	Na ² O	H ² O
a.	49.90	16.04	7.81	14.49	10.08	0.56	1.68	1.46 — 102.01
b.	49.97							
c.	56.20	15.26	13.40	9.50	3.21			
d.	51.98	16.27	13.53	7.34	5.85	3.30	1.20	2.71 — 102.18
e.	54.44	18.06	9.64					

HYPOBROMOUS ACID. BrHO.—The formation of bleaching liquids analogous to the hypochlorites by the action of bromine on solutions of the alkalis and alkaline earths was noticed by Balard in his original memoir on bromine (*Ann. Ch. Phys.* [2] xxxii. 337), and subsequently by Löwig (*Pogg. Ann.* xiv. 14, 485), Fritzsche (*J. pr. Chem.* xxiv. 294), and Gay-Lussac (*Compt. rend.* xiv. 951). Balard also found that bromine-water forms with mercuric oxide a sparingly soluble oxybromide of mercury and a bleaching liquid which, by distillation in a vacuum, yields a liquid also possessing bleaching properties, and supposed to be hypobromous acid (i. 679).

More recently, Spiller (*Jahresber.* 1869, 97; 1862, 73) and Dancer (*Chem. Soc. J.* xv. 447) have shown that when bromine is added to excess of solution of nitrate of silver, half the bromine is precipitated as bromide of silver, while the other half remains in solution as hypobromous acid, forming a strongly bleaching liquid, from which, according to Dancer, the hypobromous acid may be distilled under a pressure of 50 mm. of mercury, the liquid then boiling at 50°. The distillate, which does not contain free bromine, is straw-yellow, has an acid reaction, bleaches strongly, and decomposes when heated above 60°. It gave by analysis numbers corresponding with the formula of hypobromous acid.

Hypobromous acid is likewise obtained in solution by agitating bromine-water with excess of mercuric oxide or oxide of silver. When bromine is brought in contact with excess of dry mercuric oxide, the mixture becomes very hot. By heating the two substances together in a sealed tube to 100° a powder is obtained which smells like chloride of lime and bleaches when moistened with water; it is a mixture of mercuric bromide, oxide and hypobromite. If the bromine is in excess, a solid mass is formed consisting merely of mercuric bromide and oxide. Oxygen is set free in both cases. (Dancer.)

All attempts to prepare hypobromous anhydride by methods similar to those which yield hypochlorous anhydride (i. 908) were unsuccessful, the compound being decomposed, both at common temperatures and at -18°, into bromine and oxygen.

HYPOCHLORIC ACID. Syn. with Perchloric oxide. (See CHLORINE, OXIDES OF, i. 912.)

HYPOCHLORITE. (*Grüne Eisenerde.*)—A mineral occurring at Schneeberg, Johanngesengstadt, and Bräunsdorf in Saxony, in minute greenish crystals and grains, or massive and earthy. It contains, according to Schüler's analysis, 50.24 per cent. silica, 14.65 alumina, 13.03 oxide of bismuth, 10.54 protoxide of iron, and 9.62 phosphoric anhydride, with a trace of manganese, and is perhaps a silicate of bismuth and iron mixed with phosphate of aluminium. (Dana, ii. 182.)

HYPOCHLORITES. ClMO.—The formation, general properties and reactions of these salts, and the methods of estimating the quantity of available chlorine contained in them, have been already described under CHLORINE (i. 904, 908). For the preparation of hypochlorite of calcium, its uses as a bleaching and disinfecting agent, and the methods of estimating its commercial value, see *Ure's Dictionary of Arts, &c.* i. 904; also *Richardson and Watts's Chemical Technology*, vol. i. pt. 3, pp. 360-425.

A sample of "chloride of lime," analysed by F. Rose under the direction of Fresenius (*Ann. Ch. Pharm.* cxviii. 317), yielded 26.72 per cent. CaCl_2O , 25.61 CaCl_2 , 23.05 CaO, and 24.72 combined and hygroscopic water. On repeatedly triturating it with fresh quantities of water to a thin pulp, the chloride of calcium was found to dissolve at the first trituration, the hypochlorite only at the third. Hence Fresenius concludes that the two salts exist in the bleaching powder merely in a state of mixture, or at most as a loose combination easily decomposed by water. He regards bleaching powder as a mixture of hypochlorite and basic chloride or oxychloride of calcium, $\text{CaCl}_2\text{O} + (\text{CaCl}_2 \cdot 2\text{CaO}) + 4\text{H}_2\text{O}$. The basic chloride is resolved by water into chloride and hydrate of calcium.

Solutions of the hypochlorites of the alkali-metals have long been used as disinfecting agents. The so-called chloride of soda or Labarraque's disinfecting liquid, is a mixture of hypochlorite and chloride of sodium, prepared by passing chlorine into a solution of caustic soda or carbonate of sodium, or by decomposing hypochlorite of calcium (bleaching powder) with carbonate or sulphate of sodium. In the first mode of preparation, about 40 lbs. of soda-crystals are dissolved in about 20

gallons of water, and a stream of chlorine is passed through the solution till it has attained a specific gravity of 1.08. A rise of the density above this point indicates the formation of chlorate of sodium. To prepare the disinfecting liquid by the second method, about 20 lbs. of good bleaching powder are dissolved in about 26 gallons of water, and to the filtered liquid is added a solution of 40 lbs. soda-crystals in about 9 gallons of warm water. The filtered solution constitutes Labarraque's liquid.

Chloride of Potash or *Eau de Javelle* is a mixture of hypochlorite and chloride of potassium prepared by similar methods.

A mixture of hypochlorite of magnesium, prepared by decomposing chloride of lime with an equivalent quantity of sulphate of magnesium, is said by Clausen to be more efficacious than other chlorine-compounds for bleaching flax and hemp.

Hypochlorite of Aluminium, prepared by mixing equivalent quantities of sulphate of aluminium and hypochlorite of calcium, is recommended by Orioli (Rep. Pat. Inv. April 1860) as a bleaching and antiseptic agent. It is very easily decomposed, and therefore acts very rapidly on organic matters. It may also be used as a mordant instead of acetate of aluminium, all the hypochlorous acid being disengaged at the heat of the dye-bath while the alumina remains attached to the fibre.

Hypochlorite of Zinc is also used as a mordant, and is recommended by Varrentrapp (Dingl. pol. J. clviii. 378), on account of its ready decomposibility, as a bleaching agent. The action of chloride of lime may be advantageously accelerated by the addition of chloride of zinc instead of a mineral acid.

HYPOCHLOROUS ACID AND ANHYDRIDE (i. 908).—This gas is absorbed by sulphuric anhydride, and when the latter compound, in a state of perfect dryness and in quantities of not more than 5 or 6 grms. at a time, is saturated with hypochlorous anhydride, a dark-red thickish liquid is formed, which solidifies on cooling to a mass of light red needles apparently consisting of $\text{Cl}^{\text{O}}\cdot 4\text{SO}^{\text{A}}$. These crystals melt at 55° , and detonate when suddenly raised to a higher temperature. They are instantly decomposed by water into sulphuric and hypochlorous acids; hence the compound acts as a powerful oxidising agent on sugar, alcohol, and other organic substances. Iodine decomposes it, with evolution of chlorine and formation of iodic acid.

When hypochlorous anhydride is passed into liquid sulphurous anhydride, a very brisk reaction takes place as soon as the containing vessel is removed from the freezing mixture, chlorine being evolved and a red viscid substance remaining, composed of sulphuric and hypochlorous anhydrides in a proportion not yet determined. (Schütz-enberger, Compt. rend. lii. 136; liii. 638; Jahresber. 1861, p. 142.)

HYPOGÆIC ACID. $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}} = \begin{matrix} \text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}} \\ \text{H} \end{matrix} \left. \vphantom{\begin{matrix} \text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}} \\ \text{H} \end{matrix}} \right\} \text{O}$.—An acid belonging to the oleic series $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$, discovered in 1856 by Gössmann and Scheven (Ann. Ch. Pharm. xiv. 230) in oil of earthnut (*Arachis hypogæa*). It is isomeric, if not identical, with physetoleic acid, discovered in 1844 by Hofstädter (Ann. Ch. Pharm. xci. 177) in sperm-oil (see PHYSETOLEIC ACID), also with the acid obtained by oxidation of axinic acid ($\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$), an acid produced by the saponification of the fatty substance, agé or axin, contained in the Mexican plant, *Coccus Axin*. (F. Hoppe, J. pr. Chem. lxxx. 102.)

Preparation from Earth-nut oil.—The fatty acids of the oil are dissolved in alcohol; arachidic and palmitic acids are precipitated by ammonia and acetate of magnesium; the precipitate is removed; and the filtrate is mixed with ammonia and an alcoholic solution of neutral acetate of lead. The precipitate is collected after a few days, pressed, and dissolved in ether; the ethereal solution is agitated with aqueous hydrochloric acid; the chloride of lead is filtered off; the filtrate is shaken up with water which has been freed from air by boiling; the ethereal layer which separates again on leaving the liquid at rest is taken off; and the ether is removed by distillation. The remaining liquid on cooling deposits yellowish crystals, which may be purified by pressure and recrystallisation from alcohol at a very low temperature. An additional quantity of crystals may be obtained from the mother-liquor. (Gössmann and Scheven.)

Axinic acid yields by oxidation, aginin insoluble in ether, and the acid, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$, which may be dissolved out by ether, and crystallises from the ethereal solution.

Hypogæic acid crystallises in stellate groups of needles, inodorous, melting at 34° or 35° (physetoleic acid melts at 30° and solidifies at 28°), easily soluble in alcohol and in ether.—1. When exposed to the air, it acquires a yellowish colour and rancid odour, and then crystallises with difficulty, even at very low temperatures.—2. When subjected to dry distillation, it first gives off a reddish-yellow liquid, then yellowish-white crystalline sebacic acid, and lastly, a fetid oil, leaving a small quantity of charcoal.

Nitrous acid converts hypogæic acid into the isomeric compound gaidic acid, which is related to it in the same manner as elaidic to oleic acid. It forms a colourless crystalline mass, permanent in the air, melting at 38° , solidifying in the radio-crystalline

form on cooling, and volatilising undecomposed at higher temperatures. (Caldwell and Gössmann, Ann. Ch. Pharm. xcix. 305.)

Hypogæic acid is monobasic. The *barium-salt* is obtained by adding alcoholic acetate of barium to an alcoholic solution of the acid mixed with excess of ammonia, in white grains which dissolve when heated and separate again on cooling.

Hypogæate of Copper, $C^uH^{10}CuO^4$, is obtained, in like manner, by mixing alcoholic cupric acetate with a hot alcoholic solution of the acid containing ammonia, and separates on cooling in violet-blue crystalline grains, soluble in alcohol and cohering to a translucent wax at 75° .—**Gaidate of copper** is obtained by mixing aqueous gaidate of sodium with cupric sulphate, as a scarcely crystalline precipitate, which dissolves with difficulty in alcohol, and separates therefrom in granules. It melts without decomposition at a temperature above 120° .

Hypogæate of Ethyl, $C^eH^{12}(C^eH^3)O^2$, is obtained by passing hydrochloric acid gas through a solution of hypogæic acid in alcohol of 95 per cent. and separates on warming the liquid, as an oil which may be freed from adhering acid by washing with small quantities of alcohol, and dried in a stream of carbonic anhydride between 100° and 120° . It is yellow, inodorous, lighter than water, but sinks in alcohol, in which it is but slightly soluble. Not volatile without decomposition.

Gaidate of Ethyl is prepared by passing hydrochloric acid gas through a solution of gaidic acid in absolute alcohol, precipitating after 12 hours with water, and subjecting the separated mixture of gaidic ether and gaidic acid to a second treatment with hydrochloric acid. The product is washed and dried at 100° in a stream of hydrogen. It is a colourless, lamino-crystalline mass, which melts between 9° and 10° , and volatilises undecomposed at a higher temperature. It is inodorous, lighter than water, heavier than alcohol, and sparingly soluble in alcohol.

Gaidate of Silver is obtained by precipitation as a white amorphous mass which, when washed, and especially if heated with water, alcohol or ether, turns black without dissolving.

Gaidate of Sodium is obtained by dissolving the acid in aqueous carbonate of sodium, evaporating, and exhausting the residue with absolute alcohol; the solution on cooling deposits the salt as a translucent jelly: from dilute solutions it separates in crystalline grains.

HYPOGALLIC ACID. $C^H^4O^4$. (Matthiessen and Foster, Chem. Soc. J. xvi. 350.)—An acid produced by the action of boiling concentrated hydriodic acid on hemipinic acid (p. 142):

It is isomeric with carbohydroquinonic, protocatechuic and oxysalicylic acids, and intermediate in composition between salicylic acid, $C^H^4H^2O^3$, and gallic acid, $C^H^4H^2O^4$.

Hypogalllic acid, when pure, is only slightly soluble in cold water, but dissolves easily in hot water, alcohol, and ether; its solution reacts strongly acid with litmus-paper. It separates from hot water in small prismatic crystals, united into stellate groups, and containing $1\frac{1}{2}$ at. water of crystallisation, which they lose at 100° . The acid melts at about 180° , but as it begins to decompose even at a lower temperature, its melting-point could not be accurately ascertained.

Hypogalllic acid gradually turns brown when heated in the air to a little above 100° ; the same change occurs more quickly when a solution of it, especially if neutral or alkaline, is evaporated. Added to solution of *nitrate* or *ammonio-nitrate* of silver, it causes an immediate precipitation of metallic silver, even in the cold; with *sulphate* of copper and a slight excess of potash, it gives a yellowish green solution, from which an orange-yellow precipitate is thrown down on warming; in a mixture of *sesquichloride* of iron and *red prussiate* of potash, it immediately produces a blue precipitate; when boiled with solution of *mercuric chloride*, it reduces it to calomel. With *sesquichloride* of iron, it gives an intense indigo-blue coloration, which is changed to violet by a very small quantity of ammonia, and to blood-red by excess of ammonia, no precipitate being produced, unless too much chloride of iron has been used; the colour is destroyed by strong acids, but restored by neutralisation with alkali, and partially by addition of water. A solution of the acid immediately becomes brown on addition of *alkali*, the colour quickly becoming darker by exposure to the air. With *ammonia* and *chloride* of barium or calcium, it gives a brownish white flocculent precipitate; with *acetate* of lead, a pale yellow precipitate.

Hypogalllic acid is decomposed by heat into carbonic anhydride and a substance which solidifies in the neck of the retort to a colourless crystalline mass. The decomposition begins at about 170° , and goes on rapidly at 200° . The crystalline product melts, in the crude state, at about 90° ; it dissolves easily in water, and crystallises in needles when the solution is evaporated. It is rapidly attacked by nitric

acid, even when diluted, giving a red-brown solution. With sesquichloride of iron it gives a bluish-black amorphous precipitate; with acetate of lead it gives a white or yellowish-white precipitate, soluble in an excess of acetic acid. It slowly assumes a darker colour by exposure to air in contact with alkali. This substance has not yet been prepared in sufficient quantity for complete investigation.

The three acids above mentioned as isomeric with hypogallic acid, have about the same solubility in water, alcohol, and ether, as the latter; they all likewise give a dark coloration with the smallest trace of sesquichloride of iron; reduce nitrate of silver; become dark brown when mixed with alkali and exposed to the air; give a yellowish-white precipitate with acetate of lead; and at a high temperature are all decomposed into carbonic anhydride and oxyphenic acid or hydroquinone. Nevertheless, no two of these acids appear to have quite the same properties. The following are the most important points in which differences have been observed. Hypogallic acid crystallises with $1\frac{1}{2}$ molecule of water (14.9 per cent.), carbohydroquinonic and protocatechuic acids with 1 molecule (10.4 per cent.), and oxysalicylic acid without water. Hypogallic and oxysalicylic acids give a dark-blue colour with sesquichloride of iron, the other two acids a dark-green colour. Hypogallic acid reduces nitrate of silver immediately in the cold; carbohydroquinonic acid reduces it slowly in the cold, rapidly when boiled; oxysalicylic acid has no action on nitrate of silver in the cold, but reduces it completely when boiled. Carbohydroquinonic acid reduces cuprous oxide from a mixture of cupric acetate, tartaric acid, and excess of potash; protocatechuic acid causes no reduction of the same solution. Hypogallic acid causes a precipitate in a mixture of chloride of barium and ammonia; protocatechuic acid only on addition of alcohol. Some of these differences may perhaps be due to accidental causes, depending on the different sources and modes of preparation.

HYPO-IODIC ACID. See IODINE, OXACIDS OF.

HYPONIOBIC ACID. See NIOBIUM.

HYPONITRIC ACID. Syn. with Pernitric oxide. (See NITROGEN, OXIDES OF.)

HYPONITROMECONIC ACID. Syn. with Nitromeconin. (See MECONIN.)

HYPONITROUS ACID. Syn. with Nitrous acid.

HYPOPHOSPHOROUS ACID. See PHOSPHORUS, OXYGEN-ACIDS OF.

HYPOSCLERITE. A name applied by Breithaupt to a mineral from Arundel, which, according to Rammelsberg, is probably albite mixed with augite. (See ALBITE under FELSPAR.)

HYPOSTILBITE. Syn. with Stilbite.

HYPOSULPHAMYLIC ACID. Syn. with Amyl-sulphurous acid. (See SULPHUROUS ETHERS.)

HYPOSULPHARSENIOUS ACID. Syn. with Disulphide of Arsenic. (See ARSENIC, SULPHIDES OF, i. 386.)

HYPOSULPHETHYLIC ACID. Syn. with Ethyl-sulphurous acid. (See SULPHUROUS ETHERS.)

HYPOSULPHINDIGOTIC ACID. } See INDIGO-SULPHURIC ACIDS.
HYPOSULPHOCERULIC ACID. }

HYPOSULPHOGLUTIC ACID. Syn. with SULPHOGLUTIC ACID.

HYPOSULPHOMETHYLIC ACID. Syn. with Methyl-sulphurous acid. (See SULPHUROUS ETHERS.)

HYPOSULPHONAPETHALIC and **HYPOSULPHONAPETHINIC ACIDS.** See SULPHONAPHTHALIC ACIDS.

HYPOSULPHOPHOSPHORIC and **HYPOSULPHOPHOSPHOROUS ACIDS.** See PHOSPHORUS, SULPHIDES OF.

HYPOSULPHURIC and **HYPOSULPHUROUS ACIDS.** See SULPHUR, OXYGEN-ACIDS OF.

HYPOVANADIC ACID. See VANADIUM.

HYPOXANTHINE. An azotised organic substance discovered by Scherer (Ann. Ch. Pharm. lxxiii. 328) in the spleen of man and in the ox, and since found to exist in many other parts of the animal body. It is probably identical with *Sarcosine* (q.v.)

HYSSOPINE. A doubtful alkaloid, said by Herberger to exist in the herb of *Hyssopus officinalis*.

HYSSOP, OIL OF. A volatile oil obtained from *Hyssopus officinalis* by

distillation with water. It is yellow when fresh, but turns red by keeping; has a sharp taste and smells like camphor.

HYSTATITE. Syn. with **ILMENITE**.

I

IASPACHATES. A variety of agate.

IBERITE. A silicate from Montoval, near Toledo, occurring in large six-sided prisms with basal cleavage. Hardness = 2.5. Specific gravity = 2.89. Contains, according to Norlin (Kongl. Vetensk. Akad. Förhandlingar, 1844, 215), 40.90 per cent. SiO_2 , 30.74 Al_2O_3 , 15.47 FeO, MnO 1.33, 0.40 CaO, 0.81 MgO, 4.57 K_2O , 0.04 Na_2O , 5.56 H_2O = 99.82. Fuses to a dark pearl before the blowpipe. It is probably allied to dichroite.

ICE-SPAR. A name sometimes applied to a transparent variety of felspar found in Vesuvian lavas: the term includes pellucid varieties of other species of felspar. (Dana.)

ICELAND-SPAR. Transparent calc-spar. (See **CALC-SPAR**.)

ICHTHIDIN. A substance contained in the immature eggs of cyprinoid fishes.

ICHTHIN. The azotised constituent of the eggs of cartilaginous fishes. It is easily extracted from the eggs of the ray by pouring the yolk into a large quantity of distilled water, washing the dense granules which fall to the bottom till the wash-water contains only traces of albumin and saline matters, and finally exhausting them with alcohol and ether.

Ichthin thus obtained forms homogeneous, white, transparent grains, soft to the touch, insoluble in water, alcohol, and ether. Hydrochloric acid dissolves it without violet coloration; it is also readily soluble in dilute acetic and phosphoric acid, and in other acids in the concentrated state. Solutions of potash and soda dissolve it slowly; ammonia does not act upon it. It gives by analysis 50.2 to 61.0 per cent. carbon, 6.7 to 7.8 hydrogen, 14.7 to 15.4 nitrogen, and 1.9 phosphorus (?). It does not appear to contain sulphur. It leaves but a trace of ash when burnt. (Valenciennes and Frémy, *Compt. rend.* xxxviii. 480, 528.)

ICHTHULIN. The very young eggs of cyprinoid fishes contain, besides ichthin, a strongly albuminous liquid which holds in suspension certain mineral salts, together with ichulin, which may be precipitated by water. When first precipitated, it is viscid like gluten; but when treated with alcohol and ether, it loses its viscosity and becomes solid and pulverulent. Like ichthin, it dissolves in acetic and in phosphoric acid, also in hydrochloric acid, without violet coloration. It contains 52.5 to 53.3 per cent. carbon, 8.0 to 8.3 hydrogen, 15.2 nitrogen, 1.0 sulphur, and 0.6 phosphorus (?). It seems to disappear as the eggs approach maturity, and to be replaced by albumin. (Valenciennes and Frémy.)

ICHTHYOCOLL or ISINGLASS. See **GELATIN** (ii. 826).

ICHTHYOPETHALMITE. Syn. with **APOPHYLLITE** (i. 351).

ICICA-RESIN. A resin very similar to elemi, obtained from trees very common in Guiana, belonging to the order *Terebinthacea*. It occurs in small masses or opaque grains, having a yellowish-white colour, and a sweet, rather agreeable odour, the strength of which is increased by heat. It is friable and tasteless. It gives up nothing to water, and is but sparingly soluble in alcohol, requiring for complete solution 45 parts of cold alcohol of 36°, and 15 parts of boiling alcohol; it dissolves also in $\frac{3}{4}$ parts of oil of turpentine at ordinary temperatures. It is insoluble in alkalis. Its alcoholic solution does not precipitate lead or silver salts.

ICICA-resin is composed of three distinct substances, separable by their different degrees of solubility in alcohol.

a. If the resin be completely dissolved in boiling alcohol, one of these substances, viz. brean, crystallises on cooling. It has the composition of cholesterolin, and forms white, tasteless, needle-shaped crystals, insoluble in water and in alkalis, sparingly soluble in alcohol, and having a neutral reaction. It melts at 167°, and solidifies on cooling to a mass resembling amber. By dry distillation it yields empyreumatic oils, and a volatile, solid, amorphous substance which collects in the neck of the retort, and a small residue of charcoal. It is dissolved, with red colour, by sulphuric acid, and precipitated unaltered by water. Nitric acid decomposes it, with evolution of nitrous fumes, forming a yellow body soluble in excess of nitric acid, and precipitated on addition of water.

b. On removing the brean and concentrating the mother-liquor, a certain quantity of the same substance, in an impure state, first separates, and afterwards another crystalline resin, icican, which has the same melting point as brean, and resembles it in most of its other properties, but is distinguished by its greater solubility in alcohol. It gives by analysis 82.01 per cent. C, 11.66 H, and 6.34 O, which may be represented by the formula $C^{20}H^{40}O$. Its composition is about the same as that of the resin of *Ceroxylon Andicola*.

c. The mother-liquor of icican, after being completely freed from crystallisable matter, deposits a small quantity of a yellow amorphous resin, which melts below 100° , and is much more soluble in alcohol and ether than brean or icican. Its alcoholic solution is slightly acid to test-paper, but the resin does not dissolve in alkalis. It contains 77.93 per cent. C, 10.69 H, and 11.47 O, corresponding approximately with the formula $C^{20}H^{40}O^2$. (Scribe, Ann. Ch. Phys. [3] xiii. 166.)

IDIOTYPE. A term applied by Guthrie (Chem. Soc. J. xiii. 35) to bodies derived by replacement from the same substance, including the typical substance itself; ammonia, for example, is idiotype with ethylamine, phenylamine, and all the organic basis derived from it by substitution, and these are idiotype one with the other.

The same term was applied by Wackenroder (J. pr. Chem. xxiv. 18) to certain non-crystalline organic bodies which, according to his observations, exhibit certain similarities of structure.

IDOCRASE. See VESUVIAN.

IDRIALIN. $C^{10}H^{10}O$ (?).—The essential constituent of idrialite, from which it is obtained either by dry distillation in an atmosphere of carbonic anhydride—or better, by boiling the mineral with rock-oil or oil of turpentine; the liquid on cooling solidifies in masses, which may be freed from the solvent by means of bibulous paper.

Idrialin forms colourless scales, which melt at a very high temperature, with partial decomposition. When distilled, it partly volatilises, but at least $\frac{1}{10}$ of it is decomposed at the same time, even in an atmosphere of carbonic anhydride. It is insoluble in water, even at the boiling heat, and nearly insoluble in alcohol and ether; the best solvent for it is boiling oil of turpentine. It gives by analysis 91.7 to 92.0 per cent. carbon, and 5.1 to 5.4 hydrogen, agreeing nearly with the formula above given—which requires 91.07 C, 5.11 H, and 2.92 O. (Bödeker, Ann. Ch. Pharm. lii. 100.) Dumas and Laurent regarded it as a hydrocarbon $C^{10}H^{10}$, but these results were calculated according to the old atomic weight of carbon.

Idrialin heated with strong sulphuric acid forms a solution of a fine blue colour, like that of sulphindigotic acid. The solution diluted with water forms with bases peculiar salts, among which the potassium-salt is distinguished by its beautiful crystalline character.—Idrialin boiled with strong nitric acid yields a red powder (Laurent's nitrite of idrialase) destitute of taste and odour, insoluble in water and ether, soluble in sulphuric acid, to which it imparts a mahogany colour. In potash it dissolves with brown colour. Heated in a closed tube, it decomposes with explosion and emission of light. According to Laurent's analysis, it contains 62.7 to 63.3 per cent. carbon, 3.2 to 3.0 hydrogen, and 10.5 nitrogen, approximating to the formula $C^{12}H^{12}(NO^2)^2O$. (65.2 C, 2.9 H, and 9.0 N).

IDRIALITE. The mineral from which idrialin is obtained. It is found in the quicksilver mine of Idria, mixed with cinnabar, and is sometimes called *inflammable cinnabar* (*Quecksilberbrandertz*). It is massive and opaque, with greasy lustre, greyish or brownish-black colour, and blackish streak inclining to red. Specific gravity, 1.4 to 1.6. Hardness, 1 to 1.5.

IDRYL. Bödeker found in a product obtained by the dry distillation of the quicksilver ore of Idria in a close vessel, two peculiar hydrocarbons, one of which (*idryl*) formed mammellated groups, fusible at 86° , volatile without decomposition, very soluble in alcohol, ether, acetic acid, and oil of turpentine; while the other formed scales melting above 100° , volatilising before melting, and much more soluble than the former. Their composition agreed nearly with the formula, $\pi C^{10}H^2$ (94.7 C and 5.3 H).

IGASURIC ACID. Pelletier and Caventou (Ann. Ch. Phys. [2], x. 142). An acid contained, in very small quantity, combined with strychnine, in the bean of St. Ignatius; also in *nux vomica*, and in the root of *Strychnos colubrina*. It is prepared by washing the magnesia which has served for the preparation of strychnine, with cold water, till the colouring matter is removed, then boiling it with a large quantity of distilled water, which dissolves the igasurate of magnesium, precipitating it with acetate of lead, decomposing with sulphydric acid, and evaporating to a syrup. The acid is then deposited, after a while, in small hard granular crystals. It has a sour, styptic taste, and is very soluble in water and in alcohol. Corriol regards it as identical with lactic acid; but, according to Marsson (Ann. Ch. Pharm. lxvii. 296), this identity does not exist, for igasuric acid precipitates acetate of lead, which lactic acid does not.

The *igasurates* are for the most part soluble in water and in alcohol. The *ammonium-salt* is perfectly neutral, does not precipitate the salts of iron, mercury, or silver, but colours copper-salts green, and then forms a greenish-white precipitate sparingly soluble in water.

IGASURINE. An alkaloid, discovered in 1853 by Desnoix (J. Pharm. [3], xxv. 202). It exists in *nux vomica*, and is found in the mother-liquors from which strychnine and brucine have been precipitated by lime at the boiling heat. These mother-liquors, if sufficiently concentrated, deposit the igasurine in crystals on the sides of the vessel. It may be purified by dissolving in water acidulated with hydrochloric acid, treating the solution with animal charcoal, precipitating by ammonia, and recrystallising.

Igasurine crystallises in colourless prisms, having a silky lustre. It is more soluble in water than strychnine or brucine, dissolving in 200 parts of cold and 100 parts of boiling water; it is sparingly soluble in ether, very soluble in alcohol. The alcoholic solution turns the plane of polarisation to the left: $[\alpha] = -62.9^\circ$. It has not been analysed, but its atomic weight appears to be intermediate between those of strychnine and brucine.

Igasurine, when heated, melts and gives off water (about 10 per cent.); at a higher temperature, it is decomposed, with evolution of ammoniacal vapours. Strong sulphuric acid communicates to it a rose-colour, which passes to yellow, and then to yellowish-green. Nitric acid colours it deep red like brucine; on adding a few drops of stannous chloride, the colour changes to violet. Chlorine, passed into a very dilute solution of hydrochlorate of igasurine, produces first a rose, then a red, then a yellow colour, each bubble of gas being enveloped by a white pellicle, which is gradually deposited in the pulverulent form. If the stream of chlorine be discontinued, the precipitate redissolves on agitation, and the solution soon afterwards loses its red colour, retaining only a slight greenish tint. Iodide of potassium, added to a solution of igasurine, produces a crystalline precipitate after a considerable time; iodurated iodide of potassium immediately forms a brown precipitate. Igasurine is not precipitated by chlorate of potassium, but its solutions yield a yellow precipitate with tetrachloride of platinum, white with tannin, and with infusion of galls.

Igasurine is intensely poisonous, being intermediate in power between strychnine and brucine.

Igasurine dissolves easily in dilute acids, and is precipitated from the solutions by potash, soda, and ammonia, the precipitate redissolving in excess of the alkali, especially in potash. It is also precipitated in needle-shaped crystals by acid carbonate of sodium, or potassium, in presence of tartaric acid.

The salts of igasurine are for the most part crystallisable. The sulphate forms colourless, silky crystals, soluble in about 4 pts. of boiling water, and 10 pts. of cold water. The hydrochlorate resembles the sulphate in form, but dissolves in 2 pts. of hot, and about 4 pts. of cold water. The nitrate forms colourless crystals, more soluble in water than either of the preceding salts.

According to Schützenberger (Compt. rend. xlv. 1234; Ann. Ch. Pharm. cviii. 348), igasurine, prepared as above from the seeds of *Strychnos nux vomica*, yields by treatment with hot water, and fractional crystallisation, no fewer than nine distinct bases, all colourless, very bitter, and acting like strychnine. They crystallise in transparent needles, or in nacreous bulky geodes. They are reddened by nitric acid like brucine, which they also resemble in their chemical reactions, but they are more soluble in water and in alcohol. They all contain water of crystallisation (3 or 4 at.), which they give off at 100° . Schützenberger distinguishes them as a, b, c, &c. igasurine, and assigns to them the following formulae:

- Igasurine a. $C^{20}H^{22}N^2O^4.3H^2O$ very slightly soluble.
 " b. $C^{18}H^{22}N^2O^4.3H^2O$ slightly soluble.
 " c. $C^{18}H^{22}N^2O^4.3H^2O$ moderately soluble.
 " d. $C^{17}H^{22}N^2O^4.3H^2O$ "
 " e. $C^{16}H^{22}N^2O^4.3H^2O$ "
 " f. $C^{15}H^{22}N^2O^4.3$ or $4H^2O$ "
 " g. $C^{14}H^{22}N^2O^4.3H^2O$ very slightly soluble.
 " h. $C^{12}H^{22}N^2O^4.3H^2O$ moderately soluble.
 " i. $C^{10}H^{22}N^2O^4.3H^2O$ "

Igasurine f yields, by oxidation with nitrous acid, a base having the formula $C^{17}H^{22}N^2O^4$, which crystallises in colourless needles, containing 4 at. water, melting in their water of crystallisation at 100° , and coloured red by nitric acid.

In the absence of confirmatory evidences, these results must be considered rather doubtful.

IGLESIASITE. Syn. with HOEN-LEAD. (See LEAD, CHLORIDE OF.)

IGLITE or **IGLOITE**. Syn. with **ARRAGONITE** (i. 358).

ILDEFONSITE. A columbite from Idefonso, in Spain, having a submetallic vitreo-adamantine lustre. Specific gravity 7.416 (Dana, ii. 355).

ILICIC ACID. (Moldenhauer, Ann. Ch. Pharm. cii. 350).—An acid contained in the leaves of the holly (*Ilex aquifolium*). It is known only in combination with bases. To prepare the calcium-salt, an aqueous decoction of the leaves is precipitated with basic acetate of lead; the filtrate, freed from lead by sulphydric acid, is heated with hydrate of lead; the dissolved lead is again removed by sulphydric acid; and the filtrate is reduced to a syrup. The laminae formed after some days are purified by pressing, dissolving in water, precipitating with alcohol, and recrystallising with the help of animal charcoal, whereby colourless ilicic acid of calcium is obtained.

Illicic acid of calcium contains 12.86 per cent. calcium, and is readily soluble in water, but insoluble in alcohol. An aqueous solution does not precipitate salts of manganese, zinc, iron, copper, or silver, but produces a precipitate with stannous chloride, and with the neutral and basic acetates of lead. When the lead-salts are decomposed by sulphydric acid, a colourless syrup is formed, which still contains lime, and by neutralisation with carbonate of barium, yields amorphous illicic acid of barium.

Holly-leaves gathered in January contain gum, or a similar substance, which interferes with the extraction of the acid.

ILICIN. The bitter principle of *Ilex aquifolium*. According to Déleschamps (Report. Pharm. xli. 230), the decoction of the leaves is precipitated with basic acetate of lead; carbonate of potassium is added to make the liquid filter, and to precipitate any excess of the lead-salt; and the filtrate is acidified with dilute sulphuric acid, again filtered, saturated with carbonate of calcium, and evaporated to a syrup. Alcohol extracts from the syrup a light brown, very hygroscopic substance, which, in thin layers, dries up to small shining scales. Or, the aqueous extract is exhausted with alcohol, the alcoholic solution evaporated, and the dry residue exhausted with water at 40°. The filtrate is precipitated with basic acetate of lead, freed from excess of lead by sulphydric acid, evaporated, and treated with alcohol, which takes up the ilicin, and leaves it behind on evaporation. The aqueous solution of the alcoholic extract may also be treated, as above, with acetate of lead, dilute sulphuric acid, and carbonate of calcium in succession, the filtrate evaporated, and the ilicin extracted from the residue by alcohol. It is a bitter, amorphous, brown, very hygroscopic mass (still containing a little potash), converted by acids at a gentle heat into a black substance, with empyreumatic odour. It is soluble in water and alcohol, insoluble in ether.—Lebourdin (Ann. Ch. Pharm. lxxvii. 254) agitates the decoction of the leaves with animal charcoal, then heats it therewith to boiling; leaves it to cool; removes the now colourless and tasteless liquid; washes the charcoal with cold water; boils it with alcohol; and leaves the filtrate to evaporate: it then leaves a colourless, very bitter syrup, and finally an amorphous, neutral jelly, easily soluble in water and in alcohol.—Moldenhauer's ilicin (Ann. Ch. Pharm. cii. 352) appears also to be different from this. Moldenhauer removes the alcohol from the alcoholic extract of the leaves by distillation, and the separated resin by filtration; precipitates with basic acetate of lead; washes the yellow precipitate, and decomposes it under water with hydrosulphuric acid. The sulphide of lead, after being well boiled with water, yields the ilicin to alcohol, as a very bitter, dark brown substance, resembling tannin, and slightly in water.—Bennemann (N. Br. Arch. xciii. 4) gives the name of ilicin to crystals which he obtains as follows: He precipitates the decoction with basic acetate of lead; decomposes the washed precipitate under water with sulphydric acid; filters the liquid from the sulphide of lead, and evaporates to dryness. By repeatedly exhausting the residue with alcohol, and leaving the solution to evaporate, needles were finally obtained, but not in sufficient quantity for further examination.

ILIXANTHIN. $C^{11}H^{20}O^{11}$. (Moldenhauer, Ann. Ch. Pharm. cii. 346).—A substance occurring in the leaves of the holly (*Ilex aquifolium*). The leaves gathered in January contain scarcely any ilixanthin, while those gathered in August contain a large quantity. The leaves are exhausted with alcohol of 80 per cent.; the tincture thus obtained is freed from the greater part of the alcohol by distillation; and the residue is set aside to crystallise. The granules, which separate after some days, are dried, washed with ether to remove the green colouring matter of the leaves, dissolved in alcohol, and again separated by evaporation and addition of water; they are, lastly, recrystallised from hot water. A further quantity of ilixanthin may be obtained from the mother-liquor by reducing it to a syrup, dissolving in absolute alcohol, evaporating the alcoholic solution, dissolving the residue in water, and precipitating with basic acetate of lead. The washed precipitate is decomposed under hot water with sulphydric acid, and the filtrate is evaporated to a syrup, whereupon the ilixanthin crystallises out in straw-yellow microscopic needles, which melt at 198° to transparent red-yellow drops.

Ilxanthin boils and decomposes at 216° . It does not reduce an alkaline solution of *cupric oxide*, even on prolonged boiling. It is nearly insoluble in cold water, but dissolves easily in hot water, forming a yellow solution; also in alcohol, but is insoluble in ether. It dissolves in warm concentrated *hydrochloric acid*. The colour of the aqueous solution is changed to orange-yellow by *alkalis* and *alkaline carbonates*, but becomes colourless on addition of sulphuric acid. *Ferrous* and *cupric salts* do not affect ilxanthin; *ferric chloride* colours it green. Neutral or basic *acetate of lead* produces in the aqueous solution of ilxanthin a splendid yellow precipitate, soluble without colour in acetic acid.

Ilxanthin forms a yellow dye on cloth prepared with alumina or iron mordants.

ILMENITE. Titaniferous Iron. See TITANATES.

ILMENIUM. According to Hermann (J. pr. Chem. xxxviii. 91, 119; xl. 475; lxxv. 52), Siberian yttroutantalite, or yttrilmenite, contains a peculiar metal which forms an acid, *ilmenic acid*, closely resembling *niobic acid* (see NIOBIUM), but, nevertheless, distinguished from it by its lower specific gravity, by the insolubility of its hydrate in hydrochloric acid, and by forming with sulphuric acid a compound which is decomposed by a large quantity of water, leaving a residue of hydrated *ilmenic acid*. According to H. Rose, however (Pogg. Ann. lxxi. 157), the supposed *ilmenic acid* is merely *niobic acid*, more or less impure. Rose also regards yttrilmenite as identical with *uranotantalite* or *Samarskite* (q. v.)

ILVAITE. See LILVHITE.

IMABENZILE. $C^{14}H^{11}NO$. (Laurent, Rev. scient. x. 122; J. pr. Chem. xxxii. 312).—Produced, together with benzilam and benzilimide, by the action of ammonia on benzile:

Benzile is dissolved in warm absolute alcohol; dry ammoniacal gas is passed through the still warm solution; and the liquid is left to cool, while the passage of the gas is continued. After 24 hours, the liquid, together with the sediment which has formed, is heated to the boiling point, and filtered at the same temperature. Imabenzile then remains on the filter, and may be purified by washing with ether.

Imabenzile is a white inodorous powder, which separates from its solution in boiling ether-alcohol, in microscopic right rhombic prisms with dihedral summits, whose faces rest on the obtuse lateral edges. It melts at 140° , remains soft and glutinous on cooling, and then solidifies without crystallising. It is quite insoluble in boiling alcohol and ether. It is partially decomposed during fusion. When subjected to dry distillation, it neither gives off gas nor leaves any carbonaceous residue. When gently heated with *nitric acid*, it gives off red vapours, and yields a yellow oil, which solidifies in the crystalline form on cooling, dissolves in alcohol, and crystallises therefrom in small needles united in tufts, but is insoluble in ammonia. It is not altered by boiling with hydrochloric acid. It dissolves in gently heated *sulphuric acid*, and the solution, mixed with water, deposits benzilam. It dissolves readily in boiling alcoholic potash; and water added to the solution throws down benzilimide, while nothing but potash remains dissolved.

IMASATIC ACID. Syn. with ISAMIC ACID.

IMASATIN. $C^6H^4N^2O^3$. (Laurent, Ann. Ch. Phys. [3] iii. 483).—A compound produced by boiling a solution of isatin in ammonia. It is of a greyish-yellow colour, often inclining to brown or green, and crystallises sometimes in lamellated grains, sometimes in radiated spheres of a darker colour. It is insoluble in water and in ether, very sparingly soluble in boiling alcohol. It is decomposed by dry distillation, yielding a large quantity of charcoal and a sublimate of colourless needles. It is not attacked by boiling hydrochloric acid. Caustic potash dissolves it, and the solution, diluted with water and neutralised by an acid, yields a whitish, gelatinous precipitate.

Dichlorimasatin, $C^6H^3Cl^2N^2O^3$, is a powder of slightly reddish colour, produced by the action of ammonia on an alcoholic solution of chlorisatin.

Tetrabromimasatin, $C^6H^3Br^4N^2O^3$. Reddish-yellow scales produced by the action of ammonia on tetrabromisatin.

IMATRA STONES. Stony concretions found in a marly formation on the Schuttgebirg in Finland. They were regarded by Parrot (Peterb. Acad. Bull. 1839, vi. 183) as petrified molluscs, on the ground that they contained calcium and sulphur, neither of which elements were found by him in the formation in which they were imbedded. On the other hand, Virlet (Bull. Géol. ii. 219; iv. 22; Jahrb. 1847-8, p. 1298) regarded them merely as calcareo-aluminous concretions produced by molecular attraction. The concretions (A), and the formation (B) in which they are found,

have been analysed by Ulex (Jahresber. 1861, p. 1086); the latter, also (B') by Salzéat (*ibid.*, 1298):

	SiO ²	CaCO ³	Al ² O ³	Fe ² O ³	Mn ² O ⁴	H ² O	Alkali	TiO ² and MgO	
A.	70.8	..	15.1	8.8	2.1	3.7	= 100.0
B.	31.8	51.1	8.2	6.5	2.4	= 100.0
B.	34.1	47.8	9.0	4.0	2.0	..	0.5	traces	= 97.4

IMESATIN. C⁸H⁵N²O. (Laurent, *loc. cit.*)—Obtained by passing dry ammonia gas into a boiling solution of isatin in absolute alcohol, in which a slight excess of pulverised isatin is suspended. It forms colourless right prisms, with rectangular base, inodorous, insoluble in water, moderately soluble in boiling alcohol, very sparingly in ether. Heated with a small quantity of alcohol and hydrochloric acid, it dissolves readily and decomposes, yielding isatin and sal-ammoniac. The same decomposition is produced by potash.

Chlorimesatin, C⁸H⁵ClN²O, resembles imesatin, and is obtained in like manner from chlorisatin. It forms yellow hexagonal scales, sparingly soluble in boiling alcohol, nearly insoluble in ether. It is slowly decomposed by boiling water, with evolution of ammonia. When heated, it gives off ammonia, yields a sublimate of yellow needles, and leaves charcoal.

IMIDES. Monamides, in which 2 at. hydrogen are replaced by a diatomic radicle; e.g. *succinimide*, N(CO)²H; *pyro-lartrimide*, N(C⁶H⁴O)²H. (See AMIDES.)

IMPERATORIA OSTRUTHIUM. (*Masterwort*).—The root of this plant (analysed by Keller) contains 0.2 per cent. of a resin called imperatorin or peucedanin; 16.0 fat and volatile oil; 5.6 extract soluble in water and alcohol; 8.8 gum and salts soluble in water; 9.2 starch and extract soluble in boiling water; 41.2 vegetable fibre, and 19.0 water (and loss). (Pelouze and Frémy, *Traité*, vi. 398.)

IMPERATORIN. See PEUCEDANIN.

INCINERATION. See ASH (i. 417).

INDELIBRONE. C⁶H³Br²N²O⁴.—A yellow substance, insoluble in water, produced by the action of bromine on isamic acid. (Laurent.)

INDIANITE. A variety of anorthite (i. 308) found in the Carnatic, differing somewhat from ordinary anorthite (from Vegavius) in the composition of the protoxides which it contains. According to Laugier's analysis (Mem. du Mus. d. hist. nat. vii. 341), it contains 42.0 to 43.0 per cent. SiO², 34.0—34.5 Al²O³, 15.0—15.6 CaO, 3.35—2.6 Na²O, 3.20—1.0 Fe²O³, and 1.0 water.

INDIAN INK or CHINA INK. A black pigment, the best varieties of which are imported from China. It is composed of a very fine black, said by Præchot to be obtained from camphor, cemented together with gelatin.

INDIAN RED. A mineral from the Persian Gulf, used as a pigment. The hard coarse powder has a dark red colour, with a tinge of purple. Specific gravity 3.843. The following analyses, A, of the entire mineral, B, of the portion soluble in hydrochloric acid, are by How (Edinb. New Phil. J. new series, ii. 306; Jahresber. 1835, p. 925):

	SiO ²	Fe ² O ³	Al ² O ³	CaO	MgO	SO ²	CO ²	H ² O	
A.	30.17	56.69	3.79	2.65	1.43	2.28	1.73	1.62	= 100.26
B.	..	3.91	2.22	2.65	0.87	2.28	1.73	..	= 13.66

The principal portion (insoluble in hydrochloric acid) is a ferric silicate, Fe²O³. 1.25. The name Indian red is also applied to another pigment of similar colour, consisting chiefly of sesquioxide of iron.

INDIAN YELLOW or PURREE. A yellow pigment consisting essentially of euxanthate of magnesium. (See EUXANTHIC ACID, ii. 609, and PURREE.)

INDICAN. C¹²H¹¹NO¹¹ (Schunck, Phil. Mag. [4] x. 73; xv. 29, 117, 288; Jahresber. 1855, p. 660; 1858, p. 465.—Gm. xvi. 1.).—A colourless substance existing in woad, and most probably in other plants which yield indigo-blue. It likewise occurs in human urine, both healthy and diseased, and when present in considerable quantity, causes the urine, after spontaneous fermentation, or on addition of acids, to deposit, sometimes indigo-blue, sometimes indirubin. It may be detected by precipitating the urine with basic acetate of lead, collecting the precipitate which forms in the filtrate on addition of ammonia, and decomposing it with cold dilute acids, the filtrate then depositing, first, indigo-blue, then indirubin, and afterwards other products of the decomposition of indican. Indican is also found in the blood of man, and in the blood and urine of the ox. (Carter, Ed. Med. J., Aug. 1859.)

Preparation.—From woad-leaves, carefully dried and pulverised while warm.—1. The leaves are exhausted with cold alcohol in a percolating apparatus; the green tincture

is precipitated with alcoholic sugar-of-lead and a little ammonia-water; and the pale green precipitate, after washing with cold alcohol, is decomposed under water by a stream of carbonic anhydride; it then loses its colour, and yields a yellow solution, which, when freed from dissolved lead by sulphydric acid, and evaporated over oil of vitriol, yields indican.—2. The tincture prepared with cold alcohol is concentrated, after addition of a little water, by passing a stream of air over it at the common temperature; the fat which separates is removed by filtration; the filtrate shaken up with recently precipitated cupric hydrate; the liquid again filtered; the filtrate freed from dissolved copper by sulphydric acid; and the liquid separated from the sulphide of copper is evaporated at the temperature of the air. From the residual brown syrup, cold alcohol dissolves out the indican, leaving undissolved a brown viscid mass which contains oxindicanin. By mixing the alcoholic solution with 2 vol. ether, further products of decomposition are precipitated, whilst the indican is obtained by evaporating the filtrate. When thus prepared it still retains a little fat.

Properties.—Indican forms a yellow or yellow-brown syrup, which cannot be dried without decomposing. It has a slightly bitter and repulsive taste, dissolves in water, with yellow colour, also in alcohol and ether. The alcoholic solution forms, with acetate of lead, a sulphur-yellow precipitate, which increases on addition of ammonia; the aqueous solution is precipitated by acetate of lead only after addition of ammonia.

Decompositions.—1. Indican decomposes even when gently warmed, and at a stronger heat swells up and emits vapours which condense to an oil, solidifying partially in the crystalline form.

2. The aqueous solution is decomposed by heat, and by spontaneous evaporation, yielding the following products:

a. *Oxindicanin*, $C^{10}H^{12}NO^{16}$. This compound separates on spontaneous evaporation, and may be purified by repeated solution in water and precipitation by alcohol. It is a brown viscid combustible gum, having a nauseous taste; by boiling with dilute sulphuric acid, it is resolved into indifuscin and indigluclin:

b. *Oxindicasin*.—Produced when an aqueous solution of indican is evaporated by heat, the indican, according to Schunck, being first converted, with separation of indigluclin, into indicanin, the latter, with absorption of oxygen, into oxindicanin, and this last being resolved, with assumption of water, into oxindicasin and indigluclin:

It is purified like the preceding, which it resembles. Its aqueous solution, precipitated with excess of neutral acetate of lead, yields a yellow lead-salt containing $C^{10}H^{12}N^2.4Pb^2O$.

c. *Indicasin*.—The liquid filtered from the lead-salt of oxindicasin, and containing excess of lead-acetate, yields, when treated with a large quantity of alcohol, a pale yellow precipitate = $C^{10}H^{12}N^2O^{22}.6Pb^2O$.

3. In contact with *soda-ley* or *baryta-water*, indican is resolved into indicanin and indigluclin:

A solution of indican, left for several days in contact with *soda-ley*, yields, with acids, *indirubin* produced from the indicanin; after longer standing, *indirubin* is likewise obtained, and in some cases the latter is the only product.

4. Indican is decomposed by dilute acids in the cold, and more quickly when heated. The decomposition is induced by tartaric and oxalic acids, as well as by mineral acids, less easily by acetic acid. Aqueous indican mixed with dilute sulphuric acid, becomes turbid on standing, and deposits blue flocks, the formation of which ceases after 24 hours. The filtrate, after standing for some time, and still more when heated, deposits a brown powder, while leucine and indigluclin remain in solution, together with certain volatile products, viz. carbonic, formic, acetic, and perhaps propionic acid, which escape when the liquid is heated.

The substance insoluble in water is a mixture of six different bodies. On exhausting it, first with cold, then with warm dilute *soda-ley*, *indihumin*, *indifuscin*, and *indirubin* are dissolved; the residue yields to alcohol, α - or β -*indifulvin* and *indirubin*, together with residues of indifuscin, while *indigo-blue* remains in solution. Instead of indifuscin, *indifuscone* is sometimes obtained. Schunck gives the following formulae:—

a. Formation of indigo-blue or its isomer, indirubin, and of indigluclin:

Part of the indigo-blue is said to split up into leucine, formic acid, and carbonic anhydride:

b. Formation of α -indifulvin, indigluclin, and formic acid:

c. Formation of β -indifulvin, indigluclin, formic acid, and carbonic acid:

d. Formation of indihumin, indigluclin, propionic acid, and carbonic anhydride:

e. Formation of indifuscone, indigluclin, acetic acid, and carbonic anhydride

f. Formation of indiretin, indigluclin, carbonic anhydride, and water:

INDICANIN. $\text{C}^6\text{H}^5\text{N}^2\text{O}^{12}$. (Schunck, Phil. Mag. [4] xv. 183.)—This compound is produced, together with indigluclin, by the action of aqueous alkalis or baryta-water on indican:

Indicanin is left in contact with baryta-water; the liquid is precipitated with dilute sulphuric acid; and the filtrate is freed from excess of sulphuric acid by carbonate of lead, from lead by sulphydric acid, and evaporated in a stream of air at mean temperature. The residue is dissolved in alcohol; the solution is mixed with twice its volume of ether, which precipitates indigluclin; and the filtrate is left to evaporate.

Indicanin is a yellow or brown bitter syrup, soluble in water, alcohol, and ether. When heated on platinum-foil, it swells up strongly and leaves charcoal. By dry distillation it yields a brown oil in which white needles form. When boiled with acids, it yields indigluclin and indirubin, and if impure, likewise indiretin and indifuscin. Formation of indirubin:

When boiled with soda-ley, it gives off ammonia.

Aqueous indicanin forms a slight precipitate with neutral acetate of lead; from alcoholic indicanin an alcoholic solution of neutral acetate of lead throws down a copious sulphur-yellow precipitate, soluble in excess of the lead-acetate, precipitable by ammonia, and containing $\text{C}^6\text{H}^5\text{N}^2\text{O}^{12} \cdot 3\text{Pb}^2\text{O}$.

INDIFULVIN. (Schunck, *loc. cit.*)—This name is applied to two compounds, distinguished as α indifulvin, $\text{C}^{22}\text{H}^{20}\text{N}^2\text{O}^5$, and β indifulvin, $\text{C}^{11}\text{H}^{20}\text{N}^2\text{O}^5$, which are obtained, together with indifuscin, indigluclin, indigo-blue, indihumin, indiretin, and indirubin, by treating indican with dilute acids.

Preparation.—Indican is heated with dilute sulphuric acid; the flocks which separate are collected (the solution which runs off being preserved for the preparation of indigluclin), washed with cold water, and treated, first with cold, then with warm dilute soda-ley, which dissolves one portion, and leaves another containing α - and β -indifulvin, indirubin, and indigo-blue. The alkaline solution is precipitated with hydrochloric acid, and the precipitate is collected, washed, and treated with boiling ammonia, which dissolves indifuscin and indiretin, and leaves indihumin. The ammoniacal solution, neutralised with acetic acid, yields a precipitate of indifuscin, and an additional quantity of this product is precipitated from the filtrate by alcoholic sugar-of-lead. The indiretin which still remains in solution is separated by ammonia, in combination with lead-oxide and contaminated with indifuscin; it is separated from the lead-oxide by treating the precipitate with acetic acid and then with hot hydrochloric acid, and purified by repeated solution in alcohol, which leaves the indifuscin undissolved.

The mixture of α - and β -indifulvin, indirubin, and indigo-blue, insoluble in dilute soda-ley, gives up to boiling alcohol everything excepting the indigo-blue. The purple-brown alcoholic solution, mixed with ammonia and alcoholic sugar-of-lead, deposits residues of substances soluble in soda-ley; and on separating these, then adding excess of acetic acid, distilling off the alcohol, and diluting largely with water, purple-brown flocks are obtained, from which, when purified with dilute soda-ley, a small quantity of cold alcohol extracts indifulvin. On boiling the residue with an alkaline solution of protochloride of tin, filtering hot, and exposing the filtrate to the air, a purple-red

deposit is formed, consisting of indirubin. This is washed with water and dissolved in alcohol. The portion insoluble in the alkaline solution is a mixture of indirubin and indifulvin.

Indifulvin is obtained of various composition, α or β , according to circumstances not well understood. It is a brittle, friable, reddish-yellow resin, which, when heated, melts, burns with flame, and leaves charcoal. Heated in a glass tube, it gives off a strong-smelling vapour, condensing to a brown oil, which solidifies in the crystalline form. Dissolves in strong sulphuric acid, with green-brown colour, and chars when heated. By ordinary nitric acid, it is scarcely attacked, even at the boiling heat; but it dissolves in fuming nitric acid, and is precipitated by water in orange-yellow flocks. By heating and evaporating the liquid, a yellow resin is obtained, together with crystals soluble in water, and different from oxalic acid. It is slowly decomposed by chromic acid. It does not dissolve in aqueous alkalis, even at the boiling heat, or on addition of grape-sugar, or dichloride of tin.

INDIFUSCIN, $C^{14}H^{10}N^2O^2$, and **INDIFUSCONIN**, $C^{22}H^{16}N^2O^2$.—These compounds are produced in greatest quantity by the action of dilute sulphuric acid on indican which has been previously exposed to the air. A brown powder is then formed, containing from 59.4 to 67.5 per cent. C, 5.78 to 7.12 N, and 29.12 to 20.23 O, so that it appears to agree, sometimes with one, sometimes with the other of the formulæ just given. When heated, it emits vapours, with an odour of burning turf, and yields an oily distillate. It burns without fusion; colours chromic acid green; with boiling nitric acid, it yields oxalic and picric acids; dissolves in strong sulphuric acid, with brown colour, giving off sulphurous anhydride when heated. It is insoluble in boiling water; dissolves easily in alcoholic ammonia, whence it is precipitated in brown flocks by acids; also in aqueous alkalis and alkaline carbonates, and is precipitated therefrom by metallic salts; sparingly soluble in boiling alcohol.

INDIGLUCIN, $C^{14}H^{10}O^4$. (Schunck, Phil. Mag. [4] x. 73; xv. 183; Jahresber. 1856, 659; 1858, 465; Gm. xv. 302.)—Produced, together with the products above mentioned, by heating indican, indicanin, oxindicanin, or oxindicasin, with water, acids, or alkalis (pp. 247, 248).

Preparation.—Tincture of wood-leaves, prepared with cold alcohol, is evaporated in a current of air; the residue is mixed with cold, very dilute sulphuric acid, and the fat which falls to the bottom is immediately separated by filtration. The filtrate serves instead of the acidulated aqueous solution of indican. The decomposition, which begins in the cold, is kept up by gentle heating, whereupon the solution becomes turbid, and a mixture of six insoluble substances separates (p. 247); the liquid is then filtered, the residue washed with cold water, and decomposed in the manner described under indican. The filtrate, freed from sulphuric acid by carbonate of lead, and from lead by sulphuric acid, evaporated to a syrup in a stream of air, dissolved in alcohol, and mixed with a large quantity of ether, deposits leucine in crystals, and indiglucon as a syrup. The latter, after the removal of the crystals, is dissolved in water; the solution is mixed with acetate of lead; the scanty precipitate is removed; and the yellow lead-compound of indiglucon is precipitated from the filtrate by aqueous ammonia. The lead-salt decomposed by sulphydric acid under water, and treated with animal charcoal till a sample gives a white precipitate with ammoniacal sugar-of-lead, yields a solution from which, by evaporation, solution of the residue in alcohol, and addition of ether, the indiglucon is precipitated in the form of a syrup.—2. In the preparation of indicanin from indican, by mixing the latter with baryta-water and leaving it at rest, then removing the baryta, evaporating the filtrate in a current of air, dissolving the residue in alcohol, and precipitating by ether, indiglucon is separated as a syrup. This syrup is dissolved in alcohol, mixed with excess of alcoholic sugar-of-lead, the brown precipitate removed, and the solution precipitated with ammonia. The lead-compound of indiglucon is purified and decomposed as in method 1.

Indiglucon is a colourless or light yellow syrup having a slightly sweet taste, soluble in water and in alcohol, but precipitated from the alcoholic solution by ether.

It swells up when heated, and gives off an odour of caramel. With boiling nitric acid, it forms oxalic acid. With strong sulphuric acid, it becomes carbonised. When boiled with soda-ley, it turns yellow, and separates brown flocks. From an alkaline cupric solution it reduces cuprous oxide; from an aqueous and still more from an ammoniacal solution of nitrate of silver, it reduces metallic silver; similarly with trichloride of gold. It is not fermentable, but turns acid by prolonged contact with yeast.

Aqueous indiglucon dissolves hydrate of calcium, and the solution on boiling deposits copious yellow flakes, which dissolve on cooling, and are precipitated by alcohol. From a mixture of indiglucon with baryta-water alcohol throws down yellow flakes.—Aqueous indiglucon is precipitated by neutral or basic acetate of lead, only after addition of ammonia; the precipitate has the composition $C^{14}H^{10}Pb^{10}O^{12}.3Pb^{10}O$.

oxygen has been absorbed. When the liquid no longer rises, it is drawn off into the *beating vat* (*Schlageküpe*, *batterie*) which stands lower, where it is kept stirring for an hour and a half or two hours, whereupon carbonic anhydride is evolved and the indigo at first separates in large flakes. When, after being repeatedly stirred, it forms grains like fine sand, and the solution is clear, the indigo is allowed to settle. After two or three hours, the liquid is drawn off from the deposit. If the fermentation is properly conducted, the indigo settles readily down, the liquid is of a malaga-brown colour, and forms a thick foam which rapidly disappears. The deposit is boiled for three or four hours in a copper vessel and then thrown upon a linen filter; it is afterwards pressed, cut into squares, and dried by heat. 1000 pts. of the solution of the leaves yield from 0.5 to 0.7 pts. of indigo; more is precipitated on the addition of potash-ley or lime-water, but it is not so pure.

Respecting the manufacture of indigo in the Caucasus, see *Dingl. pol. J.* 126, 304.

2. *From dry leaves.*—In the southern parts of India, the leaves of the indigo plant are dried, and packed up for a month, more or less, at the expiration of which time they assume a light lead colour; by additional keeping the lead-colour gradually darkens till it becomes black. Experience has proved that the leaves will not give out any colouring matter to cold water till the first change has commenced, when the maximum quantity of indigo seems to be developed; and that from this period it diminishes. If from fear of rain the plant be cut too soon, the leaves should be kept proportionally longer; but if, from want of sufficient sunshine, the cutting be deferred till after the plant is fully ripe, the leaves will not require to be kept so long.

These leaves, after due keeping, are transferred to the steeping-vat, where they are infused in water, in the proportion of about one volume of leaves to six of water, and allowed to digest for two hours, with occasional stirring. The water is then run off through strainers into the beating-vat, where it is agitated by the paddles of ten or twelve natives for about two hours, during which time the fine green liquor gradually darkens to a blackish hue. Lime-water is now thrown into the vat, and well mixed with the liquor. The supernatant Madeira-coloured liquid is run off after repose, and the subsided blue indigo is drained on cloth. Next morning it is mixed with water in a copper and boiled; after which the whole is thrown on strainers, and the indigo collected is dried and formed into cakes. (Weston, *Journal of Science*, xxvii. 206.)

Indigo is obtained in the same way in the south of France from a hot extract of *Nerium tinctorium* and *Polygonum tinctorium* (J. Pharm. xxvi. 276; J. pr. Chem. xvi. 180). Indigo was formerly prepared from woad in a similar manner, by employing tepid water and precipitating with lime-water; a deeper colour was imparted to the product by extracting the carbonate of calcium with hydrochloric acid. The preparation of indigo from *Polygonum tinctorium* is rendered difficult by a resin which the plant contains. This resin is separated by mixing the bruised leaves with one-tenth of their weight of protosulphate of iron, and adding a sufficient quantity of water, together with an excess of carbonate of potassium; the whole is then thrown upon a filter, and the solution mixed with sufficient nitric acid to render it slightly acid. On neutralising with carbonate of potassium, it becomes blue and deposits all the indigo-blue within 24 hours; the indigo has then the same properties as that obtained from *Indigofera*. (Gaudry, N. J. Pharm. v. 133.)

Purification.—Commercial indigo contains from 50 to 60 per cent. of pure indigo-blue, the remainder consisting of indigo-gluten, indigo-red, indigo-brown, and a number of brown resinous products, &c., formed either by decomposition of the indigo-blue produced in the first instance, or directly from the indican itself (p. 246). Certain substances are also occasionally added to indigo for the purpose of adulteration.

Indigo may be purified from most of these foreign matters by treating it successively with dilute sulphuric or hydrochloric acid, with boiling water, and with alcohol. This treatment however does not yield a chemically pure product, and it is better to resort to the process of the vat, which consists in converting the indigo-blue into indigo-white by the action of reducing agents, and subsequently reoxidising it. This process is also one of great industrial importance, being that which is used by dyers for rendering indigo soluble and fixing it upon tissues.

a. *Cold Vats.*—1. *Copperas or common blue vat.* (*Cuve à la coupérose*, *Vitriol-küpe*.) In this, which is the kind of cold vat generally used for dyeing cotton, hemp, and flax, the indigo-blue is reduced by the action of protosulphate of iron. 1 pt. of finely ground indigo is mixed with hot water, in which 4 pts. of quick-lime are slaked; to this is added a solution of 3 pts. of sulphate of iron free from copper, the whole being stirred. (If the sulphate of iron is yellowish, one-third more is taken.) Water is added, to the amount of 100 or 200 times the weight of the sulphate of iron, according as the dye is required dark or light, and the whole, after being stirred, is left at rest. The proportions quoted are those most commonly used in dyeing; when the indigo is particularly pure, more lime and sulphate of iron must be taken. An excess of lime

yields a *sharp vat* (*scharfe Küpe*), from which the threads of the material do not readily take up the dye; too little lime yields a *soft vat* (*leise Küpe*), which does not dye so well. On the addition of carbonate of potassium, a compound of indigo-white with potash is formed. A sediment is formed and a yellow solution, which becomes covered with a copper-coloured film (*flower*); the solution is drawn off from the sediment, and deposits tolerably pure indigo-blue on exposure to the air.—Thomson digests commercial indigo with lime, sulphate of iron, and water, and exposes to the air the decanted solution of the compound of indigo-white with lime; he then removes the carbonate of calcium from the blue precipitate with hydrochloric acid, and the indigo-red with water, afterwards washes with water and dries.—Berzelius mixes 3 pts. of indigo (purified according to 1) with 6 pts. of quick-lime freshly slaked, 4 pts. of sulphate of iron, and 460 pts. of boiling water; he then closes the vessel and shakes repeatedly; allows the whole to subside, and removes the yellow solution by means of a siphon; again adds hot water, and draws it off after repeated shaking; and mixes the whole of the solution with hydrochloric acid; this is exposed to the air and shaken till the indigo is completely oxidised; it is then thrown on a filter and washed with water.—Erdmann mixes together 1 pt. indigo, 2 pts. sulphate of iron, 3 pts. lime, and 60 pts. water; draws off the clear solution; mixes it, stirring repeatedly, with dilute hydrochloric acid; and washes the precipitate in contact with the air. The residue yields fresh quantities of indigo-blue when again stirred up with hot water, and with lime if necessary. The indigo-blue thus obtained contains a little gypsum, at most 0.75 per cent., and indigo-red, which it is difficult to remove by boiling with alcohol; it is better to reduce the indigo again in the cold vat and precipitate it with hydrochloric acid.—According to Dumas, a little sulphide of calcium is formed in the vat, and hence sulphur is mixed with the indigo when it is precipitated by hydrochloric acid; this he removes with sulphide of carbon.

2. In the so-called *orpiment-vat*, a solution of the compound of indigo-white with potash is formed in a mixture of indigo-blue with trisulphide of arsenic, potash, and water, by the oxidation of the resulting sulpharsenite of potassium; the solution deposits indigo-blue when exposed to the air. This kind of vat is chiefly used for calico-printing, not for dyeing properly so-called.

3. In the *tin-vat*, commonly used for calico-printing, the indigo is reduced by a solution of stannous oxide in caustic potash or soda. The bath is usually mixed with an acid solution of tin, so as to neutralise the alkali and precipitate the indigo-white; the precipitate is then used for printing.

b. Warm vats.—1. *Woad-vat*. (*Pastel-vat*.) On mixing from 2 to 6 pts. of finely powdered indigo with from 30 to 60 pts. woad, 2 pts. madder, 2 pts. ran, 1 to 8 pts. potash, and $\frac{1}{2}$ pt. lime, and warming with 1000 pts. water (6000 to 7000 litres) at 80° C. (176° F.), a fermentation is set up in which water is decomposed and the nascent hydrogen forms indigo-white, which combines with the ammonia simultaneously formed. The brownish-yellow liquid first becomes green on exposure to the air, and then deposits indigo-blue; it may be used for dyeing for three to six months, provided it be kept warm, and madder, bran, indigo or potash added from time to time as required. Beetroot-molasses and malt may be advantageously used instead of madder.

The use of madder, bran, &c. in this process appears to depend upon the gummy and amylaceous substances and the pectic acid which they contain. These substances are probably transformed, first into lactic, then into butyric acid, in which transformation hydrogen is evolved, which reduces the indigo-blue to indigo-white. The woad at the same time undergoes putrefaction, and gives off ammonia, which keeps the indigo-white in solution. The lime seems to act chiefly by neutralising the excess of acid produced by the decomposition of the amylaceous and gummy matters.

2. In the *potash or Indian vat*, in which woad and lime are not used, 3 pts. of indigo are added to a mixture of 2 pts. madder, 2 pts. wheat-bran, 16 pts. potashes, and 1000 pts. water at 60° C. (140° F.); after 36 hours, 3 pts. potashes, and after 12 hours more the same quantity of potashes, are likewise added. This vat is easier to manage than the woad vat.

3. The *urine-vat* is employed only in small dye-houses and in certain localities, as at Verviers, for the dyeing of wool. The putrefying urine furnishes at once the reducing agents to convert the blue into white indigo, and the ammonia necessary to dissolve the latter. [For further details respecting the manufacture of indigo and its use in dyeing, see *Ure's Dictionary of Arts*, &c. ii. 498.]

To obtain indigo-blue in the crystalline state, 4 oz. of raw indigo and 4 oz. of grape-sugar are introduced into a flask capable of containing 12 lbs. water, to which 6 oz. of the strongest soda-ley are added. The whole is well shaken, and the flask completely filled with hot alcohol; it is then tightly corked and allowed to stand for several hours, until the solution is sufficiently clear to permit its being siphoned off into a larger flask. The flask is allowed to stand loosely covered; the solution, at first of a beautiful

yellowish-red colour, now gradually turns blue, whilst indigo separates out. The solution is filtered and the indigo is washed, first with alcohol and then with water, till the filtrate is colourless. In this manner, 2 oz. (50 per cent.) of pure indigo-blue is obtained. If the brown alcoholic solution is poured back hot into the first flask, it yields 3 per cent. more indigo; but it is then nearly exhausted (Fritzsche, Marchand).—Indigo also forms a vat immediately with grape-sugar, caustic soda, and hot water; the decanted solution, when exposed to the air, deposits indigo-blue containing a quantity of indigo-red, which may be extracted by an alcoholic solution of soda. (Fritzsche.)

Purification of indigo by sublimation.—When powdered commercial indigo is heated on a watch-glass, a silver dish, or a spoon, a network of crystals is formed, which may be removed with a pair of forceps, and the crystals carefully separated from adhering particles of carbon, under a magnifying glass (Le Royer and Dumas; Dumas).—Crum heats indigo between two platinum crucible lids, which are separated from one another by a distance not greater than $\frac{3}{4}$ inch, till the hissing sound ceases.—Berzelius sublimes indigo in an exhausted retort, of the size of a chicken's egg, cuts off the upper part of the retort when the crystals have sublimed, and separates the lower crystals from the adhering particles of carbon. The crystals are freed by ether from traces of oil and resin.—Taylor stirs up an intimate mixture of 2 pts. finely powdered indigo and 1 pt. gypsum with water into a thin paste, which he spreads upon sheet iron in layers 2 inches broad and $\frac{1}{4}$ inch deep. These are dried by exposure to the air, then heated at one end with a spirit-lamp till red vapours are evolved, and so the operation is continued. If the mass catches fire, it is extinguished by a drop or two of water. The velvety indigo can easily be separated, and may be purified by alcohol and ether. (Med. Gaz. 1843, 130.)

Preparation of Indigo-blue from Indican.—The aqueous solution of indican from woad-leaves, which must not be too dilute, is boiled with sulphuric acid or hydrochloric acid; and the abundant purple-blue precipitate is filtered off and washed, first with water and then with boiling alcohol, till the filtrate is of a pure blue colour: the residue consists of pure indigo-blue. Nitric, oxalic, tartaric, and acetic acids are also capable of converting indican into indigo-blue: acetic acid, however, acts less powerfully than the rest. (Schunck.)

Properties.—Indigo-blue sublimes in right rhombic prisms (Miller); in six-sided prisms derived from a rhombic prism of 32° and 148° , and having their bases replaced by two faces which seem to form an obtuse angle with one another (Laurent). Its lustre is semi-metallic, and by reflected light, dark-red inclining to copper-red (according to Crum, it is red when viewed obliquely under the microscope; and of a brilliant blue when viewed perpendicularly). When prepared in the wet way, it is dark blue, and acquires by pressure a dark copper colour and almost metallic lustre. It is inodorous and tasteless, and does not react upon vegetable colours.—In open vessels, it volatilises at about 288° in dark purple-red vapours; in closed vessels, it decomposes partially when heated (Crum). It volatilises without decomposition only in a current of air or in vacuo; the powder dropped on a piece of heated platinum foil, volatilises in purple vapours without leaving a residue, each particle being supported by the vapour without coming in contact with the foil (Dumas). It is quite insoluble in water, dilute acids, and alkalis, ether, and volatile oils; also in alcohol and fixed oils at common temperatures; but hot alcohol, and fixed oils heated above 100° , dissolve small quantities, and deposit it again on cooling. Sublimed indigo dissolves pretty readily in hot phenic acid, forming a blue liquid when mixed with a little alcohol, but precipitated by a larger quantity. Sublimed indigo also dissolves to a small extent in hot oil of turpentine.

Indigo-blue is isomeric with cyanide of benzoyl.

Decompositions.—1. Indigo-blue melts and boils when heated in contact with the air; at higher temperatures it burns with a bright and very smoky flame, leaving a residue of difficultly combustible charcoal (Berzelius). By exposure to air containing ozone it is quickly converted into isatin. (Erdmann, J. pr. Chem. lxxi. 209.)

2. By dry distillation, it yields a very little undecomposed sublimate, together with carbonate and cyanide of ammonium, phenylamine, empyreumatic oil, and a large residue of shining charcoal (Crum). On heating indigo-blue in vacuo, a brown oil is formed, together with a large proportion of sublimed indigo, but no permanent gas or aqueous liquid; by rapid heating, more sublimate is obtained, and a fused shining charcoal; on heating more gradually, less sublimate is formed, together with a dull earthy charcoal. (Berzelius.)

3. Dry chlorine does not act upon indigo-blue between 0° and 100° . If indigo-blue is stirred up with water into a thin paste, and chlorine passed through while the whole is kept cool, the mass becomes first greyish-green and then yellow. Neither carbonic anhydride nor any other gas is evolved. An orange-coloured deposit is

formed, and a yellowish-red solution; on distilling, trichlorophenic acid and trichlorophenylamine sublime, and a liquid distils over which smells of anisic acid, and contains hydrochloric and trichlorophenic acids. The residue in the retort dissolves in boiling water, leaving a brown resin, which is formed in small quantity only. If the mass is cooled as much as possible during the action of the chlorine, and the passage of the chlorine is interrupted before all the indigo-blue is destroyed, the boiling aqueous solution deposits, on cooling, a yellowish-red crystalline powder, which yields chlorisatin and dichlorisatin when recrystallised from alcohol. (Erdmann.)

4. Bromine acts upon indigo in the same manner as chlorine. On treating moist indigo with bromine, a yellow mass is formed, which yields, by distillation, tribromophenic acid and tribromophenylamine; the residue contains a little bromisatin, a large proportion of dibromisatin, and a little resinous matter. (Erdmann.)

5. Iodine decomposes indigo only when heated. (Berzelius.)

6. Indigo is decomposed by heating it with *chlorate of potassium* and *hydrochloric acid*. Only traces of chloranil are formed. (Hofmann.)

7. When boiled with dilute *nitric acid*, it gives off a large quantity of gas, and forms isatin and a brown resin; with a stronger acid, it forms principally nitrosalicylic acid, and with an excess of nitric acid of specific gravity 1.43, it yields picric acid; at the same time carbonic anhydride, prussic acid, oxalic acid, and the so-called artificial indigo-resin are formed. 5 pts. of fuming nitric acid becomes so violently heated with 1 pt. powdered commercial indigo that the mass takes fire.

8. Concentrated *chromic acid* destroys indigo-blue immediately, especially when heat is applied, with violent evolution of carbonic anhydride and precipitation of sesquioxide of chromium. Dilute chromic acid forms a clear yellow-brown solution with indigo; if this is heated to near the boiling point and filtered, isatin crystallises out on cooling (Erdmann). Chlorochromic acid does not act upon indigo-blue. (Thomson.)

9. On boiling indigo-blue with *peroxide of lead*, a pale yellow solution is formed, which becomes turbid on cooling, and leaves a yellow powder when evaporated to dryness. This substance being suspended in water and decomposed with sulphydric acid, yields a brownish-yellow filtrate, which on evaporation leaves a residue consisting of a small quantity of brown resin and a few crystals. The sulphide of lead contains a brown resin, melting at 100°, which may be extracted by boiling alcohol, and precipitated by water; boiling water extracts from it a substance which, on evaporation, deposits crystals mixed with resin. (Erdmann.)

10. *Manganic sulphate*, *manganate of potassium*, and *permanganate of potassium* decolorise indigo (Lefort, Rev. scient. 16, 358). On heating indigo-blue for a considerable time with aqueous *osmic acid*, oxalic acid is formed. (Buttlerow, J. pr. Chem. lvi. 278.)

11. When the vapour of *sulphuric anhydride* is passed over roughly pulverised commercial indigo, the latter swells up, becomes heated, and a beautiful purple-red liquid is formed, which is transparent in thin layers, and solidifies into a crimson mass. In contact with the air, it evolves sulphurous anhydride (probably on account of the impurities of the indigo), and dissolves in common sulphuric acid with a violet colour; on dissolving it in water, charcoal separates out and a dark blue solution is formed (Döbereiner; Bucholtz; Bussy). Indigo dissolves, with evolution of heat, in excess of fuming or of common *sulphuric acid* (no gas is evolved if the indigo is pure) with formation of sulphindigotic acid; if an excess of sulphuric acid is not added, more or less sulphophenic acid is formed. According to Berzelius, hyposulphindigotic acid is also formed when indigo is dissolved in fuming sulphuric acid. Indigo-blue dissolves in cold sulphuric acid, first with a yellow colour, which afterwards becomes green, and finally of a beautiful blue (Housmann, Journ. de Phys. 1788; March, Chevreul). From the solution, while still yellow, undecomposed indigo-blue may be precipitated by water; the yellow colour changes to blue in a few hours in a closed vessel, since sulphophenic acid is formed, which is gradually converted into sulphindigotic acid. When indigo is more strongly heated with sulphuric acid, sulphurous anhydride is evolved, and a brown oily liquid formed (Döbereiner). Liquid sulphurous anhydride does not act upon indigo (Bussy). Phosphoric anhydride and hydrated phosphoric acid are without action upon indigo; also concentrated hydrochloric acid. (Döbereiner.)

12. Indigo-blue is but slightly attacked by prolonged boiling with dilute *potash*; when the boiling point has reached 100°, the indigo is completely decomposed, whilst no gas is given off, and only traces of ammonia and phenylamine are evolved with the aqueous vapour (Fritzsche). According to Gerhardt (Rev. scient. x. 371), indigo-white and isatate of potassium are formed in this reaction:

According to Fritzsche, a yellowish-red solution is first formed, on which a dark coloured substance floats, and from which yellow crystals of chrysanilate potassium are separated by continued boiling; on cooling, it solidifies into a crystalline mass, consisting principally of chrysanilate of potassium. The crystalline mass, when water is poured over it, immediately yields indigo-blue (in the same state as from the indigo-vat); the filtered solution also continues to deposit indigo-blue when exposed to the air. According to Gerhardt, Fritzsche's chrysanic acid is nothing but a mixture of isatin, indigo-white, and perhaps also other products resulting from the further action of the potash. The indigo-blue is formed by oxidation of the indigo-white.

Indigo-blue fused with *hydrate of potassium* yields first isatic acid, as above, then phenylcarbamie acid resulting from the decomposition of the latter. (Gerhardt.)

and by further decomposition, salicylic acid (Cahours) and phenylamine (Fritzsche):

13. Indigo-blue placed in contact with water, an *alkali*, and a *deoxidising substance*, becomes at first coloured green, and is then converted into indigo-white, which forms a yellow solution with alkalis. In this reaction, water is decomposed, the hydrogen being used in the formation of indigo-white, *e. g.* with *stannous oxide*:

The following substances react in a similar manner: phosphorus, phosphorous acid, sulphurous acid, sulphydric acid, potassium-amalgam, sulphide of potassium, sulphide of sodium, sulphide of arsenic, sulphide of antimony, zinc, tin, iron, ferrous, stannous, and manganous oxides, grape-sugar, and substances undergoing fermentation or putrefaction, as sugar, gluten, urine, woad, madder. Warm putrid urine dissolves indigo-blue, the ammonia-compound of indigo-white being formed. According to Löwenthal, on the contrary (J. pr. Chem. lxx. 463), this reduction of blue to indigo-white is not produced by salts of sulphurous or phosphorous acid, by sulphide of potassium, sulphide of calcium, manganous salts, or arsenite of sodium; but indigo-blue dissolved in sulphuric acid is reduced to indigo-white, when mixed with excess of acid carbonate of potassium or sodium, and then treated with sulphydric acid. Löwenthal is of opinion that indigo-white is not indigo-blue *plus* hydrogen, but indigo-blue *minus* oxygen.

Testing and Valuation of Indigo.—Commercial indigo occurs in small lumps or cubic leaves of a violet-blue colour; when of good quality it is very light; assumes a coppery aspect when rubbed with a hard polished body; and is free from flaws or cavities traversed by brown or whitish veins. The best sorts are light enough to float on water.

External characters, however, give but very uncertain indications of the amount of real colouring matter contained in a sample of indigo; hence it becomes necessary to resort to chemical methods of estimating the amount of pure indigo-blue. Good sorts of indigo contain about 60 per cent., but the proportion is often much reduced by fraudulent admixture of foreign substances, such as sand, vegetable mould, powdered lead, starch, &c. Some foreign matters are also unavoidably introduced in the process of manufacture.

The indigo is first dried over the water-bath to estimate the hygroscopic water; which, in samples not fraudulently moistened, varies from 3.5 to 6 per cent. The dried indigo is then calcined in a platinum crucible to determine the amount of ash. Good indigo generally yields from 7 to 10 per cent. The presence of sand, lead-powder, &c., may then easily be detected by washing the ash with water.

The presence of starch, sometimes coloured with iodine, is indicated by the pale colour, greater density, and friability which it imparts to the lumps of indigo. It may be further detected by treating the indigo with slightly alkaline water, neutralising the filtered liquid with a few drops of acid, and testing with iodine.

The older methods of estimating the proportion of real indigo-blue in commercial indigo depend, for the most part, on the decoloration produced by chlorine and other oxidising agents.

1. *With chlorine water.*—A weighed quantity of the finely pulverised indigo is added by small portions to a measured quantity of a saturated aqueous solution of chlorine, as long as it dissolves with yellow colour, and the quantity thus dissolved is ascertained by weighing the residue. A similar trial is then made with perfectly pure indigo-blue,

and a comparison of the two results gives the proportion of colouring matter in the sample of commercial indigo under examination. As the strength of the chlorine-water alters very quickly, it cannot be titrated long beforehand. (Berzelius.)

2. *With chloride of lime.*—The indigo is first dissolved by digestion for five or six hours at 60° or 60° with fuming sulphuric acid; the solution is thoroughly mixed with distilled water, and poured into a graduated burette, and from this vessel it is added drop by drop to a measured quantity of aqueous chloride of lime, till the blue colour just becomes permanent. A similar experiment being then made with an equal weight of pure indigo blue, the colouring power of the two samples is in the inverse ratio of the quantities of the blue solution consumed in the two experiments. (Schlumberger, Bull. Soc. industr. de Mulhouse, vol. xv.)

3. *With hydrochloric acid and chlorate of potassium.*—1 grm. of finely pulverised indigo is digested for some hours with 10 grms. of fuming sulphuric acid, agitating from time to time to assist the solution. The liquid is then poured into a basin containing a kilogramme of water, 50 grms. of strong hydrochloric acid are added, and the liquid is heated to the boiling point. On the other hand, 0.25 grm. of chlorate of potassium is dissolved in 100 grms. of water; and the solution is poured into a graduated burette, and added drop by drop to the boiling indigo solution till the blue colour changes to red-brown. The richness of the sample of indigo is directly proportional to the quantity of chlorate consumed. (Bolley, Ann. Ch. Pharm. lxxv. 242.)

4. *With sulphuric acid and acid chromate of potassium.* The mode of proceeding is the same as that just described; 10 grms. of pure indigo-blue prepared by Fritzsche's method require for decoloration exactly $7\frac{1}{2}$ pts. of the acid chromate. (Penny, Chem. Soc. J. v. 297.)

All these methods are liable to the objection that it is difficult to institute an exact comparison between the different shades of colour resulting from the oxidation of the indigo in different cases, the pure green tint thus produced in solutions of pure indigo-blue giving place to a dirty olive or brownish-green when crude indigo is used, in consequence of the impurities contained in it. Moreover, in dissolving indigo in strong sulphuric acid, it is scarcely possible to avoid the formation of sulphurous acid, the presence of which will of course raise the apparent percentage of indigo-blue in the sample. By employing these methods indeed, it is common to find, in a good sample of indigo, more than 80 per cent. of pure indigo-blue, whereas the best qualities seldom contain above 60 per cent., and average qualities not more than 40 to 50 per cent.

The following methods, which depend upon the reduction instead of the oxidation of the indigo, give more exact results.

5. *With Protosulphate of Iron.*—A weighed quantity of the finely pulverised indigo is well mixed with an equal weight of pure lime previously slaked with water. The mixture is poured into a stoppered bottle of known capacity, and the mortar is well rinsed with water, which is added to the rest. The bottle is now heated in a water-bath for several hours, and a quantity of finely-powdered sulphate of iron is added; the bottle is then filled up with water; the stopper is inserted; and, after the contents have been well shaken, the whole is left at rest for several hours, till the indigo is reduced and the sediment has sunk to the bottom. A portion of the clear liquor is then drawn off with a siphon, and the quantity of liquid having been accurately measured, it is mixed with an excess of hydrochloric acid, and the precipitate, after having been oxidised (by exposure to the air), is collected on a weighed filter, and washed with water. Lastly, the filter with the indigo-blue is dried at the heat of the water-bath, and weighed, and the weight of the filter having been subtracted from that of the whole, the weight of the indigo-blue is ascertained. Suppose, for example, that the whole quantity of liquid was 200 measures, and that 50 measures have been drawn off, yielding 10 grains of indigo-blue; then the total quantity of indigo-blue in the sample is 40 grains. For 60 grains of indigo it is necessary to take from 1 lb. to 2 lbs. of water. This method, though rather tedious, gives better results than any of the preceding. The quantity of indigo-blue indicated by it is usually somewhat less than the actual quantity contained in the sample.

6. *With stannous chloride.*—The tin-solution is titrated with a solution of pure indigo-blue, prepared by dissolving the substance dried at 210°–230° C. (410°–446° F.) in 16 pts. of strong sulphuric acid, with addition of pounded glass to divide the indigo and facilitate the solution. The indigo-solution thus obtained is diluted with water, till a litre of it contains exactly 1 grm. of indigo-blue. The indigo to be examined is then dissolved in a similar manner, and the titrated tin-solution is added to it from a burette till the blue colour changes through green to light-yellow. Iron, if present in the indigo, must first be removed by digestion in hydrochloric acid, with addition of pounded glass. (E. Mulder, Scheik. Onderz. iii. [1] 37; Jahresber. 1860, p. 613.)

7. *With zinc.*—A solution of indigo in sulphuric acid is dilute with water and hydrochloric acid, and decolorised by zinc in an atmosphere of carbonic anhydride. A

measured volume of this solution is then introduced into a graduated tube filled with air or oxygen-gas, and the volume of oxygen absorbed is read off after a few hours. A similar experiment is then made with pure indigo-blue, and the value of the commercial sample is determined by comparison of the results.

INDIGO-BROWN. (Chevreul, Ann. Chim. lvi. 5; Berzelius, *Lehrb.* iii. 686; Gm. xiii. 48.)—A brown substance of uncertain composition, existing together with indigo-blue, indigo-gluten, and indigo-red, in all kinds of commercial indigo. To obtain it, the indigo-gluten is first removed by treating the indigo with dilute sulphuric, hydrochloric, or acetic acid, and then with boiling water. On digesting the residue in hot strong caustic alkaline lye, the indigo-brown dissolves, together with a small portion of indigo-blue, forming a dark-brown, almost black solution, from which, after filtration, the indigo-brown may be precipitated by an acid. The precipitate contains a considerable quantity of indigo-blue, from which it may be freed for the most part by dissolving it in carbonate of ammonium, evaporating the filtrate to dryness, dissolving the residue in water, filtering from the undissolved portion, consisting chiefly of indigo-blue, and precipitating the filtrate with sulphuric acid.

Indigo-brown thus prepared forms a dark brown transparent resin, almost tasteless, and quite neutral. By dry distillation, it yields ammonia and an empyreumatic oil. It is decomposed by nitric acid and by chlorine. It unites both with acids and with bases. With the *alkalis*, it forms dark brown compounds, easily soluble in water. The *baryta-compound* is sparingly soluble, and the *lime-compound* insoluble. By boiling the alkaline compounds with lime in excess, the indigo-brown may be separated and rendered insoluble. This is perhaps one of the uses of lime in the indigo-vat (pp. 251, 252).

Indigo-brown bears a considerable resemblance to Schunck's indihumin (p. 264), one of the products of the decomposition of indican.

INDIGO-GLUTEN. This substance is extracted from crude indigo by treating it with dilute sulphuric, hydrochloric, or acetic acid, then with boiling water, and remains on evaporating the solution as a yellow, transparent extract, soluble in spirits of wine, easily soluble in water, less soluble in acid liquids. Its taste is like that of the extract of meat. It yields by dry distillation much ammonia and a fetid oil, and behaves in most respects like ordinary vegetable gluten.

INDIGO-GREEN. Berzelius obtained a green substance by adding potash in small portions to an alcoholic solution of an alkaline hyposulphindigotate, till it became green, washing the precipitate with a little alcohol, decomposing it with oxalic acid, freeing the filtrate from oxalic acid by trituration with a little carbonate of calcium, then filtering and evaporating to dryness. The green solid residue thus obtained dissolved easily in water, forming a green solution, which, when mixed with lime-water, became yellow on exposure. It formed a green precipitate with acetate of lead, none with mercuric chloride or tincture of galls. (Berzelius.)

Chevreul also obtained a green substance from indigo, but it appears to have been merely indigo-brown mixed with a little indigo-blue.

INDIGO-PURPLE. See SULPHOPHENIC ACID (p. 260).—The preparation of a "purple-blue" from indigo for dyeing is described by L. and E. Boilley (Dingl. pol. J. clix. 318), and has been patented in this country by Johnson (Rep. pat. Invent. Dec. 1860). It probably consists of sulphindigotate or sulphophenic acid of sodium. To prepare it, finely pulverised indigo is added to twenty times its weight of acid sulphate of sodium in the state of fusion, and the mixture is heated and stirred till a sample colours water violet. The paste thus produced is then intimately mixed with 70 to 80 times its weight of water; and the colouring matter is precipitated by common salt (2 lbs. to 1 lb. of the paste) and washed with water containing that salt. After drying, it forms a mass of interlaced silky crystals having a coppery lustre. (For further details, and specimens of fabrics dyed with this preparation, see Rép. Chim. app. 1860, p. 215.)

INDIGO-RED. A red substance occurring, together with indigo-gluten and indigo-brown, in commercial indigo. It was first noticed by Chevreul, afterwards more fully examined by Berzelius.

The indigo-gluten and indigo-brown having been removed in the manner already described, the residue is exhausted with boiling alcohol of specific gravity 0.85. A dark-red solution is then obtained which, when filtered and distilled, deposits indigo-red as an amorphous blackish-brown powder quite insoluble in water and in alkaline liquids. By distillation in a vacuum, it yields a white crystalline sublimate (the so-called colourless indigo-red, as well as unchanged indigo-red. Strong sulphuric acid dissolves it, forming a dark-yellow solution, which deposits nothing on addition of water. The dilute solution is decolorised by wool, which at the same time acquires a dirty yellowish-brown or red colour.

When the fresh leaves of *Polygonum tinctorium* are exhausted with ether, and part of the ether is distilled off, indigo-blue separates out; and on evaporating the remaining solution to dryness, and exhausting the residue with alcohol, filtering from a slight brown residue, again evaporating to dryness, and exhausting the residue with hot water, which extracts a little yellow colouring matter, a hard brittle friable resinous substance separates of a fine red colour, and probably agreeing essentially with the red common crude indigo. It is insoluble in water, slightly soluble in *potash*, *ammonia*, and *acetic acid*, easily in *alcohol* and *ether*. The alcoholic solution turns red on addition of *baryta-water*, *lime-water*, *basic acetate of lead*, or *nitrate of silver*, and dark red with *stannous chloride*. With solution of *alum* it forms a beautiful red lake, not acted upon by alkaline carbonates.

The indigo obtained from the flowers of *Tankervillia cantonensis* contains a red substance, soluble in alcohol, but insoluble in water and in ether.

For further details respecting these indigo-reds, which are probably identical in the main with Schuecn's indirubin (p. 268). See *Gmelin's Handbook*, xiii. 45.

INDIGO-SULPHURIC ACIDS. When indigo-blue is macerated in fuming sulphuric acid, heat is evolved, and a deep-blue solution is formed, called *sulphate of indigo*, *Saxony* or *composition-blue*, containing sulphindigotic acid, $C^8H^4NO.SO^2$. The liquid has a deep-blue colour, and may be diluted with water without becoming turbid; if, however, the sulphuric acid is not in excess, there generally remains a purple powder, consisting of sulphophœnicic acid, $2C^8H^4NO.SO^2$, insoluble in dilute acids, but soluble, with blue colour, in pure water. According to Berzelius, there is also formed a third acid, called hyposulphindigotic acid, which has not been analysed. The indigo-blue cannot be recovered from these acids by any known methods. Their solution loses its colour after a while, and is instantly turned yellow by a small quantity of nitric acid: this reaction is used in qualitative analysis for the detection of nitric acid.

Hyposulphindigotic acid. *Hyposulphocæruleic acid.* To isolate this acid, the alcoholic solution of its ammonium-salt, obtained in the manner presently to be described (see SULPHINDIGOTIC ACID), is mixed with an alcoholic solution of acetate of lead; the whole is completely precipitated by addition of a little ammonia, and the precipitate is suspended in water and decomposed by sulphydric acid. A yellow liquid is then obtained, which, on exposure to the air, becomes blue, and is converted into hyposulphindigotic acid. By evaporating this solution, the acid is obtained as an amorphous mass, which becomes moist in contact with the air, dissolves readily in water, and reacts like sulphindigotic acid with sulphydric acid, zinc, iron, and charcoal.

The hyposulphindigotates resemble the sulphindigotates in many respects, but are distinguished by their solubility in alcohol of 84 per cent. When gently heated, they give off sulphurous anhydride without changing colour; at a higher temperature, they turn green and yield a sublimate of sulphite of ammonium.

The *ammonium*-, *potassium*- and *sodium*-salts are obtained by steeping wool dyed with sulphate of indigo in solutions of the corresponding alkaline carbonates, evaporating the resulting solutions to dryness, and exhausting the residues with alcohol, which takes up only the hyposulphindigotates.

The *aluminium-salt* resembles the corresponding salt of sulphindigotic acid.

The *barium-salt* is obtained by precipitating the potassium-salt with carbonate of barium, in dark-blue flocks, very soluble in pure water; the solution, when evaporated, deposits films having a coppery lustre.

The *calcium*- and *magnesium*-salts are very soluble in water and in alcohol.

The *lead-salt* is obtained by precipitating an alcoholic solution of the ammonium-salt with alcoholic acetate of lead. It is a blue powder, which dissolves slowly but completely in water: it is sparingly soluble in alcohol, and has an astringent taste.

Sulphindigotic Acid. $C^8H^4NO.SO^2$. *Sulphate of indigo*, *Soluble blue indigo*, *Sulphindigotic acid*, *Sulphocæruleic acid*.—Indigo may be dissolved in strong (monohydrated) sulphuric acid (SH^2O^4), as well as in the fuming acid (which contains sulphuric anhydride in solution), but it requires 15 pts. of the former, and only 6 pts. of the latter; moreover, the solution in common sulphuric acid requires the aid of heat, which gives rise to the formation of sulphurous acid; it may, however, be facilitated by triturating the indigo with pounded glass so as to divide the particles.

The acid solution is diluted with from 30 to 50 times its bulk of water; the liquid is filtered from the precipitated sulphophœnicic acid; the filtrate is digested at a gentle heat with wool or woollen stuff (previously prepared by washing, first with soap and then with water containing 1 per cent. carbonate of sodium, and finally with pure water), until no more colouring matter is taken up, the excess of sulphuric acid remaining in solution. The wool, dyed blue by sulphindigotic and hyposulphindigotic acids, is washed with water till the latter no longer becomes acid, and digested

with water containing a little carbonate of ammonium; the blue solution is poured off from the decolorised wool, and evaporated to dryness at 80° ; and the residue is exhausted with alcohol of 83 per cent., which dissolves the hyposulphindigotate of ammonium, and leaves the sulphindigotate. The latter is dissolved in water, and precipitated by acetate of lead; the dark-blue precipitate is washed with water, then suspended in water, and decomposed by sulphydric acid; and the yellow or colourless solution, which turns blue on exposure to the air, is evaporated to dryness at 80° (Berzelius). According to Joss, sulphindigotate of ammonium is not effectually separated from the hyposulphindigotate by alcohol; it is better, therefore, to digest the indigo-solution with wool only so long as it forms a precipitate with acetate of barium, by which hyposulphindigotic acid is not precipitated.

Properties.—Sulphindigotic acid forms a solid mass having a peculiar agreeable odour and an acid taste; it has a weak but decided acid reaction (Joss). It becomes moist in the air, and is very soluble in water and in alcohol. It is separated from its aqueous solution by wood-charcoal, and with greater facility by blood-charcoal, but may be extracted from the charcoal by alkaline carbonates.

Wool is dyed by the aqueous acid, but not by its salts, unless an acid is added, a comparatively weak acid, such as acetic acid, being sufficient for the purpose. Boiling water and alcohol deprive the wool of only a portion of its colour, but alkalis remove it entirely (Berzelius). Sulphindigotic acid is completely decolorised by woollen stuffs; silk fabrics do not deprive it of all its colour; linen and cotton take up very little. Silk dyed with it is deprived of its colour by soap, but not by water. (Bergmann.)

Decompositions.—1. Sulphindigotic acid yields by dry distillation sulphurous anhydride, sulphite of ammonium, much water, and a little empyreumatic oil. No vapours of indigo-blue are evolved, but the sublimed sulphite of ammonia dissolves in water with a blue colour, having carried over a little of the undecomposed acid. The carbonaceous residue burns with difficulty, but completely. The sulphindigotates also do not yield any sublimate of indigo by dry distillation (Berzelius).—2. Sulphindigotic acid is decomposed by exposure to sunlight.—3. Chlorine produces a quantity of brown resin in the solution of the acid, and only a little chlorisatin and dichlorisatin (Erdmann, *J. pr. Chem.* 19, 355).—The blue colour of the acid is changed to green by chloride of lime (Schlumberger), and to reddish-brown by chloride of potassium and hydrochloric acid (Bolley).—4. Sulphindigotic acid is decomposed by nitric acid. When the barium-salt is decomposed by boiling with concentrated nitric acid and the solution diluted and filtered, it is not precipitated by chloride of barium (Berzelius).—5. The solution of sulphindigotic acid, heated with chromate of potassium, becomes ochre-yellow (Penny); mixed with permanganate of potassium, it becomes first green and then brownish-yellow (Elbers, Mohr); when heated with ferric salts, it is decolorised as by nitric acid (Wöhler, *Ann. Ch. Pharm.*, xxxiv. 236). These reactions are used for the valuation of commercial indigo (p. 266).—6. Deoxidising substances reduce sulphindigotic acid to a compound derivable from indigo-white, and change the colour of the solution to yellow. Zinc or iron filings dissolve in the solution without disengagement of hydrogen, yielding a blue liquid, which, however, is decolorised by excess of acid: the solution quickly recovers its blue colour on exposure to the air. Sulphydric acid does not decolorise the solution at ordinary temperatures; but on heating the liquid to 50° , it deposits sulphur and becomes colourless. The decoloration is prevented by the presence of free acids. If the solution containing excess of sulphydric acid is evaporated in a vacuum over slightly moistened potash, a dark-yellow viscid residue is obtained, which becomes moist and dark-blue on exposure to the air. The solution of sulphindigotic acid is likewise decomposed by stannous chloride. (For further details on these reductions, see *Gmelin's Handbook*, xiii. 60.)

Sulphindigotates. $C^{\circ}(H^{\circ}M)NO_2SO^{\circ}$.—These salts are formed by direct combination or by double decomposition. They cannot be obtained crystallised; they are dark blue, with a peculiar coppery lustre, and taste feebly saline and decidedly of indigo. The alkaline sulphindigotates are slightly soluble in cold water, and more readily in hot water; the solution is blue by reflection, and red by transmitted light.—The sulphindigotates are more readily decolorised than the free acid, by all substances which reduce indigo-blue, especially in the presence of free alkalis. Protosulphate of iron does not reduce a neutral sulphindigotate, even on warming; not even when as much alkali is added as is necessary to precipitate the protoxide of iron; but the slightest excess of alkali produces immediate decoloration, and on the addition of enough acid to neutralise the alkali, the blue colour is restored. Sulphide of potassium or calcium decolorises the solutions of the sulphindigotates, part of the sulphide being converted into sulphate. The reduced solution appears yellow when neutral, and burnt-yellow when alkaline. The neutral solution leaves, when evaporated in vacuo, a dark dry residue, which appears dark yellow when pulverised, and becomes blue on exposure to the air for several days. The solution turns blue on exposure to the air.

Ferrie and *capric* salts instantly turn the solution blue, and are converted into salts of the lower oxides. The solution reduced by *stannous chloride* deposits, on exposure to the air, a white powder, which is a mixture of stannic oxide and a product of decomposition which becomes green on exposure to the air.

Sulphindigotates, when heated, give off water without melting. When strongly heated, they decompose, evolving free ammonia, carbonate of ammonium, cyanide of ammonium, a trace of volatile oil, and afterwards of carbonic anhydride, whilst a residue of metallic sulphide is left.

Sulphindigotate of Ammonium is prepared by the process described on page 258 (Berzelius); or by precipitating sulphindigotic acid, which should not be too dilute, with ammonia or a salt of ammonia (Crum). It reacts similarly to the potassium-salt. It melts when heated and swells up, but is not decomposed, even by a pretty strong heat, and although it assumes a charred appearance, still dissolves completely in water, forming a blue solution. When more strongly heated, it yields a sublimate of sulphite of ammonium (Berzelius.) It dissolves in from 40 to 50 parts of cold water, and in a much smaller quantity of hot water (Crum), and is precipitated from the solution by the alkaline sulphates and some other salts, but much less completely than the potassium-salt. It is not soluble in alcohol. (Crum, Berzelius.)

Sulphindigotate of Aluminium is readily soluble in water, and dries up like the other sulphindigotates on the evaporation of the solution. Sulphindigotate of potassium, mixed with a salt of aluminium and a little ammonia, throws down a dark blue pulverulent basic salt, becoming blackish-blue when dried. It gives up all its acid to an excess of alkali. (Berzelius.)

Sulphindigotate of Barium is precipitated in dark blue flakes, on mixing the potassium salt with chloride of barium (Crum, Berzelius). It dissolves slightly in cold water with a bluish colour; more abundantly in hot water, imparting to it a dark colour. Owing to the great affinity of baryta for sulphindigotic acid, this salt is formed when hyposulphindigotate of potassium is mixed, first with sulphuric acid, and then with chloride of barium; an excess of sulphate of barium is, however, necessary to the reaction, and hence the precipitate has a paler colour. Sulphate of barium already precipitated likewise forms with hyposulphindigotate of potassium, a small quantity of sulphindigotate, and becomes pale blue.

Sulphindigotate of Calcium is soluble in water, but insoluble in alcohol, which precipitates it in blue flocks.

Sulphindigotate of Lead is precipitated in dark blue flocks, slightly soluble in water on mixing neutral acetate of lead with sulphindigotate of potassium. Basic acetate of lead forms a light blue precipitate, which becomes darker when dry.

Sulphindigotate of Magnesium is very soluble in water, and is not precipitated by an excess of sulphate of magnesium.

Sulphindigotate of Potassium, $C^H \cdot KNO \cdot SO^2$. This salt is obtained: 1. By steeping wool dyed blue with sulphate of indigo, in a solution of carbonate of potassium, evaporating the solution, and treating the residuo with alcohol, which extracts hyposulphindigotate of potassium. The residuo is then treated with acetic acid and alcohol to remove the excess of carbonate (Berzelius).—2. Indigo-blue is treated with excess of sulphuric acid; and after the sulphophoenic acid has been removed by filtration, the blue liquid is saturated with acetate of potassium; the resulting blue precipitate is thrown on a filter, and washed with acetate of potassium till the liquid which runs through begins to turn blue; the salt is then washed with alcohol to remove the acetate. (Dumas.)

Sulphindigotate of potassium in the dry state, forms a copper-coloured mass, yielding a blue powder; blue also by transmitted light. It rapidly absorbs moisture from the air.

When heated it does not melt or evolve any purple vapours; it is difficult to incinerate. According to Berzelius, it forms sulphopurpurate of potassium when heated with lime-water out of contact with the air; in presence of air, it forms salts of sulphodlavie, sulphofulvic, and sulphoruffic acids.

Sulphindigotate of potassium dissolves in 140 parts of cold water, and in a much smaller quantity of boiling water, a portion separating out on cooling. The solution is of a dark blue colour, transparent only when viewed in thin layers; when held up before the light of the sun or of a candle, it appears scarlet. 1 part of the salt imparts a blue colour to 600,000 parts of water. Water containing 1 per cent. of acetate of potassium does not dissolve the salt in the cold; on heating, a portion dissolves and separates out in blackish flakes on cooling. It is readily dissolved by sulphuric acid, but is not soluble in concentrated hydrochloric acid (Crum); or in alcohol of specific gravity 0.80. (Berzelius.)

If an aqueous solution of sulphindigotate of potassium is mixed with a barium- or

calcium-salt and carbonate or phosphate of sodium added, carbonate and phosphate of barium and carbonate of calcium are precipitated of a light blue colour, and phosphate of calcium of a deep blue colour. When the solution of sulphindigotate of potassium is mixed with acetate of lead and a solution of tannic acid, the precipitate of tannate of lead carries down all the colouring matter with it.

Sulphindigotate of potassium occurs in commerce as paste or dry powder, known as precipitated indigo, indigo-carmin, soluble indigo, or solid blue. It is used for dyeing linen of an azure-blue colour, and for producing very pure blue colours on wool.

Sulphindigotate of Sodium, also called indigo-carmin, resembles the potassium salt, and is used for similar purposes, but is more soluble in saline solutions.

Sulphophœnicic acid, $2C^H^4NO.SO^3$. *Indigo-purple, Phœnicin, Sulphopurpuric acid*.—This acid is formed when sulphuric acid is allowed to act upon indigo for a short time, or not in excess. To prepare it 1 pt. of indigo-blue is mixed with from 8 to 10 pts. of strong sulphuric acid, and kept for three days at a temperature of 50° or 60° ; the solution is then diluted with water, and the precipitate of sulphophœnicic acid is filtered, washed with dilute hydrochloric acid, and dried in an oil-bath at 80° — 100° (Dumas). Or powdered indigo is purified by boiling with dilute sulphuric acid, and then shaken up with from 7 to 8 pts. of strong sulphuric acid till the mixture becomes olive-green. The whole is then diluted with a very large quantity of water, and the precipitate of sulphophœnicic acid is collected on a filter and washed with water, which becomes more deeply blue in proportion as the sulphuric acid is removed. The last filtrates are evaporated to dryness. (Crum.)

As the extraction of the sulphophœnicic acid on the filter according to (1) is a very slow process, and when the greater part of the indigo-blue is converted into sulphophœnicic acid by the prolonged action of the sulphuric acid, water will no longer pass through the filter, the following method may be employed, which yields a more abundant, though less pure product. 1 pt. of powdered indigo is shaken in a flask with 10 pts. of strong sulphuric acid, till the blue colour which the indigo had at first lost is completely restored. For this purpose, from ten to twelve hours are requisite at 7° , three hours in the heat of the sun, 20 minutes at 38° , and a few moments at 100° . A large quantity of water is added; the solution is filtered; and the precipitate is taken from the filter and washed by decantation with water containing sufficient chloride of ammonium to prevent it from dissolving the sulphophœnicic acid. The solution of chloride of ammonium is allowed to run from the filter, and the precipitate is removed and suspended in a large quantity of water. After three days, the solution is poured off, and the water is renewed as long as sulphophœnicic acid continues to dissolve. The sulphophœnicic acid is then precipitated from the decanted solutions by chloride of potassium, and the precipitate is washed on a filter with water as long as the water continues to pass through. Sulphophœnicic acid thus prepared contains a little potassium-salt and a large quantity of earthy matter; after drying, it is no longer soluble in water. (Crum.)

Häffely triturates 1 pt. of finely powdered indigo with 20 pts. of common sulphuric acid; allows the whole to stand for some time, till a drop of the solution, which is at first blue, colours water or paper violet; and then mixes the solution with a large quantity of water: the action of the sulphuric acid is promoted by heating the whole to 40° . If less sulphuric acid is used, it must be more strongly heated; if only 3 pts. of sulphuric acid are employed for 1 pt. of indigo, the latter is not completely converted into sulphophœnicic acid. If fuming sulphuric acid is used, it is not easy to discover when the reaction is ended.

Properties.—Sulphophœnicic acid forms a blue mass or a purple-red powder, soluble in water, to which it imparts a blue colour. It dissolves readily, with blue colour, in sulphuric acid, especially in the fuming acid, being at the same time gradually converted into sulphindigotic acid. With a large quantity of soda-ley, it forms a yellow solution which turns blue if immediately mixed with sulphuric acid of 66° B.; but stronger sulphuric acid added after 24 hours, produces a whitish precipitate. (Gros-Benaud, Dingl. pol. J. 129, 288.)

The *sulphophœnicates* are precipitated from the aqueous solution of the acid by the addition of other salts. When dry they are red; their aqueous solutions are blue. They dissolve very sparingly in water, but more readily in alcohol. The solutions are reduced to yellow liquids by heating with sulphydric acid, by sulphate of iron and lime, or by caustic alkalis. The reduced solutions turn blue on exposure to the air, and on the addition of other salts, the salt of sulphophœnicic acid is precipitated unchanged.

The *ammonium-salt*, when heated, evolves sulphurous anhydride together with sulphite of ammonium, and a red vapour which yields a sublimate like indigo-blue. This

INDIGO-SULPHURIC ACIDS.

sublimate is often bright green on the lowest edges, like the wing-cases of cantharides, and turns brown when burnished.

The *potassium-salt*, $C^{10}H^4K^2N^2O^2SH^2O^4(?)$ is obtained by adding acetate of potassium to the aqueous solution of the acid. It is then precipitated in purple flocks, which must be washed, first with acetate of potassium, then with alcohol. It dissolves in 100 pts. of water.

The *sodium-salt* is obtained in like manner.

The solution of sulphophœnicic acid, even when very dilute, is precipitated by the salts of calcium, magnesium, aluminium, iron, tin, and copper.

Products obtained by decomposition of the Indigo-sulphuric acids.

The following products of the decomposition of these acids are described by Berzelius (*Lehrbuch der Chemie*, 4th Aufl. vii. 226); but their composition is very uncertain, and they require further examination:—

1. **Sulphoflavic acid.**—This acid is formed by heating sulphoviridate of potassium with lime-water in contact with the air.—To prepare it, sulphindigotate of potassium is heated with lime-water in an open vessel, until the solution acquires a pure red colour (if the action is too prolonged, it becomes yellow; if the access of air is kept under control, it is easier to hit the right moment). Carbonic anhydride is then passed through the liquid; the filtrate evaporated to dryness, and the green, brownish-yellow residue extracted with alcohol. The yellow solution is precipitated with acetate of lead; the lemon-yellow precipitate suspended in water and decomposed by sulphydric acid; and the solution filtered from the sulphide of lead is then left to evaporate. It forms yellow arborescent masses, having a strong acid taste and reaction. It is soluble in water and in alcohol; the solution forms with acetate of lead a lemon-yellow precipitate, insoluble in water.

2. **Sulphofulvic and Sulphorufic Acids.**—These acids are formed simultaneously with sulphoflavic acid. The residue, from which the sulphoflavic acid has been extracted by alcohol, is dissolved in water, and the bright-red solution is precipitated with basic acetate of lead. The pale-red precipitate is suspended in water, and decomposed with sulphydric acid, and the filtrate is evaporated to dryness. Absolute alcohol extracts from the residue, sulphofulvic acid, which, on evaporation, is deposited as a dark yellow, transparent mass, having the consistence of an extract; it forms a lead-salt, is readily soluble in water and in alcohol. The portion insoluble in alcohol is sulphorufic acid. This latter dissolves in water with a fine red colour, and, on evaporating the water, forms a dark red, opaque, amorphous mass, which tastes acid and strongly reddens litmus. The lead-salt is readily soluble in water and in alcohol.

3. **Sulphopurpuric Acid.**—This acid is formed by the action of alkalis upon sulphoviridic acid. 1 pt. of sulphindigotate of potassium is dissolved in 50 pts. of lime-water and heated in a covered vessel, till the solution, which has gradually turned purple red, does not become green again on cooling. After the whole has been allowed to cool in the covered vessel, the excess of lime is precipitated by carbonic acid; the filtrate is evaporated to dryness; and the residue treated with alcohol, which extracts a little sulphoflavic acid. The residue is dissolved in water, the purple-red solution precipitated with acetate of lead, and the precipitate suspended in water and decomposed by sulphydric acid; the filtered solution is then evaporated to dryness.

Sulphopurpuric acid forms a brown uncrystallised mass, dissolving in water with dark purple-red colour. The potassium-salt dissolves in water and imparts to it a dark purple-red colour, like that of permanganate of potassium. The precipitate produced by mixing the aqueous solution of the acid with acetate of lead, is slightly soluble in water, with a reddish colour; insoluble in alcohol. With excess of oxide of lead, a pale red salt is formed, which is insoluble in water.

4. **Sulphoviridic Acid.**—This is the first product of decomposition in the action of alkalis upon sulphindigotic acid.

1. To an alcoholic solution of an alkaline hyposulphindigotate, hydrate of potassium is added in small portions until it becomes green, and the green precipitate is washed on a filter with a little alcohol. The precipitate is decomposed by an aqueous solution of oxalic acid, filtered, and the filtrate is freed from excess of oxalic acid by triturating it with a little carbonate of calcium: it is then filtered and evaporated to dryness.

2. When a solution of hyposulphindigotate of barium is evaporated to dryness on a water-bath, it becomes green and yields a precipitate with basic acetate of lead, but not with the neutral acetate; and if the greyish-green precipitate is decomposed by sulphydric acid and the green filtrate evaporated to dryness, sulphoviridic acid is obtained as a dry, hard, gummy mass, having a strong acid reaction.

INDIGOTIC ACID—INDIGO-WHITE.

283

It dissolves very readily in water, and slowly, but completely, in strong alcohol the solutions appear dark green by reflected light, and dark red by transmitted light. The aqueous solution mixed with lime-water becomes yellow in contact with the air. The lead-salt is somewhat soluble in water, imparting to it a greenish colour.

INDIGOTIC ACID. Syn. with NITROSALICYLIC ACID. (See SALICYLIC ACID.)

INDIGOTIN. Syn. with INDIGO-BLUE.

INDIGO-WHITE. $C^{14}H^{12}N^2O^2$. *White Indigo, reduced or deoxidised Indigo, Indigogen* (Gm. xiii. 93; Gerh. iii. 510).—A colourless substance, produced by the action of reducing agents on indigo-blue (pp. 251, 254), and differing from a double molecule of the latter ($C^{14}H^{10}N^2O^2$) by two atoms of hydrogen. Chevreul, who was the first to isolate it, supposed that it existed ready formed in indigoferous plants, and was converted into indigo-blue by oxidation; but Schunck has shown that this view is untenable, because indigo-white is soluble only in alkaline liquids, and the juice of plants is always acid. Moreover, if the indigo-white existed in the juice of these plants, it would be converted into indigo-blue by oxidation, on coming to the surface, which is not the case.

Preparation.—Commercial indigo, purified by boiling with hydrochloric acid, next with strong potash, and afterwards with alcohol, is mixed with freshly prepared hydrate of calcium (2 parts of quick-lime to 1 of indigo) and placed in a closed vessel with 150 parts of boiling water, after which sulphate of iron equal to one-third the weight of the indigo is added, and after the vessel has been closed, the whole is carefully shaken. After two days, the solution is decanted by means of a siphon into flasks filled with carbonic anhydride, and when the flasks are nearly full, they are completely filled with boiling dilute hydrochloric acid, corked up, and placed in a vessel containing cold water. The air is thus prevented from obtaining access to the indigo-white, which separates out in white crystalline flakes. After the indigo-white has settled down, the solution is drawn off with a wide siphon, and the deposit is thrown upon a filter, which is covered with a bell-jar, into which a stream of hydrogen or carbonic anhydride is passed. The filter is washed with cold water, which has been well boiled and then corked up. Indigo-white is very easy to wash, and if the deposit is allowed to stand for several days, it becomes so consistent that it may be washed in the air without becoming deeply coloured. After the contents of the filter have been washed, they are spread, while still moist, upon a glass plate and dried in a vacuum. When the indigo-white is dry, carbonic anhydride is allowed to flow into the receiver of the air-pump, in order that the pores of the dry mass may become filled with the gas (Berzelius, Dumas).—2. Three pts. of indigo-blue which have been purified by boiling, are digested for 24 hours with 5 pts. of hydrate of calcium, 4 pts. of sulphate of iron, and 120 pts. of water, in a closed flask filled with hydrogen, and the whole is frequently shaken till the deposit assumes a greenish-yellow and the solution a reddish-yellow colour. The lime is precipitated from the latter with carbonate of potassium, and the clear solution is decanted by means of a siphon filled with hydrogen, into a flask containing a mixture of hydrochloric acid and sulphite of ammonium. The thick white precipitate which is thus formed is filtered out of contact with the air, washed with water containing a little sulphite of ammonium, and dried at 100° in a stream of hydrogen. (Liebig.)

Properties.—Indigo-white thus prepared forms a coherent greyish-white mass having a faint silky lustre; if absolutely pure, it would probably be quite white. It is tasteless, inodorous, and does not change the colour of litmus. It is perfectly insoluble in water, and in such acids as do not decompose it, but dissolves in aqueous alkalis, in alcohol, and in ether, forming yellow solutions, which, when exposed to the air, turn yellow and deposit indigo-blue.

Decompositions.—1. When indigo-white is heated in a vacuum, a little water is evolved, a small quantity of indigo-blue sublimes, and a large carbonaceous residue is left (Berzelius).—2. When exposed to the air, and in contact with various oxygen-compounds, it takes up oxygen and is converted into indigo-blue. Freshly precipitated indigo-white turns blue immediately when shaken with water containing air, even if a free acid is present. After washing, and while still moist, it becomes purple through its entire mass on exposure to the air, unless it is rapidly dried. When dry, it requires several days' exposure to the air, to oxidise it completely, first becoming bright blue, and then dark blue through the entire mass. It cannot be preserved in sealed tubes, since the air contained in its pores is sufficient for its conversion into indigo-blue. Dry indigo-whites exposed to the air at a gradually increasing temperature, suddenly becomes dark purple. When a cupric salt is added to an alkaline solution of indigo-white, a salt of the alkali, together with indigo-blue and cuprous oxide, are formed; the latter, on the addition of sulphuric acid, is decomposed into cuprous oxide, which dissolves, and a residue of metal.—3. Indigo-white precipitated from an alkaline

solution by *nitric acid*, is turned blue by a slight excess of the acid, and then more completely decomposed (Berzelius). It dissolves instantly in *sulphuric acid*, and imparts to it a dark purple colour, which passes to blue on dilution. According to Berzelius, the indigo-white is oxidised, and part of the sulphuric acid converted into hyposulphuric acid.

Metallic Derivatives of Indigo-white.—Indigo-white dissolves readily in all aqueous *alkalia* and *alkaline earths*, also in the aqueous carbonates of ammonium, potassium, and sodium, and, according to Liebig, without depriving them of their alkaline reaction. The cold solutions are pure yellow, the warm and highly concentrated solutions brownish-yellow. When exposed to the air, they immediately deposit indigo-blue.

Indigo-white forms with *lime* a neutral compound, readily soluble in water, and a basic compound which is almost insoluble; this latter is precipitated when the solution of the more neutral body is digested with hydrate of calcium, or when indigo is digested with water, sulphate of iron, and excess of lime. The precipitate of gypsum and hydrated sesquioxide of iron, which is formed at the same time, may be readily suspended in water and separated by levigation. The basic compound is of a lemon-yellow colour, and very slightly soluble in water, to which it imparts a yellow colour. On exposure to the air, it first turns green, and then bright blue. (Berzelius.)

The alkaline solutions of indigo-white are precipitated by the salts of the *earth-metals* and *heavy metals*, yielding white precipitates, which turn blue in the air more quickly than indigo-white itself. The *magnesium-compound*, being slightly soluble, is partly thrown down as a white precipitate, and partly remains dissolved in the aqueous solution, to which it imparts a yellow colour; it turns blue on exposure to the air. The *aluminium-compound* is white, but rapidly turns blue on the filter; if it be then dried, it forms a dark blue crystalline powder which sparkles in sunshine; indigo-blue may be very readily sublimed from it, and a grey earthy residue then remains. (Berzelius.)

The *manganous compound* is dirty-green, and does not yield any sublimate of indigo-blue when dried in the air and heated. The *zinc-compound* is white, but rapidly turns blue on exposure to the air, and then yields a sublimate of indigo-blue when heated. The *lead-compound* is white and slightly crystalline, turns rapidly blue on exposure to the air, and if then heated, detonates slightly, and yields reduced lead. The *ferrous compound* is white, but quickly turns blue on exposure to the air; if it be then heated, it does not yield any sublimate of indigo-blue. The *cobalt-compound* is grass-green, and after drying in the air, does not yield any sublimate of indigo-blue when heated. Nitrate of *silver* produces with an aqueous solution of the potassium-compound a precipitate which is at first transparent brown, and then becomes black; it is not acted upon by the air, but when heated, produces a gentle explosion and yields a sublimate of indigo-blue and a residue of metallic silver. (Berzelius.)

INDIGO-YELLOW. A substance produced by heating hyposulphindigotate of calcium with lime-water, in contact with the air. It is a transparent yellow mass, with neutral reaction; swells up when heated, emitting an odour like that of burnt animal matter, and is slowly converted into a combustible cinder. It dissolves in water and in alcohol, forming yellow solutions. The aqueous solution is precipitated incompletely by neutral acetate of lead, completely by the basic acetate.

INDIHUMIN. A product of the decomposition of indican (p. 248) perhaps identical with indigo-brown. It is obtained but sparingly, and not on all occasions. It is a brown powder, containing 62.86 per cent. carbon, 4.71 hydrogen, 7.19 nitrogen, and 25.24 oxygen, agreeing nearly with the formula $C^{10}H^8NO^8$. It burns without melting when heated, is insoluble in water and in alcohol, but dissolves in aqueous alkalis, forming a brown liquid, from which it is precipitated by acids. It dissolves in boiling nitric acid, forming a yellow solution, which, on evaporation, leaves an orange-yellow residue.

INDIN. $C^8H^{12}N^2O^8$. (Laurent, Ann. Ch. Phys. [3] iii. 471.)—A compound, probably containing the elements of two molecules of indigo-blue, produced by the action of potash on isatyde, sulphisatyde, or disulphisatyde by heating isatan or isatyde:—

It is most easily prepared by the action of potash on disulphisatyde. This substance is placed in a mortar, and potash poured upon it so that a stiff magma is formed, which is rubbed up for some time, and potash added drop by drop. When after five or six minutes the mass turns rose-coloured, alcohol is gradually added, and the whole is constantly stirred, until a dark rose-coloured paste is formed, which is diluted with alcohol, and filtered. The residue is washed, first with alcohol, and then with water. Since the indin thus obtained contains abundance of sulphisatyde, the water is removed from it by washing with alcohol, which is allowed to run through the filter; the indin is then taken from the filter and treated with very strong lukewarm potash, wherein it immediately forms a black solution, which after a few hours becomes thick with black needles of indin-potassium. (If the potash is too hot, the black colour disappears, and the indin is completely destroyed.) It is then diluted with absolute alcohol, and the solution removed with a pipette; the crystals are washed on a small filter with common alcohol, then with dilute hydrochloric acid, and finally with water; they are thus gradually reduced to red pulverulent indin. In order to obtain indin crystallised, the black crystals are dissolved in boiling absolute alcohol, and the boiling solution is mixed with hydrochloric acid; microscopic crystals then separate out on cooling.

Indin forms a deep rose-coloured powder or fine microscopic needles; insoluble in water, very sparingly soluble in alcohol and ether, even at the boiling heat. When heated, it swells up as soon as it begins to melt, yields a sublimate of needle-shaped crystals, and leaves a considerable quantity of charcoal. It dissolves with red colour in sulphuric acid, and is precipitated unchanged by water. With nitric acid, it yields nitridin, and with bromine, dibromindin.

The analyses of indin, made at different times, do not agree very well together, the carbon varying from 71.55 to 72.09 per cent., and the hydrogen from 3.0 to 4.65; the nitrogen in one analysis was found to be 11.0 per cent. The formula $C^{16}H^{10}N^2O^2$ requires 73.3 C, 3.8 H, and 10.6 N. The differences arose, according to Laurent, from the presence of hydrindin, into which a portion of the indin had been converted by the further action of the potash.

Indin-potassium, probably $C^8H^5KN^2O^2$. This compound is formed in the preparation of indin as above described, and may be prepared in a state of greater purity by warming indin moistened with alcohol, and dissolving it in strong alcoholic potash. The black solution, if immediately taken from the fire, deposits black crystals, which must be freed from the liquid by decantation, rapidly washed with absolute alcohol, then laid upon paper, and dried in a vacuum on a porous tile. The crystals rapidly attract moisture from the air, and are resolved into potash and indin. The compound gives by analysis from 11.5 to 12.0 per cent. potassium, whereas the above formula requires 13.0 per cent. The analyses agree better with the formula $C^8H^{11}KN^2O^2$, which is that of the potassium-salt of an acid, related to indin in the same manner as isatic acid, $C^8H^7NO^2$, to isatin, $C^8H^5NO^2$.

Derivatives of Indin.

Dibromindin. $C^8H^5Br^2N^2O^2$. (Erdmann, J. pr. Chem. xxii. 265. Laurent, Ann. Ch. Phys. [3] iii. 371.)—Produced:—1. By the action of bromine on indin (Laurent).—2. By heating dibromisatyde (Erdmann).—3. By the action of bromine upon disulphisatyde. (Laurent.)

To prepare it, indin is treated with bromine, whereupon hydrobromic acid is evolved, and a violet-black powder is formed (Laurent). Or dibromisatyde is heated at a temperature not exceeding 220° , and dibromisatin and undecomposed dibromisatyde are removed from the products by treating them with boiling alcohol (Erdmann). Or bromine is poured upon disulphisatyde, whereupon hydrobromic acid and bromide of sulphur are evolved, and the soft brown mass thus formed is treated with ether, which extracts resin and an orange-yellow crystalline mass, and leaves dibromindin as a violet-black powder. (Laurent.)

Prepared according to 1 and 3, it is a violet-black powder; prepared according to 2, it is blackish red. It is slightly soluble in alcohol and in ether.

When dibromindin is heated between two platinum crucible-covers, the greater part chars; placed on glowing charcoal, it yields a sublimate of shining copper-coloured laminae, which appear violet by transmitted light under the microscope. It blackens when treated with potash; if water is added and the whole boiled, the dibromindin gradually dissolves and forms a yellow solution, from which acids precipitate yellow flakes. When it is boiled with alcohol and solid hydrate of potassium, a blackish red solution is formed, from which water or hydrochloric acid precipitates violet-coloured dibromindin. (Laurent.)

Dichlorindin. $C^8H^5Cl^2$. (Erdmann, J. pr. Chem. xxii. 264.)—Produced from chlorisatyde by the action of heat, or by treating it with potash.

Chlorisatyde is heated to 200° , and the product is freed from chlorisatin and

decomposed chlorisatyde by boiling alcohol. Or, chlorisatyde is dissolved in warm potash, and allowed to cool; the mother-liquor is poured off from the deposit of chlorisate of potassium, and mixed with acetic acid, which precipitates yellow chlorisatic acid. On subsequently heating the filtrate with hydrochloric acid, it assumes a deep orange colour, and deposits violet flakes of chlorindin, which are filtered from the hot solution.

Chlorindin forms a dirty violet powder, insoluble in water, hydrochloric acid, and alcohol. It dissolves in potash, forming a yellowish solution, with which hydrochloric acid gives a yellow precipitate, soluble with yellow colour in water.

Tetrachlorindin. $C^4H^4Cl^4N^2O^2$. (Erdmann, *loc. cit.*)—Produced from chlorisatyde by the action of heat below 200° , or by the action of potash. It resembles chlorindin.

Hydrindin. $C^{22}H^{22}N^4O^3$? (Laurent, Ann. Ch. Phys. [3] iii. 475.)—A compound produced by the action of alcoholic potash upon indin, isatin, isatyde, sulphisatyde, or disulphisatyde.

Preparation.—1. Indin moistened with alcohol is warmed with strong potash-ley till the solution, which is at first black, has become colourless, and the crystals of hydrindin-potassium, which separate out on cooling, are completely freed from potash by water.—2. When isatyde is treated with potash and a little alcohol, a beautiful rose-coloured solution is formed, which, when mixed with hydrochloric acid, and gently evaporated, becomes yellow, and deposits on cooling a mixture of isatin and hydrindin, from which the isatin is extracted by treating with a little boiling alcohol.—3. Sulphisatyde dissolves completely in gently heated potash, and on cooling, the potassium-compound of hydrindin sometimes separates out in beautiful small, pale-yellow crystals; sometimes, however, the solution solidifies into a mass of needles having a silky lustre. The whole is mixed with a large quantity of water, and the crystals are washed on a filter till all the potash is extracted. The filtrate mixed with hydrochloric acid still deposits a small quantity of hydrindin, together with a substance which is perhaps indin.

Hydrindin forms a white or pale-yellow powder, insoluble in water, slightly soluble in boiling alcohol, and separating from the solution on cooling, in small rhombic or six-sided needles.

Hydrindin carefully heated above 300° , turns violet-brown and gives off 2 at. water; the residue behaves with alcoholic potash like indin.—With boiling nitric acid it forms a violet powder similar to nitrindin.

Hydrindin contains, according to the mean of Laurent's analyses, 69.80 per cent. C, 4.86 H, and 10.70 N. The formula, $C^{22}H^{22}N^4O^3$, deduced therefrom by Laurent, which represents hydrindin as composed of 2 at. indin + H^2O , requires only 4.0 per cent. H, which is much below the analytical number. Gerhardt suggested the formula $C^{22}H^{22}N^4O^4.H^2O$, which requires 70.59 per cent. C, 4.41 H, and 10.29 N, and represents hydrindin as a hydrate of a double molecule of indin + 2 at. H. The formation of hydrindin by the action of potash on indin, &c. is more favourable to Laurent's than to Gerhardt's view, provided hydrindin is the sole product of the reaction; but in reality other products are formed at the same time, so that the formation of the more highly hydrogenised compound, hydrindin, may perhaps be compensated by that of one or more compounds containing a larger proportion of oxygen. The organic molecule, $C^{16}H^{17}N^3O$, associated with the elements of sulphuric acid in Schlieper's hydrindinsulphuric acid (p. 287) differs from indin by the substitution of 2 at. H for 1 at. O; but as the mode of formation of this molecule is altogether different from that of Laurent's hydrindin, it is probable that the two have little more in common than the name.

Hydrindin-potassium. $C^{22}H^{22}KN^4O^4.3H^2O$? When hydrindin is dissolved in warm aqueous potash, this salt separates out in short, brilliant, pale-yellow prisms or silky needles, containing, according to Laurent's analysis, 60.0 per cent. C, 4.3 H, 6.6 K, and 9.0 water of crystallisation; these numbers agree better with Laurent's formula above given, which requires 60.54 per cent. C, 4.27 H, and 6.18 K, than with that which corresponds to Gerhardt's formula of hydrindin, viz. $C^{22}H^{22}KN^4O^4.3H^2O$ which requires 62.11 C, 4.37 H and 6.34 K. The salt is decomposed by washing with water, leaving nothing but hydrindin.

Nitrindin. $C^{16}H^{16}N^3O^4 = C^{16}H^{16}(NO^2)^2N^3O^2$. (Laurent, Ann. Ch. Phys. [3] iii. 478.)—Produced by boiling indin or hydrindin with nitric acid. Isatyde and sulphisatyde probably also yield nitrindin when boiled with nitric acid.

It is a bright violet powder, insoluble in water, very slightly soluble in alcohol and ether.

It decomposes rather quickly when heated in closed vessels, and leaves a residue of bulky charcoal, which glows even out of contact with the air. It gradually decomposes by boiling nitric acid. It dissolves in potash, forming a deep brown solution,

from which hydrochloric acid throws down sometimes undecomposed indin, and sometimes yellow flakes, especially if the solution has been boiled. With *sulphite of ammonium* it behaves like indin. Ammonia does not act upon it.

INDINSULPHURIC ACID. $C^1H^{11}N^2S^2O^8 = (C^1H^{11}N^2O^2SO^2).SH^2O^4$. (G. and A. Schlieper, Ann. Ch. Pharm. cxx. 24.)—An acid produced by the oxidation of hydrindinsulphuric acid (see below). The transformation may be effected by heating hydrindinsulphuric acid with a few drops of nitric acid, or by treating it with an alkaline solution of ferricyanide of potassium or hypochlorite of sodium. The hydrindinsulphates are also converted into indinsulphates by exposure to the air, especially in alkaline solution, or by heating them with nitric or nitromuriatic acid. The mother-liquor obtained in the preparation of hydrindinsulphate of barium, treated with hot nitric acid, yields large quantities of the indinsulphate. The free acid may be obtained in the crystalline form by decomposing the barium-salt with sulphuric acid, and evaporating the filtrate. It has a red colour, is easily soluble in water, sparingly in alcohol, and is precipitated from the alcoholic solution by ether, in red flocks. The aqueous solution dyes silk and wool scarlet. Its colour is altered by alkalis, probably in consequence of a change analogous to the conversion of isatin into isatic acid. By *sulphydric acid* it is reduced to hydrindin-sulphuric acid:

Indinsulphuric acid is dibasic, and appears to form soluble salts with most bases. The salts when heated yield a crystalline sublimate of a fine red colour.

The *barium-salt*, $C^1H^{10}Ba^1N^2S^2O^8.2H^2O$, is obtained, by drenching the hydrindinsulphate with dilute ammonia, exposing it to the air, and stirring frequently, as a finely crystalline powder of a fiery carmine-red colour; or, by heating the mother-liquor of the hydrindinsulphate with nitric acid, as a light powder consisting of slender dark-red, brown needles. It is moderately soluble in pure water, insoluble in aqueous chloride of barium, alcohol, and cold hydrochloric acid and nitric acids. At 100° it gives off 6.45 per cent. water (calc. 2 at. = 5.89), and the dried salt yields by analysis 33.64 per cent. carbon, 2.02 hydrogen, and 26.27 to 26.74 baryta, the formula requiring 33.39 C, 1.74 H, and 26.60 BaO.

The *potassium-salt*, $C^1H^{10}K^1N^2S^2O^8.5H^2O$, is obtained, by oxidising the solution of the hydrindinsulphate, by exposure to the air, or by means of ferricyanide of potassium, as a bulky carmine-coloured precipitate, perfectly insoluble in liquids containing potash. A hot solution of indinsulphuric acid mixed with excess of a potassium-salt, the chloride for example, deposits the indinsulphate on cooling in interlaced needles of a dark-red colour and almost metallic lustre, and so bulky that they nearly fill the liquid. The air-dried salt heated to 100° gave off, on the average, 14.24 and 14.34 per cent. water (calc. 5 at. = 14.85), and the remaining anhydrous salt gave by analysis 18.09 and 18.21 per cent. K^2O , the formula requiring 18.21 per cent.

The *silver-salt*, $C^1H^{10}Ag^1N^2S^2O^8$, is obtained by mixing a solution of the acid with excess of nitrate of silver, in small brown bulky needles yielding (at 100°) by analysis 29.39 per cent. C, 1.68 H, and 32.76 Ag; calc. 29.36 C, 1.53 H, and 33.02 Ag.

Hydrindinsulphuric acid. $C^1H^{11}N^2S^2O^8 = (C^1H^{11}N^2O^2SO^2).SH^2O^4$. (G. and A. Schlieper, Ann. Ch. Pharm. cxx. 20.)—This acid, which may be derived from indinsulphuric acid by the substitution of 2 at. H for 1 at. O, is produced by the action of sulphydric acid or sulphide of ammonium on indinsulphuric, or isatinsulphuric acid; also of zinc and hydrochloric or sulphuric acid on the latter, but not by the action of hydriodic acid.

Preparation.—A moderately concentrated solution of isatinsulphuric acid (1 pt. of the acid to 5 or 6 pts. water) is slightly supersaturated with ammonia, then mixed with half its bulk of sulphide of ammonium, and heated to boiling, the liquid then becoming brown from dissolved sulphur, and smelling strongly of ammonia. More sulphide of ammonium is then gradually added to the boiling liquid, till it smells permanently of sulphydric acid; and the boiling is continued (in a flask, to prevent oxidation) as long as a trace of ammonia escapes. The neutral pale-red solution filtered from the separated sulphur consists almost wholly of hydrindinsulphate of ammonium, which may be converted into the barium-salt by precipitation with chloride of barium, and from this the acid is obtained by decomposition with sulphuric acid.

Hydrindinsulphuric acid is obtained, by evaporation of its aqueous solution, as a colourless radio-crystalline mass, which becomes reddish when exposed to the air. It has a very sour taste, dissolves easily in water, less easily in alcohol, and is insoluble in ether.

The acid is dibasic; its salts are almost all soluble, and are easily converted into indinsulphates by oxidation, especially in alkaline solutions.

* In the original manuscript, the two acids are said to be related to one another in the same manner as indigo-white and indigo-blue; but this statement is inconsistent with the formulae.

The *barium-salt*, $C^{16}H^{16}Ba^2N^2S^2O^{10} \cdot 4H^2O$ (air-dried), is a light crystalline powder consisting of white shining scales. At 100° it gives off 11.68 per cent. water (calc. 11.37 per cent.), and the anhydrous salt yields by analysis 26.96 and 26.87 per cent. Ba^2O , the formula requiring 27.27 per cent.

Leucindin-sulphuric acid. $C^{16}H^{16}N^2S^2O^{10}$. (G. and A. Schlieper, Ann. Ch. Pharm. cxx. 33.)—This acid, which differs from the last by the elements of one molecule of water, is also produced by the action of sulphide of ammonium on isatinsulphuric acid. If in the process above described, the liquid, after filtration from the sulphur, be immediately mixed with excess of caustic baryta, instead of being evaporated, the whole of the ammonia then expelled by boiling, the excess of baryta removed by carbonic acid, and the clear yellowish solution strongly concentrated by evaporation, it deposits, after standing for a few days, white crystalline crusts of leucindin-sulphate of barium, which when recrystallised, forms hard, colourless, shining crystals containing $C^{16}H^{16}Ba^2S^2O^{10}$, with probably .5 at. water. They gave off 11.66 per cent. water at 100° , and 14.3 per cent. at 120° (mean 12.97); by calculation .5 at. = 13.1. The anhydrous salt gave by analysis (mean) 28.10 per cent. C, 3.85 H, and 22.14 Ba^2O ; calculation 27.94 C, 3.78 H, and 22.27 Ba^2O .

By decomposing the barium-salt with sulphuric acid, and evaporating the filtrate, leucindin-sulphuric acid is obtained as a white crystalline mass, having a very sour taste, easily soluble in water, sparingly in alcohol. Its alkaline solutions are not reddened either by exposure to the air, or by treatment with oxidising agents. The solution of the barium-salt is not precipitated by nitrate of silver; but on adding ammonia, a white flocculent precipitate is formed, which turns brown when warmed; acetate of lead forms a red precipitate. The barium-salt evaporated down with hydrochloric or sulphuric acid, is converted into indinsulphate of barium; it is not altered by heating with potash.

INDIRETIN. $C^{16}H^{16}NO^2$. (Schunck, Phil. Mag. [4] xv. 29, 117.)—A compound, produced, together with indihumin, indirubin, and other products, by the action of dilute sulphuric acid upon indican (p. 248). It is a dark-brown shining resin, which at 100° – 190° , contains on the average 66.04 per cent. C, 5.57 H, 3.83 N, and 24.56 O (calc. 66.05 C, 5.19 H, 4.28 N, and 24.48 O).—When heated on platinum foil, it melts, burns with a yellow, smoky flame, and leaves charcoal. By dry distillation it gives off strong-smelling vapours, and yields an oily distillate. It dissolves in oil of vitriol with brown colour, and chars when heated. With boiling nitric acid, it forms resin, and picric acid.—It dissolves easily in aqueous alkalis, and with brown colour in ammonia, being precipitated therefrom by barium, calcium, and silver-salts. It is precipitated from the alcoholic solution by neutral acetate of lead, and partially by cuprio acetate.

INDIRUBIN. $C^{16}H^{16}NO$. (Schunck, loc. cit.)—A compound, isomeric with indigo-blue (p. 249), and perhaps identical with indigo-red (p. 257), obtained in small quantity by decomposition of indican, more abundantly from Indian wood-leaves, by immersing them in a boiling alkaline solution of stannous chloride, the liquid then depositing indirubin on exposure to the air. The product thus obtained is purified by dissolving it in alkaline stannous chloride, and treating it, after reprecipitation, with caustic soda, acids, and water, and then recrystallised from alcohol. It forms long, purple, metallic-shining needles, which appear red by transmitted light, and when heated volatilise in red vapours and sublime. In the impure state, it is a brown-red amorphous powder. Contains 72.78 per cent. C, 10.50 N, 4.16 H, and 12.56 O, agreeing with the formula above given. It dissolves with purple colour in strong sulphuric acid, and is partially precipitated therefrom by water. Cold nitric acid dissolves it with purple colour, but on applying heat, decomposition takes place, attended with formation of resin and picric acid. It is slightly altered by a mixture of chromate of potassium and dilute sulphuric acid, even at the boiling heat. With chlorine under water, it forms a blue amorphous resin soluble in alcohol. Heated with soda-lime, it gives off an odour of benzoin, together with alkaline vapours, which readily condense to needles. It is insoluble in aqueous alkalis, but dissolves easily on addition of stannous chloride or grape-sugar. From the yellow solution, acids throw down dirty yellow flocks, which acquire a purple colour on exposure to the air, and impart a fast purple dye to cotton-wool immersed in the liquid and afterwards exposed to the air. It is not precipitated from the alcoholic solution by ammoniacal sugar-of-lead. Its sulphuric acid solution imparts a fine colour to wool, cotton, and silk.

INDIUM. A metal recently discovered by F. Reich and Th. Richter (J. pr. Chem. lxxix. 441) in the zinc-blende of Freiberg. Its spectrum is characterised by two indigo-coloured lines, one very bright and more refrangible than the blue line of strontian, the other fainter, but still more refrangible than the blue line of potas-

mium. It was the production of this peculiar spectrum that led to the discovery of the metal. The ore, consisting chiefly of blende, galena, and arsenical pyrites, was roasted to expel sulphur and arsenic, then treated with hydrochloric acid, and the solution was evaporated to dryness. The impure chloride of zinc thus obtained, exhibited, when examined by the spectroscopic, the first of the indigo lines above mentioned. The chloride was afterwards obtained in a state of greater purity, and from this the hydrate and the metal itself were prepared. The first line then came out with much greater brilliancy, and the second was likewise observed.

Indium has hitherto been obtained in very small quantity only, so that its properties have been but imperfectly studied. The metal itself is of a lead-grey colour, soft, very malleable, and marks paper like lead. It dissolves easily in hydrochloric acid, forming a deliquescent chloride. From the solution of this salt, it is precipitated by ammonia and potash as a hydrate, insoluble in excess of either reagent. Sulphydric acid does not precipitate it from acid solution. The oxide heated on charcoal with soda, yields a metallic globule, which when reheated oxidises to a yellowish powder. The compounds of indium impart a violet tint to the flame of a Bunsen's burner. (*Ann. Supplement*, pp. 729, 1137.)

INDUCTION, ELECTRICAL. See ELECTRICITY (ii. 384, 451).

INDUCTION, MAGNETIC. See MAGNETISM.

INDUCTION, PHOTOCHEMICAL. See LIGHT, CHEMICAL ACTION OF.

INDYLE. Syn. with INDIGO-BLUE. (*Gerh.* iii. 509.)

INFUSORIA. The following experiments on the influence of infusoria in exciting fermentation, have been made by Pasteur (*Compt. rend.* lvi. 416; *Rép. Chim.* p. 1863, p. 221). A quantity of tartrate of calcium mixed with a few thousandths of phosphate of ammonium and alkaline and earthy phosphates (either artificially prepared, or from the ashes of beer or of infusoria), was placed in a flat-bottomed bottle, the narrow neck of which was cemented to a bent glass tube; the bottle was then filled up with pure water, and the water heated to the boiling point, while the end of the bent tube was plunged into water likewise heated to boiling; by this means all the air in the solution was driven out. The surface of the water in the vessel into which the bent tube dropped was then covered with a thick layer of oil, and the apparatus was left to itself for twenty-four hours. Not the slightest trace of fermentation could then be perceived; but on quickly introducing into the bottle a small quantity of infusoria produced by spontaneous fermentation of tartrate of calcium, and immediately replacing the small quantity of water thereby dislodged, with water deaerated by boiling, and plunging the end of the tube below the surface of mercury so as completely to exclude the air, the infusoria multiplied rapidly in the deposit of tartrate, which soon disappeared completely, being replaced by a deposit consisting of the carcasses of infusoria.

Hence it appears that the fermentation of the tartrate is determined by the presence of an animalcule living without free oxygen. If the bottle is filled up with aerated water, the tartrate ferments spontaneously, and the infusoria multiply quickly, removing the oxygen present down to the last trace, and replacing it by a slightly larger volume of carbonic anhydride. The ferment finds the nitrogen and phosphates required for its development in the albuminous matter present or the ammoniacal salts and phosphates introduced. The carbon is supplied by the tartaric acid. (*See FERMENTATION.*)

On the influence of infusoria on the germination of plants, see Lemaire, *Compt. rend.* 1863, Sept. 21; *Rép. Chim.* app. 1863, p. 371.

From experiments by Morrin (*Compt. rend.* xxxviii. 932; *Jahresber.* 1855, p. 648), it appears that the development of infusoria and algæ goes on only when they can obtain a supply of nitrogen already in the state of chemical combination, as evolved by decomposing animal matters, or in the form of ammoniacal salts. They grow in water which is in contact with atmospheric air continually renewed, but do not if the air has been deprived of ammonia and organic matters by washing with oil of vitriol.

According to Salm-Horstmar (*Jahresber.* 1854, p. 145; 1855, p. 134), the green colouring matter of infusoria is optically identical with chlorophyll.

INFUSORIAL EARTH. The infusorial earth situated on the southern edge of the Lüneburg heath, near Ebedorf, has been analysed by W. Wicke (*Ann. Ch. Pharm.* xiv. 292). It consists of two layers, the upper, which is from 10 to 18 feet thick, being light-coloured, and nearly white when dry, and the lower, which is 10 feet thick, or more, of a brownish-grey colour.

	Water	Organic Matter	SiO ₂	CaCO ₃	FeO ^s	AlO ^s	Loss
Upper	100	17.66	0.75	0.75	0.18	0.18	100.18
Lower	100	17.45	0.34	0.24	0.18	0.18	100.44

INK. Every liquor or pigment used for writing or printing is distinguished by the name of ink. Inks are of various colours, but the black and red are most in use, both for writing and printing. We shall first speak of *writing inks*, which consist either of a coloured and not too thin liquid, or a finely divided coloured precipitate suspended in liquid.

1. **Black ink.**—Common black ink for writing is made by adding an infusion or decoction of nut-galls to a solution of copperas (ferrous sulphate). The infusion or decoction of the galls contains both gallotannic and gallic acids, both of which produce deep-black precipitates with ferric salts, but with ferrous salts, white precipitates which turn black by oxidation on exposure to the air. Moreover, gallic acid colours ferric salts of a much deeper black than gallotannic acid; hence it is advantageous to leave the infusion to itself for some time, either before or after mixture with the iron-salts, in order that the tannic acid contained in it may be converted into gallic acid (ii. 767, 768).

To retain the precipitate in suspension, and prevent it from forming a sediment, a certain quantity of gum is always added: the gum likewise gives a certain gloss to the ink. These are the essential ingredients of good writing ink, and any other colouring matters added, for the sake of cheapness, as substitutes for a portion of the galls, only impair its quality. Logwood is sometimes used, for the sake both of the tinge and the colouring matter which it contains.

To prevent ink from becoming mouldy, various substances are added to it, such as essential oils, finely bruised cloves, a few drops of phenic acid, and sometimes (but not advantageously) corrosive sublimate. The addition of an acid retards the conversion of the ferrous into ferric salt; the ink then remains thinner and pale while kept in the bottle, and becomes darker only as the writing dries.

The following are some of the numerous recipes for the preparation of black ink, calculated for 1,000 pts. of water:—

	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	<i>e</i>	<i>f</i>	<i>g</i>
Galls . . .	226	167	133	125	66	62	31
Copperas . .	75	73	55	24	22	31	19
Gum-arabic .	25	73	55	24	19	31	8
	<i>h</i>	<i>i</i>	<i>k</i>	<i>l</i>	<i>m</i>		
Galls . . .	50	174	50	60	42		
Logwood . .	—	—	100	20	21		
Copperas . .	32	87	16	20	21		
Sulphate of copper .	—	—	—	—	5		
Gum . . .	9	43	47	20	16		
Sugar . . .	—	—	23	1000	—		
Vinegar . . .	125	135	—	—	—		

Of the genuine inks (*a*—*g*), *a*, *b*, and *c* are too strong for ordinary use; *d*, *e* and *f* are perhaps the best; *g* would be somewhat too pale. The rest cannot be recommended, excepting for special purposes. Sulphate of copper deepens the colour of the precipitate, but renders it more compact and heavy, and therefore more apt to settle down. A certain quantity of sugar renders the ink more fluid, and permits the addition of a larger proportion of gum. It likewise renders the ink adhesive when dry, so that a copy of the writing may easily be taken off by laying a sheet of thin unsized paper, damped with a sponge, on the written paper, and passing lightly over it a flat iron very moderately heated: ink of this quality is called *copying ink*.

The so-called alizarin-inks (a mere commercial name, by no means implying that they contain the alizarin of madder) consist of common ink mixed with a little free sulphuric acid, which, like other acids, retards the oxidation of the ferrous precipitate (see IRON, OXIDES OF), so that the writing becomes black only after exposure to the air; the change being, perhaps, accelerated by the neutralisation of the sulphuric acid by the basic substances contained in the paper; the ink blackens very quickly when exposed to ammoniacal vapours. A certain quantity of sulphindigotic acid (p. 250), or its sodium-salt (indigo-carmine) is usually added, so that the ink may not *run* too pale in writing. An ink of this kind may be prepared by exhausting 40 pts. by weight of nut-galls with 112 pts. water, and then adding 7 pts. copperas and 1 pt. oxalic acid. At the same time, 1 pt. of finely pulverised indigo-blue is dissolved in 4 pts. fuming sulphuric acid; the solution after 24 hours is diluted with water and mixed with a small quantity of carbonate of soda; the precipitate is collected, washed to remove the saline solution, then suspended in water; and this liquid is added to the former till the whole exhibits a rather deep greenish-blue colour.

Chrome ink.—Runge first suggested the preparation of ink with chrome and chromate of potassium. Such ink is more easily diluted than ordinary copperas-ink, and is not liable to turn mouldy; but on the other hand, it soon becomes viscid and

gelatinous. Runge prepares it by mixing 15 pts. by weight of solid commercial extract of logwood, with 1,000 pts. water (or a decoction of 1 pt. of logwood boiled down to 8 pts. of liquid), and adds 1 pt. of yellow chromate of potassium dissolved in water. Göbel takes 24 pts. of solid logwood extract, 1,000 pts. water, and 2 pts. yellow chromate.

Vanadium ink.—Prepared by mixing a decoction of galls with vanadate of ammonia. It is black, and flows easily, because it does not contain any precipitate; it is not attacked by dilute alkalis, but acids turn it blue. (Berzelius.)

The **black-violet Rouen ink** (*encre bleue rouennaise*) is prepared by boiling 750 pts. of logwood with 6,000 pts. water, 36 pts. alum, 31 pts. gum-arabic, and 15 pts. sugar-candy, leaving the mixture to stand for two or three days, and straining through a linen cloth.

Ink in cakes.—42 pts. of good nut-galls and 3 pts. of madder are boiled in about six times their weight of water; the filtered decoction is mixed with $5\frac{1}{2}$ pts. copperas, and 2 pts. pyrolignite of iron; $1\frac{1}{2}$ pts. solution of indigo (in sulphuric acid, diluted with water) is then added; the mixture is evaporated nearly to dryness at a gentle heat, and with constant stirring; and the pasty mass is then made into cakes, and thoroughly dried. This ink dissolved in 6 pts. of hot water is said to make an excellent copying ink, and in 10 or 12 pts. water, a very fine writing ink.

Ink-powder.—A solid chrome-ink may be made by triturating together to a fine powder, 100 extract of logwood, 1 pt. neutral chromate of potassium, and $\frac{1}{2}$ pt. indigo-carmin. 1 pt. of this powder added to 32 pts. water is said to make very good ink. A mixture of 4 pts. pounded galls, 2 pts. copperas, and 1 pt. gum-arabic is also frequently sold as an ink-powder.

Copying inks.—Inks for this purpose must be rather thick, not dry too quickly, and soften when moistened again, without becoming too fluid. The following preparation is much recommended: 4 pts. by weight of logwood-extract are dissolved in a mixture of 60 pts. vinegar, and 70 pts. water, and 3 pts. copperas, 2 pts. alum, 2 pts. gum-arabic, and 4 pts. sugar are then added. This ink is at first more violet than the Rouen ink, which is also used as a copying ink.

Indelible inks.—As writing executed with ordinary ink is liable to fade in course of time, the tannate and gallate of iron being gradually decomposed, and as, moreover, it is usually effaced by the action of certain chemical reagents (oxalic acid, hydrochloric acid, chlorine), it is desirable that valuable documents should be written with an ink not liable to destruction from such agencies. Various compositions have been proposed for this purpose. Most of them consist of common ink, or some other dark-coloured liquid in which finely divided carbon (Indian ink or lamp-black) is suspended. The simplest of all is made by mixing common ink with Indian ink (p. 246) rubbed up with weak hydrochloric acid. Writing executed with such ink cannot be bleached by chlorine or destroyed by acids; but the carbon may be ultimately removed by water, even when it is as finely divided as in Indian ink, and consequently penetrates the pores of the paper to a certain extent. Ink prepared in like manner with lamp-black is easily washed away. Traill's indelible ink is prepared by steeping wheat-gluten in water for 24 to 36 hours, then dissolving it with aid of heat, in strong vinegar, of specific gravity 1.033, or in pyroligneous acid, and then rubbing it up with Indian ink or lamp-black. This ink is of a fine black colour, and cannot be obliterated by water, chlorine, or dilute acids. Kind dissolves 1 pt. honey in 14 pts. water, adds 2 pts. strong sulphuric acid, and then adds a quantity of indigo-solution sufficient to render the ink visible in writing. A hot iron is then passed over the writing, whereby not only the honey is carbonised, but likewise a portion of the paper-fibre, by the action of the free sulphuric acid. The writing cannot be effaced by any chemical reagent, and only with great difficulty by mechanical means, since the ink penetrates deeply into the paper, and the charcoal is consequently separated within the pores; the paper is, however, very much attacked.

The vanadium-ink, above described, may also be used as an indelible ink; acids merely turn it blue; chlorine destroys the black colour, but does not efface the writing, even after long washing.

Red Ink.—Red ink is usually prepared either with cochineal or with Brazil-wood. The *cochineal inks* are the brightest, but at the same time the dearest and most fugitive. The best is a solution of pure carmine in caustic ammonia; it must be preserved in well-stopped vessels. Böttger recommends 1 pt. of good carmine, 120 caustic ammonia, and $1\frac{1}{2}$ pt. gum-arabic. A cheaper but less brightly coloured ink is made by drenching 12 pts. of pulverised cochineal and 4 pts. of carbonate of ammonia (or pearl-ash) with 52 pts. hot water, then digesting and pouring off the clear liquid. Addition of a small quantity of tartar and stannic chloride renders the ink more azurlet; cream of tartar and a small weight of alum give it a crimson tint.

Brazil-wood inks are made by boiling the wood in water, adding tin-salt (stannous chloride) or cream of tartar and alum to modify the tint, and thickening with gum-

arabic, 4 pts. Brazil-wood boiled in 60 pts. water, the decoction boiled down to 36 pts., filtered, and mixed with $\frac{1}{2}$ pt. of tin-salt and $\frac{1}{2}$ pt. gum-arabic; or 8 pts. Brazil-wood, boiled with 2 pts. alum and 2 pts. cream of tartar in 120 pts. water; the liquid concentrated to 6 pts. by weight, and mixed with 2 pts. gum-arabic and 2 pts. sugar.

Blue inks.—The best is made by dissolving 30 pts. pure Prussian blue (Paris blue, ii. 227) in a solution of 4 pts. oxalic acid in 1,000 pts. water. A blue ink may also be prepared by dissolving 4 pts. of indigo-carmin in 64 pts. water, and mixing it with 1 pt. gum arabic; but it cannot be used with steel pens.

Yellow and green inks are sometimes, though very rarely, used. The former may be made with decoction of saffron or yellow berries; the latter of solution of verdigris mixed with turmeric or gamboge; or better of indigo-carmin mixed with picric acid. It may also be prepared from the green modification of chrome-alum, namely, by dissolving 3 pts. acid chromate of potassium in 8 pts. water, adding 1 pt. alcohol, then sulphuric acid by drops, and heating till the liquid assumes a brownish green colour; then diluting with 16 pts. water, adding a few more drops of sulphuric acid, leaving the liquid to stand, and adding a small quantity of gum-arabic.

Sympathetic inks.—This name is applied to inks which make characters invisible till brought out by heat or the application of some reagent. If a weak infusion of galls be used, the writing will be invisible till the paper is moistened with a weak solution of sulphate of iron. Dilute solutions of gold and silver remain colourless upon the paper till exposed to the sun's light, which gives a dark colour to the oxides, and renders them visible. Most acids, or saline solutions, diluted, and used to write with, become visible by heating before the fire, which concentrates them, and assists their action on the paper. Dilute prussiate of potash affords blue letters when wetted with solution of sulphate of iron. The solution of cobalt in aqua-regia, when diluted, affords an ink which becomes green when held to the fire, but disappears again when suffered to cool. This ink has been used in fanciful drawings of trees, the green leaves of which appear when warm, and vanish again on cooling. If the heat be continued too long after the letters appear, it renders them permanent. If oxide of cobalt be dissolved in acetic acid, and a little nitre added, the solution will exhibit a pale rose colour when heated, which disappears on cooling. A solution of equal parts of sulphate of copper and sal-ammoniac gives a yellow colour when heated, that disappears when cold.

Sympathetic inks have been proposed as the instruments of secret correspondence, but they are of little use in this respect, because their properties change by remaining on the paper for a few days; most of them have more or less of a tinge when thoroughly dry, and none of them resist the test of heating the paper till it begins to be scorched.

Marking inks.—Inks for marking linen must be able to withstand the action of water, soap, alkaline leys and acid liquids. The best are those which contain silver. They consist of a solution of nitrate of silver, usually coloured with sap-green, or other colouring matter, sometimes with lamp-black, and thickened with gum. It is best to prepare the part of the linen to be marked with a solution of carbonate of soda and gum, then smooth it with a hot iron, and after writing upon it, expose it to sunshine. The writing may be effaced by a solution of cyanide of potassium, with or without iodine.

Roder (Polyt. Notizblatt, 1856, p. 112) prepares a marking ink by dissolving 6 pts. molybdic oxide in hydrochloric acid, adding 240 pts. water, 6 pts. gum-arabic, and 2 pts. liquorice-juice. The writing is to be dried and then moistened with solution of stannous chloride. Inks containing gold or platinum have also been recommended for this purpose, but they are too costly for general use.

An ink for writing on zinc plant-labels may be made by dissolving equal parts acetate of copper and sal-ammoniac in distilled water. When characters are written with this solution on a zinc plate, the copper is precipitated, forming deep black, very durable marks.

Ink for marking copper and silver vessels may be made by boiling sulphide of antimony in strong potash-ley, leaving the liquid to cool, and filtering from separated kermes. As this liquid does not act upon iron, steel pens may be used for writing with it on the metal. The characters on copper and silver are black and very durable; on tin, lead, and zinc, less durable.

Printing ink.—All inks or paints used for letter-press, copper-plate, lithographic printing, &c. consist essentially of well-boiled drying oils (varnishes) mixed with lamp-black, or other pigment, according to the colour intended to be produced. Soap and resinous matters are sometimes added to give the boiled oil the required consistence.

The oil most frequently used for the preparation of the varnish is linseed oil; nut-oil is also used in localities where it can be had cheap; but it loses more weight in

boiling than linseed oil, and does not easily acquire a firm consistency. The oil should be old and well cleared, by deposition, from particles of mucus.

Ten or twelve gallons of the oil are set over the fire in an iron pot, capable of holding at least half as much more; for the oil swells up greatly, and its boiling over into the fire would be very dangerous. When it boils, it is continually stirred with an iron ladle; and if it do not itself take fire, it is kindled with a piece of flaming paper or wood: for simple boiling, without the actual inflammation of the oil, does not communicate a sufficient degree of the drying quality required. The oil is suffered to burn for half an hour or more, and the flame being then extinguished by covering the vessel close, the boiling is afterwards continued with a gentle heat, till the oil appears of a proper consistence; in this state it is called varnish.* It is necessary to have two kinds of this varnish, a thicker and a thinner, from the greater or less boiling, to be occasionally mixed together as different purposes may require, that which answers well in hot weather being too thick in cold, and large characters not requiring so stiff an ink as small ones.

The thickest varnish, when cold, may be drawn into threads like weak glue, by which criterion the workmen judge of the due boiling, small quantities being from time to time taken out and dropped upon a tile for this purpose. It is very viscid and tenacious, like the soft resinous juices, or thick turpentine. Neither water nor alcohol dissolves it; but it mingles readily enough with fresh oil, and unites with mucilages into a mass diffusible in water in an emulsive form. The oil loses from one-tenth to one-eighth of its weight by boiling into the thick varnish.

For letter-press printing ink, the addition of soap to the varnish is indispensable, to enable the ink to be taken up clearly from the types by the moistened paper, without smearing. The soap used for the purpose is yellow resin-soap; it is cut into thin slices, well dried, rubbed to coarse powder, and incorporated by small portions at a time with the varnish, which is then once more placed over the fire, to expel any remaining moisture.

The colouring matter of black printing ink is the best lamp-black, previously calcined to free it from empyreumatic oils and resins. Its somewhat brownish colour is corrected by the addition of a little Prussian blue or indigo.

The ink used by copper-plate printers differs in the oil, which is not so much boiled as to acquire the adhesive quality. This would render it less disposed to enter the cavities of the engraving, and more difficult either to be spread or wiped off (Ure).† The black is likewise of a different kind. Instead of lamp-black, or sublimed charcoal, the Frankfort black is used, which is a residual or denser charcoal, said to be made from vine-twigs. Lamp-black is said to give a degree of toughness to the ink, which the Frankfort does not; but the goodness of the colour seems to be the leading inducement for the use of the latter.

For red, blue, and yellow printing inks, the ordinary linseed oil varnish is not very well adapted, as its brown colour impairs the brightness of the tint. A good varnish for the purpose may be made by mixing copaiba balsam (previously subjected to rapid boiling with water for several hours in an open dish, to render it more tenacious, and diminish the unpleasant odour) with $\frac{1}{20}$ to $\frac{1}{10}$ of its weight of pulverised white curd soap, then warm the mixture a little, and incorporate it with the pigment previously rubbed to fine powder with spirit of wine, and dried. For the lighter colours, it is best to mix very deep-coloured pigments with a considerable quantity of carbonate of magnesia. In that case, light-coloured linseed-oil varnish mixed with $\frac{1}{2}$ white soap may be used. A fine red is formed of vermilion mixed with $\frac{1}{6}$ carmine, and $\frac{1}{2}$ magnesia. Blue is given by ultramarine (the darkest varieties used in calico-printing) with magnesia; yellow by chromate of lead. Prussian blue mixed with chrome-yellow and a large quantity of magnesia, or ultramarine with chromate of zinc, yields a fine green. Browns are obtained with bistre and sepia.

Lithographic printing ink is made in the same way as common printing ink, but with a larger proportion of lamp-black, and without addition of soap. (See LITHOGRAPHY.)

For further details on printing inks, see *Handwörterbuch der Chemie*, vii. 388, and *Ure's Dictionary of Arts*, &c. iii. 530.

* The description of the process given in the text is taken from *Ure's Dictionary of Chemistry* (3rd ed. 1831). Mr. Sava also, in his work on the *Preparation of Printing Ink* (London, 1822) says that good varnish for printing ink cannot be made without allowing the oil to burn. The German practice appears, however, to be somewhat different; for in the *Handwörterbuch der Chemie* (Ed. vii. p. 281) it is stated that the oil should be heated only till the vapour which rises from it can be set on fire with a piece of burning paper, but will cease to burn of itself after a little while, or at least will be easily extinguished by putting on the cover; further, that if this temperature be exceeded, there is great danger of the oil getting into a state of violent combustion, which cannot be extinguished even by covering the vessel, and may occasion an enormous loss of oil.

† In the *Handwörterbuch der Chemie* (vii. 389) it is stated, on the contrary, that ink for copper-plate printing is prepared with the thickest linseed-oil varnish, which has been allowed to burn.

INOCARPIN. A red colouring matter contained in the juice of *Inocarpus edulis*, a tree growing in Tahiti. The juice which exudes from incisions in the bark of young trees, or the pericarp of green fruits, is colourless, but soon turns red on exposure to the air (the juice of old trees is red as soon as it runs out), and dries up to a red gummy mass, soluble in water and in alcohol, insoluble in ether. The aqueous solution mixed with caustic alkalis exhibits a peculiar play of colours when shaken up with air. The reddened juice contains also a yellow colouring matter called xanthocarpin. (Cuzent, J. Pharm. xxxv. 241.)

INOSIC ACID. $C^3H^3N^3O^6$ (?) (Liebig, Ann. Ch. Pharm. [3] xxxiii. 129.)—An acid found in the mother-liquor of the preparation of creatine from flesh-juice. When this mother-liquor is concentrated, then mixed with alcohol till it acquires a milky consistence, and left to itself for a few days, it deposits a crystalline mixture consisting of creatine, inosate of potassium, inosate of barium, and various substances of unknown composition. The crystals are redissolved in hot water, and chloride of barium is passed into the solution, which then, on cooling, deposits crystals of inosate of barium; and this salt, decomposed by sulphuric acid, yields inosic acid.

Inosic acid is uncrystallisable, easily soluble in water, and has a very agreeable flavour of broth. Alcohol precipitates it from its aqueous solution. It is insoluble in ether. It does not precipitate barium- or calcium-salts, but with copper-salts it forms a bluish-green precipitate, insoluble in boiling water. With lead-salts it forms a white precipitate; and with silver-salts, a white gelatinous precipitate, having the aspect of alumina, soluble in nitric acid and in ammonia.

Inosic acid, heated with peroxide of lead and a small quantity of sulphuric acid, is decomposed, and the filtered liquid contains needle-shaped crystals. The *inosates*, heated on platinum-foil, decompose, giving off an odour of roast meat.

Inosate of potassium forms elongated quadrilateral prisms, very soluble in water, insoluble in alcohol. It gives off 22.02 per cent. of water at 100° , and the dried salt contains 20.7 per cent. potash. The *sodium-salt* crystallises in small silky needles, very soluble in water; insoluble in alcohol. The *barium-salt* forms elongated quadrilateral scales, having a nacreous lustre. 3,000 pts. of water at 16° dissolve 2.5 pts. of this salt; it is insoluble in alcohol. A solution, saturated at 70° , deposits part of the salt when raised to the boiling heat. The crystals, dried at 100° , contain 24.5 to 24.8 per cent. C, 2.6 H, 11.4 N, 31.1 to 33.8 O, and 30.4 BaO; whence Liebig deduces the formula $C^3H^3Ba^2N^3O^6 \cdot \frac{1}{2}H^2O$. Gerhardt considers the composition to be more correctly represented by the formula $C^3H^3Ba^2N^3O^6 \cdot 3H^2O$. The crystals effloresce in the air, giving off 19.07 per cent. water.

Inosate of copper is nearly insoluble in water and in acetic acid; very soluble in ammonia. *Inosate of silver* is sparingly soluble in pure water, and does not blacken by exposure to light.

INOSITE. $C^3H^3O^6$. *Inosin*. *Phascomannite*. (Scherer [1850], Ann. Ch. Pharm. lxxiii. 322; lxxxi. 375.—Vohl, *ibid.* xcix. 125; ci. 50.—Cloetta, *ibid.* xcix. 289.—W. Marmé, *ibid.* cxxix. 222.)—A saccharine substance isomeric with glucose, discovered by Scherer in the muscular substance of the heart (hence its name, from *is*, *ivós*, muscle), and since found to exist in the lungs, kidneys, liver and spleen of oxen (Cloetta), also in the brain (W. Müller); in the human kidneys and in the urine, in a case of Bright's disease: at most to the amount of 0.1 per cent. It occurs also in several plants, having been obtained from green kidney beans, the unripe fruit of *Phaseolus vulgaris* (Vohl); from the green pods and unripe seeds of the garden pea (*Pisum sativum*); the unripe fruit of the lentil (*Ervum lens*), and of the common acacia (*Robinia psuudacacia*); from the heads of the common cabbage (*Brassica oleracea*, var. *capitata*); from the herb of foxglove and from extract of digitalis (from the leaves and stems of dandelion (*Taraxacum dens-leonis*), not from the flowers or roots; from the shoots of the potato; from the green herb and unripe berries of asparagus; and from two cryptogamous plants, viz. *Lactarius piperatus*, L., and *Clavaria crocea*, Pers. (Marmé.)

Preparation.—From organs of the animal body. 1. The muscle of the heart, or other organs containing inosite, is exhausted with water, as for the preparation of creatine; the phosphates are precipitated from the liquid by baryta-water; the filtrate is evaporated; and the creatine allowed to crystallise out. The mother-liquor is treated with dilute sulphuric acid to remove the dissolved baryta, and, after removal of the sulphate of barium, heated as long as volatile acids escape. It is then, in order to remove the last traces of volatile acids and of lactic acid, repeatedly shaken up with ether as long as anything is dissolved. The liquid, separated from the ether, is mixed with alcohol till a turbidity begins to appear; then, after standing for some time, it is poured off from the precipitated sulphate of potassium, and mixed with more alcohol, whereby crystals of inosite mixed with sulphate of potassium are obtained. The crystals of the former are picked out and dissolved in a small quantity of warm water, which leaves the more difficultly soluble sulphate of potassium, and are purified by

recrystallisation (Scherer).—2. The fresh-chopped tissue is covered with water, and allowed to stand for 24 hours in a cool place, with frequent stirring; the liquid is then separated, and the residue pressed; the solution is heated with a little acetic acid to separate albumin and hæmatin, then strained, evaporated on the water-bath to one tenth, precipitated with neutral acetate of lead, and filtered; and the filtrate is mixed with basic acetate of lead, whereupon inosite is thrown down in combination with oxide of lead, accompanied by uric acid, cystine, and other substances. The precipitate, after washing, is decomposed under water by sulphydric acid, and the liquid filtered from the sulphide of lead; it then sometimes deposits crystals of uric acid, and when evaporated to a small bulk on the water-bath, and mixed with alcohol till a turbidity is produced, it yields crystals of inosite (Cloetta). Acetate of lead may also be added at once to the water used for making the extract (W. Müller).—3. The liquid from which the inosite is to be separated is concentrated by evaporation, and mixed, boiling, with three or four measures of alcohol; if a large precipitate, which sticks to the bottom, is thus produced, the liquid is poured off hot; but if only a slight, not sticky precipitate is produced, the hot solution is filtered through a previously heated funnel, and left to stand for 24 hours; crystals of inosite are then deposited, and are washed with a small quantity of cold alcohol. If the precipitate caused by hot alcohol is dissolved in a small quantity of boiling water, and treated like the first solution, a further quantity of inosite is obtained. In case no inosite separates from the cooled solution, the crystallisation may be facilitated by addition of ether until a turbidity remains after shaking. (Cooper Lane, *Ann. Ch. Pharm.* cxvii. 118.)

From kidney beans and other vegetable organs.—The fruit cut up in the bean-mill is hung in a pressing bag for half an hour in boiling water, or in steam, whereby it becomes possible to press it; the expressed liquid is then evaporated to a syrup on a water-bath, and alcohol is added till a permanent turbidity is produced. The crystals which form are purified by repeated crystallisation from water, with help of animal charcoal. (Vohl.)

Marné, after freeing the aqueous extracts of the plants above mentioned from everything precipitable by tannic acid and neutral acetate of lead, and decolorising them as completely as possible with milk of lime or animal charcoal, precipitated them with basic acetate of lead; mixed the filtrate with ammonia, whereby a second precipitate was obtained; decomposed both precipitates with sulphydric acid; concentrated the filtrate on the water-bath till it became turbid on addition of alcohol; then mixed it with a double volume of alcohol; warmed the liquid till it became clear; and left it to itself for several days, adding a little ether if necessary, as in Cooper Lane's method. The sulphide of lead sometimes obstinately retains small quantities of inosite, which can only be removed by boiling with water.

Properties.—Inosite is deposited from its concentrated aqueous solution in crystals containing 2 at. water, $C^6H^{12}O^9 \cdot 2H^2O$. According to Vohl, the crystals are tabular, like those of gypsum; according to Scherer, they are oblique prisms, arranged for the most part in groups like cauliflower-heads; according to Cloetta, they are right rhombic prisms with angles of 138.52° and 41.8° . Specific gravity = 1.1164 at 6° (Vohl). In dry air, in vacuo over sulphuric acid, or at 100° , they become white and opaque, and give off their water, leaving anhydrous inosite, $C^6H^{10}O^9$, as a white effloresced mass, which melts at a temperature above 210° , yielding a colourless liquid, which solidifies in the crystalline state when quickly cooled, and to an amorphous mass when cooled slowly, but does not lose weight or undergo further alteration (Scherer). Anhydrous inosite separates in white, opaque crystals from the aqueous solution cooled below 0° . (Vohl). Inosite has a pure sweet taste and no rotatory power.

Hydrated inosite dissolves in 6 pts. water at 19° (Vohl), in $6\frac{1}{2}$ pts. at 24° (Cloetta). The concentrated solution, of specific gravity 1.0548 at 19° , is not syrupy and not subject to spontaneous decomposition. Inosite is slightly soluble in cold aqueous alcohol, more soluble at the boiling heat; insoluble in absolute alcohol and in ether.

Inosite does not combine with chloride of sodium or chloride of potassium, these salts crystallising out unaltered from its aqueous solution. The aqueous solution forms, with basic acetate of lead, a precipitate which appears to contain $C^6H^{12}O^9 \cdot 2Pb^2O$.

Decompositions.—1. After dehydrated inosite has been melted above 210° , it swells up when more strongly heated, and evolves gas which burns with a pale blue flame; it is afterwards charred, and then burns with a brightly luminous flame, leaving an easily combustible cinder (Scherer). When quickly heated, it gives off vapours which excite tears and produces a smell of burnt sugar (Vohl).—2. Aqueous inosite is not affected by ozone (Gorup-Besanez, *Ann. Ch. Pharm.* cx. 103).—3. The solution of inosite in dilute nitric acid does not give off nitrous acid till moderately concentrated; after evaporation to dryness, it contains oxalic acid. The aqueous solution of the residue, freed from oxalic acid by carbonate of calcium, deposits on standing magnificent purple-red

sticks, soluble in dilute acids and precipitable without alteration by ammonia (Vohl). When aqueous inosite is evaporated nearly to dryness with nitric acid, and the residue is moistened with ammonia and a small quantity of solution of chloride of calcium, and again evaporated, a rose-red substance remains. This reaction affords a delicate and characteristic test of the presence of inosite (Scherer, Vohl). Inosite dissolves without evolution of gas, in cold or boiling nitric acid of specific gravity 1.52, forming a solution whence oil of vitriol precipitates nitro-inosite (Vohl).—4. Inosite dissolves without coloration in sulphuric acid, either cold or at 100°; is not blackened till more strongly heated, and then evolves sulphurous anhydride (Vohl). It is not altered by boiling with dilute acids (Scherer, Vohl).—5. It may be boiled with concentrated *potash-ley*, or with *baryta-water*, without alteration or coloration (Scherer, Vohl).—6. The aqueous solution mixed with *cupric sulphate*, yields, on addition of *potash-ley*, a bluish green precipitate which quickly disappears on addition of excess of *potash*. No cuprous oxide separates from the solution in boiling, but a light blue precipitate falls when the liquid is left to stand for several days (Scherer). Aqueous inosite yields, when heated with *potassio-cupric tartrate*, a green solution, whence a bulky green precipitate separates, the supernatant liquid again becoming blue. After removing the precipitate, the filtrate shows the same change of colour when heated (Cloetta). According to Vohl, the change of colour which occurs on heating the deep azure-blue mixture of inosite and *potassio-cupric tartrate*, is not very striking, and is due, as well as the production of the precipitate, to the presence of traces of foreign substances.—7. Inosite is not capable of undergoing vinous fermentation (Scherer). In contact with *cheese, flesh*, or decaying *membrane*, and chalk, it undergoes lactic fermentation, carbonic, lactic, and butyric acids being formed. (Scherer, Vohl.)

Nitro-inosite. $C^6H^4N^2O^{18} = C^6H^4(NO^2)^2O^8$. *Inosine hexnitrique*. (Vohl, loc. cit.)—This compound is obtained by dissolving anhydrous inosite in nitric acid of specific gravity 1.52, and precipitating the solution with sulphuric acid. The product, which, according to the temperature attained by the mixture, separates either as a powder or as oil-drops which solidify to crystalline masses, is well washed with water and recrystallised from boiling alcohol. It forms rhombohedrons, often some lines in length; melts to an oil when heated, and solidifies to an amorphous mass which becomes crystalline after a few days. It is permanent in air, either dry or moist; insoluble in water, easily soluble in alcohol.

Nitro-inosite deflagrates without residue when quickly heated, and detonates under the hammer. It is decomposed when warmed with concentrated acids. It dissolves, with dark brown colour and evolution of ammonia, in cold or warm *potash-ley*. The alkaline solution precipitates cuprous oxide from *potassio-cupric tartrate*, and a mirror of metallic silver from *ammonio-nitrate of silver*. Nitro-inosite treated with *nitric acid, ammonia* and *chloride of calcium*, shows the coloration of inosite.

INSOLINIC ACID. See TEREPHTHALIC ACID.

INTESTINAL CONCRETIONS. These concretions are of rare occurrence in man and in carnivorous animals, but occur more frequently in herbivorous animals, especially in horses. They exhibit great diversity in their properties and composition, as well as in their origin. Many owe their origin to an albuminous exudate or blood-coagulum, which is retained in the intestine, and gradually solidified by resorption of the soluble portion. These stones consist mainly of coagulated fibrin mixed with calcium-salts and remains of food, and sometimes containing a foreign body as nucleus. In a concretion of this kind from the intestine of a child, Davy found 74 per cent. fibrin, 19 per cent. of other organic matters, and 7 per cent. inorganic salts.

A second kind of intestinal concretion consists chiefly of earthy salts, calcic phosphate and carbonate, ammonio-magnesian carbonate, and magnesian carbonate mixed or unmixed with remains of food; such stones often contain a foreign nucleus. They are most frequent in vegetable feeders, especially in horses, and often attain a weight of several pounds. A concretion from the cæcum of a cart-horse, analysed by F. Simon, was spherical, perfectly smooth, greyish-yellow, weighed 12½ oz., and consisted of three layers, deposited round a fragment of granite. All three layers consisted of ammonio-magnesian phosphate, with a small quantity of alkaline phosphates, but no phosphate of calcium. The middle layer exhibited a radiating structure from the centre outwards, with woody fibres interposed in like manner amongst the stony mass. In 100 pts. Simon found 81.11 ammonio-magnesian phosphate, and 1.6 per cent. alkaline phosphates.

Children examined stones from the colon of a man, which weighed from 500 to 1,000 grms., and consisted of plum-stones, surrounded by a smooth compact mass made up of alternate layers of earthy phosphates and ligneous matter.

The formation of these stones is due to the precipitation of earthy salts originally

dissolved in the food, and their subsequent agglomeration by intestinal mucus, or round a foreign body.

A third kind of intestinal concretion consists chiefly of undigested residues of food; such stones have usually a woody consistence, and are formed round a foreign body. Laugier examined a concretion of this kind from the rectum of a man; it consisted of a nucleus of bone, surrounded by interlaced vegetable fibres, from which water extracted 14 per cent. of animal matter having a fecal odour, together with small quantities of sal ammoniac and chloride of calcium.

Another class of intestinal concretions consists of fatty matters mixed with small quantities of fibrin and calcium-salts. Lassaigne analysed a number of small concretions of this kind voided by a girl suffering from tuberculosis. They contained 74 per cent. fatty matters (for the most part free fatty acids, perhaps oleic and stearic), 21 animal matter, 4 phosphate of calcium, and 1 chloride of sodium.

Bezoar-stones (i. 584) must also be classed amongst intestinal concretions. (Handwörterbuch d. Chem. 2te Aufl. ii. [3] 374.)

INTESTINAL JUICE. The mucous secretion of the pouch-like glands of the intestinal canal (the Lieberkühnian glands of the small intestine and the follicles of the colon). When viewed by the microscope, it exhibits granulated cells and cell-nuclei, and, as commonly obtained, likewise small quantities of fat and epithelium. When filtered from these matters, it forms a tolerably clear, mucous, strongly alkaline liquid, which does not coagulate by heat, and is not precipitated by acetic acid, nor, when mixed with that acid, by chloride of barium. When mixed, however, with eight or ten times its volume of alcohol, it deposits white flocks, which dissolve easily and completely in water; the solution thus obtained is not precipitated by hydrochloric, sulphuric, or acetic acid, or by mercuric chloride, but gives precipitates with the neutral and basic acetates of lead.

The constituents of pure intestinal juice are the same as those of mucus. In 1,000 pts. of the filtered intestinal juice of a dog, Schmidt and Zander found 965·3 water, 34·7 solid matter, 9·6 pinceratic and intestinal ferments, together with insoluble salts, 16·6 biliary matters (cholic, taurocholic, and glycocholate of sodium), 6·3 taurine, 0·7 fat, 3·7 extractive matter, 0·15 potassium, 1·45 sodium, 2·11 chlorine, 0·03 phosphoric anhydride, 0·06 earthy phosphates. In the intestinal juice from the upper part of the colon of a man, Busch found from 3·8 to 7·4 per cent.; Frerichs, from 2·2 to 5·6 per cent. solid matter.

The intestinal juice converts starch very quickly into sugar, and digests albuminous substances, flesh, &c., though much more slowly than the gastric juice. (Handwörterbuch d. Chem. 2te Aufl. ii. [3] 373.)

INULIN. $C^6H^{10}O^5$. *Helenin, Alantin, Menyanthin, Dahlin, Synantherin, Sinistrin.*—A substance isomeric with, and similar in its properties to, starch, discovered by Valentin Rose in 1804. It appears to be a very widely distributed constituent of plants, and is found especially in the roots of elecampane (*Inula Helennium*), dandelion (*Taraxacum dens leonis*), chicory (*Cichorium Intybus*), feverfew (*Pyrethrum Parthenium*), and meadow saffron (*Colchicum autumnale*); in the tubers of the potato, the dahlia, and the Jerusalem artichoke (*Helianthus tuberosus*), in *Lerp-manna* (from *Eucalyptus dumosa*), and probably in the seeds of the sun-flower (*Helianthus annuus*), and in certain lichens, viz. *Lichen frarincus* and *Lichen fastigiatus*.

Preparation.—*a. From Elecampane-roots.*—The roots are boiled with a large quantity of water, the decoction is evaporated, the extract exhausted with cold water, and the inulin which remains undissolved is washed (Gaultier, Stratingh).—Or the roots are exhausted with hot water in a percolating apparatus; the concentrated effusion is evaporated to 10° or 12° Bm. and mixed with 2 pts. alcohol; and the inulin thereby precipitated is purified by reprecipitation with alcohol from its concentrated solution, and decolorised with animal charcoal (Thibault).—The helenin mixed with inulin prepared from elecampane-roots is extracted by boiling with alcohol. (Crockwit.)

b. From Potatoes or Dahlia-tubers.—1. The pulverulent deposit which separates in the cold from the expressed juice of potatoes is dissolved in hot water, and the solution is filtered, evaporated, and left to cool, whereupon it deposits inulin (Braconnot).—2. The nearly transparent juice expressed from dahlia-tubers is left to stand for some hours, whereupon it solidifies, from separation of inulin, to a stiff paste, which is to be washed and dried (Ludwig, N. Br. Arch. 82, 163).—3. Dahlia-tubers rubbed to a pulp are washed on a hair-sieve in a thin stream of water, as long as the liquid continues to run through milky, and the inulin which separates from it on standing is collected; or in case it is slow in settling down, the turbid liquid is heated till it boils, the coagulated vegetable albumin is skimmed off, and the remaining liquid is left to cool; it then, after a few days, deposits a thick pulp easy to wash (Liebig, Ann.

Pharm. 2, 285).—4. Dahlia-tubers rubbed to a pulp are washed with cold water on a linen or woollen cloth; the residue is boiled for half-an-hour with 2 pts. water and a small quantity of chalk; the liquid is expressed; the extract, after being decolorised with animal charcoal and clarified with albumin, is evaporated till a film forms on it; and the inulin which separates on cooling is washed with cold water, and purified by solution in hot water and cooling. (Payen.)

Parnell uses peeled and washed dahlia-tubers, boils them for an hour and a half with 5 pts. of water, and purifies the inulin which separates from the evaporated extract by precipitating its aqueous solution with alcohol. Croockwit purifies the inulin thus obtained by boiling it with alcohol.

c. From Dandelion-roots. Obtained in the same way as from dahlia-tubers. (Wittstein, Report. 71, 362; Herberger, Report. 52, 399).

d. From Chicory-roots. The aqueous decoction is precipitated by neutral acetate of lead; the filtrate freed from lead is evaporated till a film forms on the surface; and the inulin which separates from it is purified by precipitating its aqueous solution with alcohol. (Woskresensky.)

e. From Lerp-manna. The substance is exhausted with boiling alcohol; the residue, consisting of starch, cellulose and inulin, is well boiled with water, and the inulin, which separates from the filtered extract on cooling, is collected and washed till the wash-water no longer exhibits the reactions of starch. (Anderson.)

Properties.—Inulin is a soft, white, tasteless, inodorous powder, resembling starch. When dried on glass or porcelain, it forms a translucent, brittle, dazzling white mass, which swells up in water. Specific gravity = 1.356 (Payen), 1.462 (Dubrunfaut). It is very hygroscopic, and sticks to the teeth and to moist paper. It exhibits laevo-rotatory power = $34^{\circ} 42'$. (Dubrunfaut, Compt. rend. xlii. 803.)

Most of the analyses which have been made of inulin agree nearly with the formula $C^6H^{10}O^5$. Woskresensky, however (J. pr. Chem. xxxvii. 309) obtained quantities of carbon and hydrogen much too large for this formula: he accordingly represents inulin by the formula $C^{22}H^{40}O^{14}$ (or $C^{21}H^{38}O^{14}$), and supposes that the inulin analysed by other chemists must have undergone partial oxidation; but the near accordance of most of these analyses renders this view improbable.

Inulin, immersed in cold water, or exposed to moist air, absorbs water, and crumbles to a dull-looking powder, consisting of *hydrated inulin*, $C^{12}H^{20}O^{10} \cdot 3H^2O$.

Inulin dissolves very sparingly in cold water, freely in boiling water, but the solution does not form a jelly like that of starch; it is insoluble in alcohol, which also precipitates it from its aqueous solution. It dissolves with brown colour in strong sulphuric acid, and is precipitated therefrom by ammonia, but not by water or alcohol. It is insoluble in hydrochloric acid, and in cold glacial acetic acid, but dissolves in the latter when warmed: The aqueous solution is not precipitated by chlorine-water, but forms a white precipitate with infusion of galls.

Inulin absorbs 8 per cent. ammonia, and dissolves in cold aqueous potash, forming a solution which leaves on evaporation a nearly colourless gum, and when mixed with acids, deposits, after a while, unaltered inulin.

Inulin dissolves in aqueous cuprammonia (an ammoniacal solution of cupric oxide), without previous tumefaction (Cramer, J. pr. Chem. lxxiii. 16), the solution yielding after a few hours, a copious blue amorphous precipitate, insoluble in water and in ammonia, soluble in tartaric and nitric acids (Schlossberger, J. pr. Chem. lxxiii. 373). It dissolves gradually in aqueous nickel-ammonia. (Schlossberger.)

The aqueous solution of inulin forms a white precipitate with baryta-water, and with chloride of barium mixed with potash.

It does not precipitate aqueous *acetate of lead*, either neutral or basic, but with a solution of the neutral acetate containing ammonia, it forms a white precipitate containing quantities of lead-oxide varying in amount from 51·23 to 62·43 per cent. It is not precipitated by *ferrous, ferric, or cupric sulphate, mercuric nitrate, nitrate of silver, or chloride of gold*.

Decompositions.—1. Inulin heated above 100° melts, with colouring and loss of weight, and is converted into a pitchy, sweetish substance, very soluble in water (Braconnot), insoluble in water and in alcohol (Payen). By dry distillation it yields acetic acid, having a brown colour, but free from oily matter. When thrown on glowing coals, it emits the odour of burnt sugar.—2. Heated with water to 100°, it is slowly but completely converted into non-crystallisable, hæro-rotatory, fermentable sugar.—3. By boiling with *nitric acid*, inulin is converted into malic, oxalic, and acetic acids, but not into mucic acid. Its solution in fuming nitric acid is not precipitated by water.—4. When heated with strong *sulphuric acid*, it turns yellow, then brown, and is ultimately carbonised.—5. By *dilute acids*, either hot or cold, inulin is converted into sugar, without evolution or absorption of gas.—6. Aqueous *arsenic acid* dissolves inulin, with aid of heat; after continued action, the cooled solution no longer deposits inulin, but leaves, on evaporation, a rose-coloured mass, which afterwards becomes darker, and finally black, grape-sugar being first formed, afterwards formic and ulmic acids.—7. *Oxide of lead* converts inulin wholly or partially into glucic acid, which, if afterwards exposed to the air, is changed into apoglucic acid. A warm aqueous solution of inulin reduces other salts of lead, also those of copper and silver. When an ammoniacal solution of acetate of lead is precipitated by aqueous inulin, the filtrate separated from the white precipitate deposits spangles of lead after a few hours, and contains formic acid.—8. Inulin is not *fermentable*. Neither its rotatory power nor any of its other properties is altered by *diastase*.—9. It is digested in the stomach, and does not pass, as inulin, either into the urine or into the feces.

Inulin is distinguished from starch by its reaction with *iodine*, which imparts to it only a fugitive brown colour; by its solubility in aqueous cuprammonia, by its power of reducing certain metals from their solutions; and by its inalterability under the influence of ferments.

IODACETIC ACID. $C^2H^3IO^2 = \begin{matrix} C^2H^3IO \\ H \end{matrix} \left. \vphantom{\begin{matrix} C^2H^3IO \\ H \end{matrix}} \right\} O$. (Perkin and Duppa, Phil.

Mag. [4] xviii. 54.)—This acid is obtained, as an ethyl-compound, by the action of iodide of potassium on bromacetate of ethyl diluted with three measures of alcohol, the mixture being digested at 40° in the dark for about two hours, and the iodic acid ether then distilled off. To obtain the free acid, the ether is converted into a barium-salt by digestion with hydrate of barium; this salt is decomposed by cautious addition of sulphuric acid; and the filtrate is crystallised in a vacuum.

Iodic acid forms thin, tough, colourless, rhombohedral plates, having a very sour taste, and not deliquescent. It melts at 82°, with slight decomposition, and solidifies again at 86°. It is decomposed, like bromacetic acid, by moist oxide of silver, with formation of glycollic acid:

Iodacetate of Ammonium is very soluble, crystalline, and non-deliquescent. The *potassium-salt* exhibits similar properties. The *barium-salt*, $C^2H^3IBaO^2$, is crystalline, moderately soluble in water, and precipitated by alcohol. The *lead-salt* crystallises in prisms, but easily splits up in solution into iodide of lead and glycollic acid:

Iodacetate of Ethyl is an oily liquid, heavier than water, and having a very irritating odour. *Iodacetate of Amyl* is oily, heavier than water, has the odour of pears, and gives off an irritating vapour.

Di-iodacetic Acid. $C^2H^3I^2O^3$. (Perkin and Duppa, Chem. Soc. Qu. J. xiii. 1.)—The ethyl-compound of this acid, obtained by acting on dibromacetate of ethyl with iodide of potassium, is converted into a calcium-salt by means of milk of lime; the calcium-salt is decomposed by hydrochloric acid, avoiding an excess; and the solution is left to crystallise. The acid is thus obtained as a beautifully crystalline sulphur-yellow compound, volatile at ordinary temperatures, and slightly soluble in water. It has a faintly acid taste, with metallic after-taste. It does not blister the skin.

The *di-iodacetates* are slightly yellow, crystalline, and permanent, excepting the *potassium and sodium-salts*, which are deliquescent. The *barium-salt*, $C^2H^3I^2BaO^3$, forms rhombohedral crystals, which give off iodine when heated. The *calcium-salt* forms yellow silky needles, also decomposed by heat. The *lead-salt*, $C^2H^3I^2PbO^3$, is

obtained as a crystalline precipitate by adding a solution of the sodium-salt to acetate of lead, both being largely diluted. The silver-salt, prepared in like manner, forms a yellow crystalline powder, which, when gently heated, decomposes with slight explosion and evolution of iodine.

Di-iodacetate of Ethyl, $C^2H(C^2H^3)I^2O^2$, is a yellowish liquid, having a pungent, burning taste, and extremely irritating odour. It is insoluble, or nearly so, in water. Ammonia rapidly converts it into di-iodacetamide, $N.H^2.C^2HI^2O$, which is a pale yellow substance, sparingly soluble in water.

IODACETYL. C^2H^3IO .—The radicle of iodicetic acid.

IODAL. $C^2HI^2O = C^2I^2O.H$. *Hydride of Tri-iodacetyl* (i. 34).—This compound is said to be obtained by adding iodine to a mixture of alcohol and nitric acid. The iodine rapidly disappears, and an oil separates which may be purified by agitation with water and distillation over chloride of calcium. It begins to boil at 25° , but the boiling point gradually rises to 115° . Potash converts it into iodoform (Aimé, Ann. Ch. Phys. [2] lxiv. 217). Johnston (Phil. Mag. [3] ii. 215) obtained, by a similar process, an oily liquid which boiled at 110° , but decomposed and turned brown at the same time. Johnston regarded the product as iodate of ethyl (see Gmelin's Handbook, ix. 186). Schoonbroodt (Bull. Soc. Chim. de Paris, 1861, p. 109), by adding hypochlorite of potassium to an alcoholic solution of iodine till the latter was decolorised, obtained a copious precipitate consisting of small shining needles, easily soluble in water, sparingly in alcohol, and resolved by potash-ley into formic acid and iodoform: hence it was probably iodal.

IODAMIDES and IODAMMONIUMS. Under these terms may be included a number of compounds, mostly of an explosive character, produced by the action of iodine on ammonia. The composition and properties of these products vary according to the mode of preparation adopted.

I. Iodamides. By digesting iodine in excess of aqueous ammonia; by adding a large excess of aqueous or alcoholic ammonia to a saturated solution of iodine in alcohol, and then diluting with water; by adding ammonia to a solution of iodine in nitro-muriatic acid (which contains protochloride of iodine, ICl); or by decomposing the explosive compound called chloride of nitrogen, with iodide of potassium—a black powder is precipitated which when dry is violently explosive. It must be collected on a filter, and washed with water; and to guard against accidents in drying, it is advisable to divide the filter, with the moist precipitate upon it, into small pieces, and expose them to warm dry air at considerable distances from each other. Or the precipitate may be dried under a receiver filled with ammonia gas, in which case, according to Millon, there is no fear of explosion.

The product obtained by either of these processes, commonly called iodide of nitrogen, is a brownish-black soft powder, which when dry explodes from the slightest cause, producing a loud report and destroying any solid bodies that may be near it. The explosion is attended with a faint flash of violet light, nitrogen being set free as gas, and iodine in the form of very fine powder. It may be exploded by friction, even under water, and in the dry state can scarcely be touched without exploding, the slightest elevation of temperature, and even the friction produced by sliding over the surface of smooth paper, being sufficient to explode it. When moist, it decomposes slowly in contact with the air, yielding nitrogen, iodic acid, and hydriodic acid. A similar decomposition is produced more rapidly by boiling water, or by alkaline solutions. Sulphydic acid decomposes it, producing hydriodic acid, ammonia, and a deposit of sulphur. With sulphurous acid, it yields iodide of ammonium, hydriodic acid, and sulphuric acid. Bromine-water decomposes it instantaneously, chlorine more slowly: strong nitric acid attacks it violently. (Gladstone.)

This description applies to all the products obtained by the processes above-mentioned; nevertheless, these products are not absolutely identical in composition; but they all appear to be iodamides—that is to say, ammonia-molecules having the hydrogen more or less replaced by iodine—combined in some instances with ammonia itself. Gay-Lussac regarded the product of the action of iodine on ammonia as a compound of iodine and nitrogen alone, in fact, as tri-iodamide, NI^3 , and, according to recent analyses by Stahl Schmidt (see p. 281), this compound does appear to be formed under certain conditions; but repeated experiments by several chemists have shown that the explosive compound thus produced frequently also contains hydrogen: for when small portions of it in a state of perfect dryness are repeatedly exploded under a bell-jar, iodide of ammonium is deposited on the sides of the vessel.

According to Millon (Ann. Ch. Phys. [2] lxi. 78), the compound is mono-iodamide, NH^2I , and the decomposition just mentioned takes place as represented by the equation:

Bineau (*ibid.* [3] xv. 71), by determining the quantities of hydriodic acid, ammonia, and nitrogen produced in its decomposition by sulphydric acid, was led to adopt the formula, NHI^2 , which is that of di-iodamide:

Gladstone (Chem. Soc. Qu. J. iv. 34) takes the same view of its constitution. By decomposing with sulphydric acid, the compound produced by the action of ammonia on an alcoholic solution of iodine, he finds that it contains 2 at. iodine to 1 at. nitrogen, while its decomposition by aqueous sulphurous acid is represented by the equation:

He also finds that the formula NHI^2 is in accordance with the formation of the compound by the action of hypochlorite of calcium or iodide of ammonium (observed by Playfair), that reaction being attended with evolution of ammonia, according to the equation:

Bunsen (Ann. Ch. Pharm. lxxxiv. 1) has also examined the constitution of iodide of nitrogen, and arrived at different conclusions. He observes that the mode of formation of the explosive compound from iodine and ammonia, with hydriodic acid as the only secondary product, shows that it must be a substitution-product of ammonia, of the form NI^2 , NHI^2 or NH^2I , associated at most with ammonia and hydriodic acid; 2. That it cannot contain hydriodic acid, because it dissolves in hydrochloric acid without evolution of gas, and forms a solution containing ammonia and protochloride of iodine, but no hydriodic acid; 3. That, to determine its composition, it is sufficient to ascertain how much ICl and how much NH^3 it yields with hydrochloric acid, and to see which of the following equations agrees with the results:

Preparations obtained by mixing cold and more or less saturated anhydrous alcoholic solutions of iodine and ammonia, which were not decomposed by washing with absolute alcohol, gave, when dissolved in hydrochloric acid, quantities of ammonia, iodine, and chlorine, in the atomic proportion of 2 : 3 : 3, showing that the constitution of the compound thus formed was $\text{NI}^2.\text{NH}^3$. A preparation obtained by adding ammonia to a solution of iodine in nitro-muriatic acid diluted with water, and washed as quickly as possible with cold water, gave, with hydrochloric acid, quantities of ammonia and protochloride of iodine in the atomic proportion of 5 : 12, showing that its formula was $4\text{NI}^2.\text{NH}^3$. When washed with water for any length of time, even till the greater part of the compound was decomposed, with separation of iodine and nitrogen, the undecomposed portion still yielded more than 1 at. ammonia to 3 at. chloride of iodine, a proof that ammonia entered essentially into its constitution. Bunsen is of opinion that there exist two distinct compounds, $\text{NI}^2.\text{NH}^3$ and $4\text{NI}^2.\text{NH}^3$, formed in the manner shown by the equations,

The formation of the so-called iodide of nitrogen by the action of ammonia on a solution of iodine in nitro-muriatic acid, would be inconsistent with this view, if that solution contained, not ICl , but, as is sometimes supposed, ICl^2 , because NI^2 could not be formed from the latter. Bunsen has, however, shown that the solution of iodine in nitro-muriatic acid contains only ICl . The formation of the explosive compound from ICl is explained by the equation,

The immediate products of its explosion are nitrogen and hydriodic acid:

which latter is, for the most part, resolved by the high temperature into iodine and hydrogen, while another portion unites with the ammonia of the compound, forming iodide of ammonium, thereby setting free quantities of iodine and nitrogen equivalent to this ammonia.

The compound obtained by Bineau and by Gladstone, *viz.* di-iodamide NHI^2 , is intermediate between the two compounds obtained by Bunsen:

Bunsen's first compound NI^3NH^1 , may be represented as tri-iodammonium, $\text{N} \left\{ \begin{smallmatrix} \text{H}^3 \\ \text{NHI}^3 \end{smallmatrix} \right.$ and the second compound $4\text{NI}^3\text{NH}^3$, might be formulated in a similar manner.

Lastly, it appears from the experiments of Stahlschmidt (Pogg. Ann. cxix. 421; Bull. Soc. Chim. de Paris 1864, p. 149), that di- or tri-iodamide may be produced according as alcoholic or aqueous ammonia is added to an alcoholic solution of iodine. By mixing alcoholic solutions of ammonia and iodine, he obtained a compound yielding by analysis quantities of iodine and nitrogen in the proportion of 2 at. I to 1 at. N, therefore NHI^2 .

On the other hand, a product obtained by adding aqueous ammonia to an alcoholic tincture of iodine, yielded by decomposition with *sulphydic acid*, products containing 8 at. I to 1 at. N, according to the equation,

The same substance treated with *iodide of methyl*, yielded in 24 hours, two layers of liquid, the upper consisting of aqueous hydriodic acid and iodide of ammonium, while the lower contained iodoform and penta-iodide of tetramethyl-ammonium:

On treating the lower liquid with boiling absolute alcohol, a solution was obtained which deposited the penta-iodide in shining green crystals, while iodoform remained in the mother-liquor; and this mother-liquor being treated with potash, gave off ammonia and yielded iodoform, together with yellow crystals having the composition of di-iodomethylamide $\text{N} \left\{ \begin{smallmatrix} \text{I}^2 \\ \text{CH}^3 \end{smallmatrix} \right.$. The saline residue contained butyrate of potassium and other salts.

If the tri-iodamide used in the preceding reaction still retains ammonia, the products obtained are penta-iodide of tetramethylammonium, and a compound of 2 at. iodoform with mono-iodide of tetramethylammonium, $\text{C}^4\text{H}^{12}\text{NI}^5 = (\text{CH}^3)^4\text{NI} + 2\text{CHI}^3$.

By acting with ammonia on penta-iodide of tetramethylammonium (which contains 4 at. iodine in a state of less intimate combination than the fifth, and ready to act like free iodine), Stahlschmidt has obtained a compound containing $\text{C}^4\text{H}^{12}\text{N}^2\text{I}^5$, which may be regarded as a compound of di-iodamide, NHI^2 , with tri-iodide of tetramethyl-ammonium. The same compound is formed on mixing alcoholic tincture of iodine with an ammoniacal solution of mono-iodide of tetramethyl-ammonium. It is a black powder, which explodes at 100° , or in contact with sulphuric acid, giving off nitrogen, and leaving the penta-iodide. The same decomposition takes place on heating its alcoholic solution. Sulphydic acid reduces it to mono-iodide of tetramethylammonium. Nitric acid decomposes it slowly. Heated with potash, it yields iodoform. It is insoluble in most liquids, but dissolves slightly in absolute alcohol. (Stahlschmidt.)

II. Iodammonium. NH^3I ; or *Iodide of Ammonia*, $\text{NH}^3\text{.I}$.—Dry iodine absorbs dry ammonia-gas, 100 parts of iodine taking up 8.3 pts. of ammonia at $+10^\circ$, 9 pts. at 0° , and 9.4 pts. at -18° . The product is a blackish-brown very tenacious liquid, having a metallic aspect, smelling of ammonia and iodine, and imparting a brown stain to the skin and to paper. When heated, it gives off a portion of the ammonia and sublimes in violets vapours. Its lustre and tenacity are destroyed by excess of ammonia. It dissolves readily in alcohol, and is resolved by water into iodide of ammonium and di-iodamide:

In a current of hydrochloric acid gas, it is completely decomposed, yielding nitrogen gas, sal-ammoniac, iodide of ammonium, and free iodine. (Millon, Ann. Ch. Phys. lxxix. 78.)

According to Bineau, 100 pts. iodine absorb 20.55 pts. ammonia-gas, yielding a product having the composition $\text{N}^4\text{H}^3\text{I}^2$. This may be represented as an *iodide of*

Millon's compound, if its composition has been correctly determined, is remarkable as presenting the only known instance of an ammonium-molecule existing in the free state.

III. Iodide of Iodammonium. $\text{NH}^3\text{I}^2 = (\text{NH}^3\text{I}).\text{I}$.—This compound, discovered

Iodide of iodammonium dissolves in ether, alcohol, chloroform, sulphide of carbon, and aqueous iodide of potassium. When heated, it is partly resolved into iodine, and an iodiferous liquid, which may be distilled without decomposition, and is probably Millon's or Bineau's "iodide of ammonia."

The caustic *alkalis* effect the same decomposition as water, but more quickly, on account of the greater affinity of their metals for iodine.

Acids determine the formation of ammonia, *e. g.*:

IODAMMONIUM. (See p. 282.)

IODANILINE. SYN. with IODOPHENYLAMINE. See PHENYLAMINE.

IODANISIC ACID. $C^6H^5IO^3$. Produced, together with hydriodate of oxanisamic acid, by the action of hydriodic acid on diazoanis-oxanisamic acid:

IODARSENIOUS ACID. See ARSENIC OXYDIDE OF (i. 386).

IODATES. See IODINE, OXYGEN-ACIDS OF.

IODAURATES. See GOLD, IODIDES OF (ii. 929).

IODETHYLAMINE. See ETHYLAMINE (ii. 538).

IODETHYLENE. See ETHYLENE, IODATED (ii. 579).

IODHYDRIC ACID. See Iodide of Hydrogen (p. 284).

IODHYDRINS. Compounds derived from glycerin or from glycide (ii. 896), by assumption of the elements of hydriodic acid and elimination of water. Only two have hitherto been obtained; both of which are glycidic ethers, viz.:—

284 IODIDE OF ACETYL — IODIDE OF HYDROGEN.

The first has been already described (ii. 899). The second is obtained by saturating glycerin with hydriodic acid, keeping the liquid in a close vessel at 100° for forty hours, and then treating it with potash and ether. It is a syrupy liquid of a golden yellow colour, and specific gravity 1.783. It has a saccharine taste, dissolves about one-third of its bulk of water, but is not itself soluble in water. It is soluble in alcohol, and still more in ether. It is not volatile without decomposition. It burns without residue, giving off vapours of iodine. Potash decomposes it slowly at 100° , producing iodide of potassium, a liquid which appears to be identical with glycerin, and a volatile liquid, probably oxide of glyceryl ($C^3H^3O^2$). The iodine in cod-liver oil is perhaps in the form of this, or a similar compound. (Berthelot and De Luca, Compt. rend. xxxix. 748.)

IODIDE OF ACETYL. See ACETYL (i. 35).—The iodides of other organic radicles are also described under the several radicles.

IODIDE OF ALUMINIUM. See ALUMINIUM (i. 157).—The iodides of other metals are also described under the several metals.

IODIDE OF AMMONIA. See IODAMMONIUM (p. 282).

IODIDE OF AMMONIUM. See AMMONIUM-SALTS.

IODIDE OF BORON. See BORON (i. 627).

IODIDE OF HYDROGEN. HYDRIODIC or HYDRIODIC ACID. HI. Iodine does not combine with hydrogen at ordinary temperatures, even under the influence of sunshine; but when hydrogen gas and iodine vapour are passed together through a red-hot tube, combination takes place. According to Blundell (Pogg. Ann. ii. 216), spongy platinum brings about the combination at ordinary temperatures. The affinity of iodine for hydrogen is inferior only to that of oxygen, fluorine, chlorine, and bromine; consequently iodine separates hydrogen from most of its combinations, *viz.* from phosphoretted hydrogen, sulphydric acid, ammonia, and many organic compounds, *e.g.* alcohol, ether, and volatile oils, the result being in all cases the formation of hydriodic acid (Gaultier; Colin). Iodine does not decompose water, even at a red heat, or at all events, produces mere traces of iodic and hydriodic acids (Gay-Lussac). If, however, there is likewise present any substance that can take up the oxygen of the water, hydriodic acid is produced in abundance. Hence water and iodine, in contact with phosphorus, form hydriodic acid and phosphorous acid (Gay-Lussac): with sulphurous acid, only however when a considerable quantity of water is present, they yield hydriodic and sulphuric acids. With sulphites, if largely diluted, the products are hydriodic acid and a sulphate; similarly with hyposulphites; with arsenious acid, hydriodic acid and arsenic acid; with stannous salts, hydriodic acid and a stannic salt; and with certain metals, hydriodic acid and a metallic oxide.

Preparation.—1. *In the gaseous state.*—*a.* 1 pt. of phosphorus and 9 pts. of iodine are moistened with a small quantity of water, or covered with moistened glass-powder, and heated in a retort connected with a mercurial trough. Towards the end of the operation, hydriodate of phosphamine (p. 201) may sublime. Personne (Compt. rend. lii. 468) recommends the use of amorphous phosphorus for this purpose. The phosphorus is to be introduced into a tubulated retort, covered with a layer of water, and iodine added by successive portions, while the whole is gently heated. A regular stream of hydriodic acid-gas is then given off quite free from iodine-vapour.—*b.* 1 pt. of phosphorus is gently heated with 14 pts. of iodide of potassium, 20 of iodine, and a small quantity of water. If the evolution of gas becomes too violent, the vessel must be plunged into cold water; if it becomes too slow, heat must be again applied (Millon, J. Pharm. xxviii. 299):

2. *In the liquid state.*—Iodine and persulphide of hydrogen, which, when they come in contact, unite, and form a yellowish-brown liquid, are placed together at the closed end of a dry glass tube; and at a short distance from them, in a bend of the tube, is placed a small quantity of water. If the tube be then sealed, and the first-mentioned liquid brought in contact with the water, decomposition takes place, resulting in the separation of sulphur and hydriodic acid, a considerable portion of the latter condensing in the liquid state. (Kemp, Phil. Mag. [3] vii. 444.)

3. *In aqueous solution.*—The aqueous acid may be prepared by passing the gas obtained by either of the preceding methods into water, which absorbs it very rapidly and in large quantity; or directly: 1. By distilling iodine with phosphorus and a large quantity of water.—2. By passing sulphydric acid gas into water in which iodine is diffused, the liquid being well agitated all the while, till the iodine has disappeared, and the liquid, which was brown at first, has become colourless; the liquid is then filtered and heated to commencing ebullition, in order to expel the excess of sulphydric

acid (Gay-Lussac). Since the sulphur, as it precipitates, envelopes the iodine which still remains undissolved, Le Royer and Dumas recommend the process of saturating water with iodine—decanting the liquid from the undissolved portion—converting the dissolved iodine into hydriodic acid, by means of sulphydric acid—digesting in this liquid a fresh portion of iodine, which dissolves much more abundantly in the hydriodic acid already produced—decanting again—once more saturating with sulphydric acid—again digesting with iodine, &c., &c. Another method is that of Stratingh, which consists in passing sulphydric acid gas through a solution of iodine in 16 pts. of alcohol, filtering, diluting with 32 pts. of water, and freeing the product by distillation from alcohol and excess of sulphydric acid. The acid prepared in this manner is liable, however, to be mixed with a product of disagreeable odour, arising from the action of the sulphydric acid on the alcohol.—3. Iodide of barium dissolved in water is exactly decomposed by the equivalent quantity of sulphuric acid, and the product is separated by filtration from sulphate of barium (Glover, Phil. Mag. [3] xix. 92).—4. Granulated lead is agitated with iodine and water till the liquid becomes colourless; sulphydric acid gas is then passed through, and the liquid decanted (Joss, J. pr. Chem. i. 133). The aqueous solution of the acid obtained by either of these methods may be concentrated by heating it in a retort.

Properties.—Hydriodic acid is a colourless gas, which reddens litmus strongly, and produces dense white fumes in moist air. It has a very sour suffocating odour, extinguishes flame, and is not itself combustible. Its specific gravity, according to Gay-Lussac's determination, is 4.429, which shows that the gas is composed of equal volumes of hydrogen and iodine-vapour united without condensation; for the density thence deduced is $\frac{127 + 1}{2} = 64$ referred to hydrogen in unity, and $64 \times 0.0693 = 4.4362$ referred to air.

Hydriodic acid gas may be liquefied by pressure (p. 284). The liquid acid has a yellow colour, and solidifies at -51° , forming a transparent colourless mass intersected by fissures, like ice.

The aqueous acid smells like the gas; its taste is pungent at first, afterwards astringent and sour. When concentrated, it fumes strongly in the air. Its specific gravity and boiling-point vary with its strength. An acid containing 57.0 per cent. HI boils constantly at 127° under a pressure of 774 mm. A weaker or a stronger acid may be reduced to this strength by distillation under the ordinary pressure (in an atmosphere of hydrogen, to avoid decomposition). When dry hydrogen gas is passed through weaker or stronger acid, till the remaining acid attains a constant strength, this acid is found to contain from 60.3 to 60.7 per cent. HI, if the experiment is made at a temperature between 15° and 19° , and from 58.2 to 58.5 per cent. HI, if it has been performed at 100° . (Roscoe, Chem. Soc. J. xiii. 160.)

Decompositions.—1. A mixture of hydriodic acid and oxygen gases passed through a red-hot porcelain tube is resolved into water and iodine (Gay-Lussac). The aqueous solution undergoes a similar decomposition when exposed to the air, becoming brown from separated iodine.—2. The following compounds give up their oxygen to the hydrogen of the hydriodic acid, forming water and separating iodine. Hydrated peroxide of hydrogen is converted by it into water (Thénard). Sulphurous anhydride and hydriodic acid gases yield water, sulphur, and iodine:

If water is present, the two acids have no action on one another (Dumas). Hydriodic acid gas, or its concentrated aqueous solution, is decomposed by strong sulphuric acid, yielding water, sulphurous acid, and free iodine:

On the addition of water, sulphuric acid and hydriodic acids are reproduced. Aqueous iodic acid and hydriodic acid yield water and iodine:

Hypochlorous acid decomposes hydriodic acid, both in the gaseous form and in the state of aqueous solution (Balard). *Nitric acid* yields iodine, water, and nitric oxide (Gay-Lussac). *Ferric salts* are converted by hydriodic acid into ferrous salts, iodine being at the same time precipitated (Gay-Lussac).—3. *Chlorine gas*, in small quantity, converts hydriodic acid gas into hydrochloric acid and iodine:

in larger quantity, into hydrochloric acid and trichloride of iodine; e.g.

(Gay-Lussac). In a similar manner, *bromine* and hydriodic acid gas yield hydro-

bromic acid gas and iodine, the action being attended with evolution of heat (Balard). Hence hydriodic acid imparts a blue colour to starch on the addition of chlorine or bromine (not in excess), or of sulphuric, nitric, or iodic acid, or a mixture of hydrochloric acid and chlorate of potassium.—4. *Potassium, zinc, iron, mercury*, and other metals, immersed in this gas, are converted into iodides, 1 volume of hydrogen being at the same time liberated from 2 volumes of hydriodic acid gas (Gay-Lussac).—5. With most *basic metallic oxides*, hydriodic acid forms water and a metallic iodide. Some of these iodides separate immediately, so that, with the salts of certain metallic oxides, aqueous hydriodic acid forms precipitates consisting of metallic iodides, and distinguished by the following colours: Oxide of bismuth, brown; oxide of lead, orange-yellow; mercurous oxide, greenish-yellow; mercuric oxide, scarlet; oxide of silver, yellowish-white. Other metallic iodides remain dissolved in the liquid, and in that state may be regarded as hydriodates of metallic oxides. With *metallic peroxides*, e.g. the peroxide of manganese or of lead, hydriodic acid forms a metallic iodide (or hydriodate), water, and free iodine; e.g.

With many *organic compounds*, hydriodic acid reacts in the same manner as with inorganic compounds, sometimes deoxidising them, with formation of water and elimination of iodine, sometimes simply exchanging its hydrogen for a radicle of the organic compound. Examples of the first mode of action are afforded by *mannite*, with which hydriodic acid yields iodide of hexyl, water, and iodine (p. 154), and by *erythromannite*, with which it yields in like manner iodide of tetryl (ii. 505). An instance of the second mode of action is exhibited by *salicylate of methyl* (wintergreen oil), with which hydriodic acid forms iodide of methyl and salicylic acid. (Lautemann, Ann. Ch. Pharm. cxxv. 13.)

It is by reactions of this kind that Matthiessen and Foster (Chem. Soc. J. xvi. 358) have shown that cotarnine and its derivatives are methylised compounds. (See COTARNINE, ii. 90; HEMIPINIC ACID, iii. 142; OPIANIC ACID, and NARCOTINE.)

Hydriodic acid unites directly with ammonia, phosphamine, and other organic amines, phosphines, arsines, stibines, &c., forming salts, which may be regarded either as hydriodates of these ammonia-derivatives, or as iodides of the corresponding derivatives of ammonium, e.g. hydriodate of triethylamine, $\text{N}(\text{C}^2\text{H}^5)^3\text{HI}$, iodide of triethylammonium, $[\text{N}(\text{C}^2\text{H}^5)^3\text{H}]^+\text{I}^-$. Similarly with other organic bases.

It likewise unites directly with many hydrocarbons containing even numbers of hydrogen-atoms; the olefines and camphenes, for example. Greville Williams, by distilling the hydrocarbons obtained from Boghead naphtha with fuming hydriodic acid, obtained compounds which might be regarded as hydriodates of olefines, $\text{C}^6\text{H}^{12}\text{HI}$, or as iodides of the corresponding monatomic alcohol-radicles, $\text{C}^6\text{H}^{11}\text{I}$, as when treated with alcoholic ammonia, they yielded the hydriodates of the corresponding amines, $\text{C}^6\text{H}^{11}\text{N.HI}$. The hydriodates of the olefines are not, however, in all cases identical with the corresponding monatomic alcoholic iodides; hydriodate of amylene, for example, is merely isomeric with iodide of amyl; for when treated with moist oxide of silver, it yields a hydrate of amylene, not exhibiting the properties of common amylie alcohol. Similarly with hydriodate of hexylene (p. 188).

IODIDE OF NITROGEN. See IODAMIDES (p. 280).

IODIDES, METALLIC. These compounds are obtained by the same processes that yield the chlorides and bromides.

1. By the direct action of iodine on a metal, frequently even at ordinary temperatures, as in the case of mercury. The combination is attended with development of heat, sometimes with flame, which is coloured violet by the iodine vapour (e.g. potassium sodium).

2. By the action of iodine on certain metallic oxides, hydrates, or carbonates. Iodine displaces the oxides of potassium, sodium, barium, and calcium at a red heat, and that of oxide of silver at ordinary temperatures. When solutions of caustic or carbonated alkali are treated with iodine, mixtures of iodide and iodate are produced, which last salt is decomposed by heat into iodide and oxygen. Iodine and peroxide of barium, when mixed with water, decompose into iodide of barium and oxygen, thus:

3. By the action of certain metals, such as potassium, zinc, and iron, on hydriodic acid, the metal then replacing the hydrogen.—4. By saturating hydriodic acid with oxides, hydrates, or carbonates. With a peroxide and hydriodic acid, iodine is liberated.—5. The insoluble iodides are prepared by adding hydriodic acid or the solution of a metallic iodide to solutions of the heavy metals.

All iodides are destitute of metallic lustre; some of them are very beautifully

coloured. Their specific gravity is often lower than the mean specific gravity of their constituents: such is the case with the iodides of potassium, lead, copper, and silver. (Boullay.)

But few metallic iodides are decomposed by heat alone; the iodides of gold, silver, platinum, and palladium, however, give up their iodine when heated. Most metallic iodides when ignited in open vessels, so that the air has excess to them, give up their iodine, and are converted into oxides; such, however, is not the case with the iodides of potassium, sodium, bismuth, and lead. *Chlorine*, at red heat, decomposes the metallic iodides, converting them into chlorides, and either setting the iodine free or forming chloride of iodine. *Bromine* acts in a similar manner. Chlorine-water likewise liberates the iodine. *Hydrochloric acid* gas decomposes metallic iodides at a red heat, forming hydriodic acid gas and a metallic chloride. Concentrated *sulphuric* and *nitric acid* and likewise *acid sulphate of potassium* decompose all metallic iodides on the application of heat, the products being iodine, which escapes in violet vapours (which give a blue colour to paper moistened with starch), and a sulphate or nitrate of the corresponding metal. When this change is produced by nitric acid, pernitric oxide is formed at the same time; sulphuric acid and acid sulphate of potassium evolve sulphurous anhydride, sometimes also sulphydric acid. Sulphuric acid or acid sulphate of potassium with peroxide of manganese, peroxide of lead, or chromate of potassium, produces the same decomposition, but without evolution of sulphurous anhydride. A bead of microcosmic salt saturated with *oxide of copper* communicates a beautiful green colour to the blow-pipe flame on the addition of a metallic iodide (Berzelius). Metallic iodides agitated with sulphuric acid and *sulphide of carbon*, communicate an amethyst-red tint to the latter.

Very few metallic iodides remain unaltered in contact with *water*: such, however, is the case with the iodides of bismuth, lead, copper, and several of the noble metals. Some of them are converted by water into an oxide, which is precipitated, and hydriodic acid which dissolves in the water (iodide of tin): or into a precipitated compound of iodide and oxide of the metal, and a solution of the iodide in aqueous hydriodic acid (the iodides of antimony and tellurium). Most metallic iodides are perfectly soluble in water; and the solution may be regarded as containing either the unaltered iodide, or a hydriodate of the oxide formed by double decomposition (e.g. the iodides of the alkali metals, iron, nickel, cobalt, &c.).

The soluble iodides are extremely poisonous. When evaporated out of contact of air, they generally leave anhydrous metallic iodides, which partly separate in the crystalline form before the water is wholly driven off. The earthy hydriodates, however, are resolved, on evaporation, into the earthy oxides and hydriodic acid, which escapes. A very small quantity of *chlorine* colours the solution yellow or brown, by partial decomposition; and a somewhat larger quantity takes up the whole of the metal, forming a chloride (or hydrochlorate), and separates the iodine, which then gives a blue colour with starch; a still larger quantity of chlorine gives the liquid a paler colour, and converts the separated iodine into trichloride of iodine, which does not give a blue colour with starch, and frequently enters into combination with the chloride produced. Strong *sulphuric acid* and somewhat concentrated *nitric acid* colour the solution yellow or brown; and if the quantity of the iodide is large, and the solution much concentrated or heated, they liberate iodine, which partly escapes in violet vapours. *Starch* mixed with the solution, even if it be very dilute, is turned blue—permanently, when the decomposition is effected by sulphuric acid; for a time only when it is effected by nitric acid, especially if that acid be added in large quantity. If the sulphuric acid contains sulphurous acid, which is very likely to be the case with fuming oil of vitriol, it does not produce the blue colour, even when added in large excess. If a liquid in which iodine is present (urine, for example) contains much organic matter, which may decompose the sulphuric acid and form sulphurous acid, it will not produce the blue colour with starch and sulphuric acid unless it be diluted with water (Dupasquier, J. Pharm. 28, 218). If the solution likewise contains a salt of *iodic acid*, most acids produce a brown colour and separate iodine; because, by virtue of their affinity for the base of the iodate, they facilitate the mutual decomposition of the hydriodic and iodic acid: $\text{IHO}^3 + 5\text{HI} = 3\text{H}^2\text{O} + 3\text{I}^2$. The separation of iodine, and the blueing of the starch likewise takes place on adding hydrochloric acid to the solution, together with a stannic, ferric, or cupric salt, or a salt of chromic acid. Also, if the solution of the iodide be covered with gelatinous starch, the negative pole of a small voltaic battery immersed in the former, and the positive pole in the latter, the starch is turned blue in the neighbourhood of the positive wire, even if the solution contains a much larger quantity of bromide or chloride than of iodide (Steinberg, J. pr. Chem. xxv. 288). If the aqueous solution of a metallic iodide contains only $\frac{1}{1000}$ part of iodine, it gives a strong blue colour with dilute gelatinous starch, on the addition of aqua-regia: with $\frac{1}{100,000}$ part of iodine, the

precipitate is violet; with FeCl_3 rose-coloured; and with FeSO_4 a pale rose-colour is produced after the lapse of a few hours (Harting, J. pr. Chem. xxiii. 46). If the solution likewise contains a large quantity of metallic chloride, the blueing of the starch is not readily produced by the addition of nitric acid, in consequence of the formation of chloride of iodine: in this case, a solution of starch in boiling dilute sulphuric acid may be added to the solution of the iodide, and then a very small quantity of chlorine water, the liquid being stirred at the same time. (Berzelius.)

The aqueous solution of an iodide gives a brown precipitate with salts of *bismuth*; orange-yellow with *lead-salts*; dirty-white with *cuprous* salts, and also with *cupric* salts, especially on the addition of sulphurous acid; greenish-yellow with *mercurous* salts; scarlet with *mercuric* salts; yellowish-white with *silver-salts*; lemon-yellow with *gold-salts*; brown with *platinic* salts, first however turning the liquid dark brown-red; and black with salts of *palladium*, even when extremely dilute. All these precipitates consist of metallic iodides, many of them soluble in excess of the soluble iodide: the silver precipitate is insoluble in nitric acid and very little soluble in ammonia.

When iodine is added to an aqueous solution of a salt of hydriodic acid, the liquid takes up an additional quantity of iodine, equal, according to Baup (J. Pharm. ix. 46) to that which it already contains. It thereby acquires a dark-brown colour, and is supposed by some chemists to contain a *metallic polyiodide* or a salt of *hydriodous acid*; but the affinity by which the iodine is retained is very feeble.

Many metallic iodides absorb *ammonia* in definite proportions, forming compounds which may be regarded as iodides of ammonium-molecules, having part of the hydrogen replaced by a metal.

Some of these compounds unite with the *oxides* of the corresponding metals, forming *oxyiodides*, e.g. antimony and tellurium.

Metallic iodides also unite with one another, forming double iodides or iodine-salts.

IODIDES, ORGANIC. 1. *Acid*.—The iodides of acid organic radicles have not been much studied. Iodide of acetyl, $\text{C}^2\text{H}^3\text{OI}$, is obtained by the action of iodide of phosphorus on acetate of potassium or acetic anhydride; and iodide of benzoyl, $\text{C}^7\text{H}^5\text{OI}$, by the action of iodide of potassium on chloride of benzoyl. These acid iodides resemble the corresponding chlorides, but are much more easily decomposable.

2. *Alcoholic Iodides, Iodhydric or Hydriodic ethers*.—The monatomic alcoholic iodides are produced by the action of hydriodic acid, or iodide of phosphorus, on the corresponding alcohols, and by that of hydriodic acid on the corresponding diatomic hydrocarbons, e.g. iodide of amyl, $\text{C}^5\text{H}^{11}\text{I}$, from amylene, C^5H^{10} , and hydriodic acid. It is doubtful, however, whether the iodides obtained by this last process are really identical, or only isomeric with those obtained from the alcohols (p. 286).

The monatomic alcoholic iodides are less stable than corresponding chlorides, sometimes decomposing under the influence of *light*, into the alcohol-radicle and free iodine, e.g. iodide of ethyl.

Heated in sealed tubes with certain metals, viz. *zinc*, *potassium*, or *sodium*, they yield a metallic iodide and the alcohol-radicle: e.g. zinc with iodide of ethyl; potassium or sodium with iodide of tetryl. With *mercury*, *tin*, *lead*, *arsenic*, *antimony*, and a few other metals, under the influence of heat, or of the sun's rays, they yield the iodides of organo-metallic bodies; thus, iodide of ethyl, enclosed in a sealed tube with strips of tinfoil, and heated in a sealed tube to 180° , or exposed to the sun's rays concentrated by a lens or mirror, yields iodide of stannethyl, $(\text{C}^2\text{H}^5)_2\text{SnI}^2$ (ii. 235). Sometimes the organo-metallic compound thus formed acts further on the iodide, giving rise to new products (ii. 533, 535). Similar reactions take place when the alcoholic iodides are heated with the arsenides, antimonides, stannides, &c. of potassium or sodium, the organo-metallic radicles being then formed with greater facility, because the alkali-metal unites with the iodine.

The alcoholic iodides, heated in sealed tubes with *ammonia*, yield a mixture of the iodides of various ammonium-bases, in which the hydrogen of the ammonium is more or less replaced by the alcohol-radicle; thus, iodide of methyl with ammonia yields a mixture of the iodides of ammonium, and of methyl-, dimethyl-, trimethyl-, and tetramethyl-ammonium. With *primary* and *secondary monamines*, they react in a similar manner, the reaction becoming less complex as the amine itself is of a higher order. With *tertiary monamines* they unite directly, yielding the iodides of ammonium-bases in which the hydrogen is wholly replaced by the alcohol-radicle, e.g.

Similarly with tertiary *phosphines*, *arsines*, *stibines*, &c.

Alcoholic iodides treated with potassium- or sodium-alcohols yield the oxides of alcohol-radicles, thus:

With silver-salts of organic acids, they yield compound ethers, e.g.:

The facility with which the alcoholic iodides are decomposed by these several reagents renders them peculiarly well adapted to the preparation of other compounds of the alcohol-radicles.

Diatomic Alcoholic Iodides.—The iodides of the olefines, $\text{C}^2\text{H}^4\text{I}^2$, which are the only known compounds of this group, are produced by direct combination; also by passing the vapours of the corresponding monatomic alcoholic iodides through a red-hot tube; e.g.:

and by the action of hydriodic acid on the diatomic alcohols (ii. 578). The few which have been prepared are crystalline solids, easily resolved into iodine and the diatomic alcohol-radicle, the decomposition taking place slowly, even at ordinary temperatures. They are completely decomposed by *alcoholic potash*, yielding iodated hydrocarbons; e.g., iodide of ethylene, $\text{C}^2\text{H}^4\text{I}^2$, is resolved into hydriodic acid, HI, and iodoethylene, $\text{C}^2\text{H}^3\text{I}$. Their reactions with *ammonia* have not been much examined, but they appear to be similar to those of the corresponding bromides. (See ETHYLENE-BASES, ii. 585.)

3. The *organo-metallic iodides* resemble the corresponding bromides and chlorides; they are obtained in the manner above described by the action of metals and alloys on the alcoholic iodides under the influence of heat or light.

IODIDES OF NITROGEN. See IODAMIDES (p. 208).

IODIDES OF PHOSPHORUS, SELENIUM, SULPHUR, and TELLURIUM. See these several elements.

IODINE. Atomic weight, 127. *Symbol*, I.—This element was discovered in 1812, by M. Courtois, of Paris, in the mother-liquor of kelp from which carbonate of soda had been prepared. Its chemical properties were examined by Clement and Desormes (Ann. Chim. lxxxviii. 304), and afterwards more completely by Davy (Phil. Trans. 1814, i. 74) and Gay-Lussac (Ann. Chim. lxxxviii. 311, 319; xci. 5). Its name is derived from the Greek word *for* (violet), on account of the colour of its vapour.

Iodine exists in many salt-springs and other mineral waters; also in sea-water, which is the great source of it. The proportion of iodine in sea-water is, however, so minute, that it can only be detected by operating upon very large quantities; but it becomes stored up in the bodies of marine plants and animals, especially in certain algae, the *Fucus palmatus*, for example. These plants are collected on the coast of Scotland, Jersey, and other places, and burnt to ashes in a shallow pit to form kelp or varec, a substance which was formerly valued chiefly for the carbonate of sodium that it yielded; but now that this salt is more economically manufactured from chloride of sodium, kelp is chiefly valued for the chloride of potassium and the iodine obtained from it, especially the latter. Iodine exists in kelp in the form of iodide of potassium and iodide of sodium, which, being much more soluble than the other constituents, remain in the mother-liquor after the carbonates and chlorides have crystallised out.

Iodine has also been found in certain land-plants; e.g., in tobacco, and in a species of *Salsola*, growing in the floating gardens on the fresh-water lakes near the city of Mexico.

Various marine animals also contain iodine, viz., the common sponge, the horse-sponge; various species of *Sertularia*, *Tubularia*, *Rhizostoma*, *Cyana*, *Doria*, *Venus*, and oysters. It is also contained in cod-liver oil, the pale oil containing, according to De Jongh, 0.0374 per cent. iodine, the pale brown oil 0.0406, and the brown oil 0.0296 per cent.

Iodine is likewise found in several minerals, viz., as iodide of mercury and iodide of silver; as iodide of potassium, sodium, or magnesium, in Chili salt-petre; as iodide of calcium or magnesium in certain dolomites; in the rock-salt of Halle in the Tyrol, probably in the form of iodide of sodium; and sublimates as iodide of ammonium, together with sal-ammoniac, in the burning coal-mine of Commentry.

Iodide of ammonium has been found in gas-water, in the coke left in the retorts, and in the ashes of coal and peat from various localities.

Chatin (Compt. rend. **xxx** 352; **xxxi**. 280; **xxxii**. 669; **xxxiii**. 519, 529, 581) has found iodine in the waters of various streams and rivers, in quantity increasing with the proportion of iron present, and more abundantly in the waters of volcanic districts than in those from the oolitic and limestone formations; also in the rain-water of Paris, Pisa, Florence, and other localities; but none in the rain-water of mountainous districts. He also states that it is sometimes present in the air in certain localities; but Lohmeyer (Phil. Mag. [4] vi. 237), Macadam (Chem. Soc. Qu. J. vi. 166) and others have failed to detect its presence in the air. Macadam has found iodine in commercial potash, in various samples of alkaline carbonates (used as reagents) in the ashes of wood-charcoal, in coals, and in numerous plants.

Preparation.—I. From *varec* or *kelp*. The material is exhausted with hot water; the solution is freed as much as possible, by evaporation and cooling, from the crystallised salts contained in it (chloride of potassium, chloride of sodium, carbonate of sodium, sulphate of sodium, &c.); and the mother-liquor—which, besides iodide of sodium, still contains sulphide and hyposulphite of sodium, and a portion of the salts already mentioned*—is subjected to one of the following processes: 1. It is heated in a subliming apparatus with oil of vitriol:

This method is not very advantageous, because the sulphurous acid evolved acts upon the iodine and the water which is present, in such a manner as to produce hydriodic and sulphuric acids. (Soubeiran.)

2. The mother-liquor is heated in a subliming apparatus with peroxide of manganese and sulphuric acid (Wollaston):

Mr. Whytelaw, of Glasgow, adds one measure of oil of vitriol, carefully and in small portions at a time, to eight measures of the mother-liquor contained in a leaden boiler—whereupon, carbonic anhydride and sulphuric acid (from the sulphide of sodium) are first evolved; and, after exposure to the air for a day or two, sulphurous anhydride (from the hyposulphite of sodium) escapes, and sulphur is precipitated. He then pours off the liquid from the crystallised sulphate of sodium into a leaden cylinder placed horizontally in a sand-bath, and fitted with a head, the beak of which passes into the first of three tubulated receivers luted one into the other; heats the mixture to 65° C. (149° F.); and, after adding the peroxide of manganese and putting on the head, gradually raises the temperature to 100°, but not higher, because at 118° C. (244° F.) chloride of iodine begins to distil over. Sometimes also cyanide of iodine collects in the last receiver in white, needle-shaped crystals. The liquid which remains in the retort still contains iodine, and on cooling, deposits crystals of iodide of lead and double iodide of lead and sodium.

3. The mother-liquor is evaporated to dryness, the residue heated with peroxide of manganese, and the iodine precipitated from the filtered solution by chlorine. This is Barruel's method, which is carried out as follows:—The residue obtained by evaporating the mother-liquor to dryness is mixed with $\frac{1}{10}$ of its weight of peroxide of manganese, and the mixture heated in an iron vessel to commencing redness (stirring all the while), but not high enough to cause the evolution of vapours of iodine; the heat is continued till a sample of the mixture treated with sulphuric acid no longer evolves sulphuric acid or deposits sulphur; that is to say, till the whole of the sulphide and hyposulphite of sodium are converted into sulphate. The mass is then dissolved in such a quantity of water that the solution may have a density corresponding to 36° of Baumé's hydrometer; chlorine gas is passed through the filtered liquid, which is constantly stirred, till a sample treated with more chlorine no longer gives a precipitate of iodine (excess of chlorine would convert the iodine into chloride and redissolve it), and the pulverulent precipitate of iodine is collected on a filter, and purified by sublimation. Mohr is of opinion that a loss of iodine may occur in this process during the heating of the evaporated residue with manganese.

4. The mother-liquor is precipitated by a copper-salt and metallic iron, and the cuprous iodide heated with peroxide of manganese (Soubeiran). The mother-liquor is diluted with water, and mixed with a solution of sulphate of copper, as long as any precipitate is produced:

the liquid containing the free iodine is separated by decantation and washing from

* A mother-liquor from *varec*, examined by Soubeiran, contained no carbonate or sulphate; the principal salts contained in it, in addition to the iodides, were the nitrates of calcium and magnesium.

the precipitated cuprous iodide, and mixed with sulphate of copper and iron filings till it no longer smells of iodine:

and the cuprous iodide thus produced is quickly separated by elutriation from the excess of iron-filings and from the liquid, before the ferrous sulphate has time to oxidate in the air. The two portions of iodide, obtained as above, are next dried at a gentle heat (a stronger heat would decompose the cuprous iodide, since it is mixed with basic ferric sulphate, and evolve iodine); the whole is mixed with twice or three times its weight of peroxide of manganese, and a sufficient quantity of sulphuric acid to form it into a paste; and the mixture is strongly heated in a subliming apparatus:

or the sulphuric acid is dispensed with, and a stronger heat applied:

In both cases, the iodine which passes over is accompanied by water derived from the hydrated cuprous iodide, from the sulphate of calcium precipitated with it, and from the sulphuric acid when it is used in the process. This water holds in solution a portion of the iodine, which may be again precipitated by sulphate of copper. By this process, 100 pts. of the mother-liquor yield 1 pt. of iodine.

II. *From the mother-liquor of the Caliche of Peru.*—This mother-liquor contains, according to Reichardt's analysis:

Nitrate of sodium	23.300
Chloride of sodium	8.594
Sulphate of magnesium	2.214
Chloride of magnesium	1.121
Iodate of sodium	0.440
Water, given off at 100°	57.406
Combined water (and loss)	6.925
	100.000

According to Grüneberg (J. pr. Chem. lx. 172), part of the iodine in this liquid is in the form of iodide of magnesium, which is decomposed, during the evaporation, into magnesia and hydriodic acid, thereby occasioning loss of iodine; this however may be prevented by the addition of caustic soda. The liquor is then treated with iron filings and sulphate of copper (as in Soubeiran's method) till the whole of the iodine is precipitated as ferrous and cuprous iodide:

and the precipitate, which also contains oxychloride of copper, is distilled with peroxide of manganese and sulphuric acid. The receiver contains crystals of iodine and chloride of iodine. The latter is heated with carbonate of potassium, which separates all the iodine, with formation of chloride and chlorate of potassium.

Jacquelin and Favre extract the iodine from the mother-liquors of caliche and commercial nitrate of sodium, by the following process, founded on the action of sulphurous acid on the iodates:

The solution of the nitre having been concentrated to 36° or 37° Bm., a sample of it is mixed with aqueous sulphurous acid, cautiously and with constant stirring, until all the iodine is precipitated; the quantity of sulphurous acid used is then noted; and from the data thus obtained, the manufacturing operations are managed.

The solution of the nitre is run into a cistern built of stone or fire-bricks, and closed with a cover coated on the under side with glass plates. The cistern is fitted with an agitator, having stoneware arms worked from above through the cover, while the solution of sulphurous acid is being mixed with the liquid. The iodine which precipitates is collected, washed, and sublimed as above.

If the iodine is present in the form of iodide and iodate together, both chlorine and sulphurous acid must be employed, the necessary quantities having been previously ascertained by test-samples. If the iodate is present in the largest proportion, the chlorine-water is first used, and then the aqueous sulphurous acid; but when the iodide is the chief ingredient, the order of treatment is reversed.

III. *From Mineral waters.*—The quantity of iodine existing in certain mineral waters and in spent artificially iodised baths may be extracted by means of charcoal, which completely precipitates free iodine on the surface of its particles, where it

remains fixed like a dye upon cloth, and cannot be removed by heat, by chlorine, or by water or alcohol either hot or cold. Animal charcoal acts most powerfully, but lamp-black is recommended for the purpose on account of its cheapness and its state of fine division. The water containing the iodine-compound having been treated with a mixture of 1 pt. sulphuric to 2 pts. nitric acid, to set the iodine free, is run on to a filter filled with charcoal, and the charcoal thus iodised is placed upon another filter, where it is mixed with hydrated protoxide of iron, whereby the iodine is converted into soluble iodide of iron, which may be obtained in the solid state by evaporating in a current of hydrogen, or distilled with peroxide of manganese and sulphuric acid in the usual way, to obtain iodine.

Purification.—The iodine obtained by either of the preceding processes may be purified by washing with a small quantity of water, pressing between paper, drying and subliming a second time. According to Serullas, the iodine of commerce may be completely purified by solution in alcohol, filtration, and precipitation with water.

For further details relating to the manufacture of iodine, see *Richardson and Watts's Chemical Technology*, vol. i. part 3, pp. 562–575.

Properties.—Iodine is at ordinary temperatures a crystalline solid, having a greyish-black colour and metallic lustre, like plumbago or specular iron-ore. It is transparent only in very thin slices, and then appears red by transmitted light. It is very soft, and easily pulverised. It crystallises by sublimation in large brilliant, rhomboidal plates, or in elongated octahedrons. Finer crystals are obtained from solution, as by exposing to the air an aqueous solution of hydriodic acid, or a solution of iodine in ether. The crystals belong to the trimetric system, having their axes in the ratio of 4 : 3 : 2.

Iodine melts at 107° C. (224.6 F.), and solidifies in a lamellated mass on cooling. It boils (when immersed in strong sulphuric acid) between 175° and 180° C. (347°–356° F.). In the open air it volatilises at ordinary temperatures, especially when moist, diffusing an odour having considerable resemblance to that of chlorine, but easily distinguished from it. Its vapour has a splendid violet colour (hence the name of the substance). The saturated vapour is so deep-coloured, that a stratum four inches thick is impervious to daylight or candlelight. The colour is seen to great advantage when a quantity of iodine is thrown upon a hot brick. Iodine-vapour is one of the heaviest of gaseous bodies, its specific gravity referred to air as unity being 8.716 according to the experiments of Dumas, and $127 \times 0.0693 = 8.801$ by calculation from the atomic weight.

Iodine dissolves but sparingly in water, 1 pt. of iodine requiring 7,000 pts. of water to dissolve it at ordinary temperatures. Alcohol and ether dissolve it more readily, forming dark brown liquids. The alcoholic solution yields crystals of iodine by evaporation, and is decomposed by water, which throws down the iodine as a brown powder. Iodine also dissolves with facility in water containing soluble iodides, or nitrate or chloride of ammonium, the solutions having a deep red colour. A liquid containing 20 grains of iodine and 30 grains of iodide of potassium in an ounce of water, is known as Lugol's solution, and is preferred in medicine to the alcoholic tincture, because it is not decomposed by dilution with water. Iodine is soluble in sulphide of carbon, a very small quantity of it being sufficient to impart to the liquid a very rich violet tint.

Iodine in its chemical reactions resembles chlorine and bromine, but is less energetic, and is displaced from most of its combinations by either of those bodies. It destroys colouring matters but slowly, and does not decompose water under the influence of the sun's rays. It exerts a destructive action on organic tissues, producing a deep yellow brown stain on the skin, paper, &c. This colour disappears after a while under the influence of heat, if the contact has not been too much prolonged.

Iodine forms with starch a compound of a deep blue colour, soluble in pure water, but insoluble in acid and alkaline solutions. Its production affords an exceedingly delicate test of the presence of iodine. If the iodine is in the free state, the blue colour is at once produced, but if it is in combination as a soluble iodide, no coloration takes place till the iodine is liberated by chlorine or nitrous acid (see IODIDES, METALLIC, p. 287). The blue compound is decolorised at a temperature of 70° or 80° C. (158°–176° F.), but recovers its colour as the liquid cools.

Iodine is employed in the laboratory for many chemical preparations, and as a test for starch. It was first introduced into medicine by Coindet of Geneva, who employed it with success for the treatment of goitre, either dissolved in alcohol, or in solution of iodide of potassium, or as iodide of sodium; and since that application, most mineral waters to which the virtue of curing goitre was ascribed, have been found to contain iodine (Boussingault, Ann. Ch. Phys. liv. 163). On the other hand, Lohmeyer (Phil. Mag. [4] vi. 237) failed to detect iodine in the air and water of certain mountainous districts which are peculiarly free from goitre. Iodine appears to have a specific action in causing the absorption of glandular swellings, and is also administered as a

tonic. Iodine swallowed in the solid state causes ulceration of the mucous membrane of the stomach, and death.

Iodine is extensively used in photography. The sensitive film of the daguerreotype plate consists of iodide of silver, produced by exposing a polished plate of the metal to the action of iodine-vapour; and surfaces of paper, collodion, albumin, &c. are rendered capable of taking photographic pictures by dipping them first in a solution of nitrate of silver and then in iodide (or sometimes bromide) of potassium.

IODINE, BROMIDES OF. Iodine forms with bromine a solid, volatile, crystalline compound, probably a protobromide, IBr (Balard), and with excess of bromine, a dark brown liquid, soluble in water, probably a pentabromide, IBr_5 (Löwig). On exposing the pentabromide together with a small quantity of water to a temperature below 0° , a crystalline hydrate is formed which at $+4^\circ$ is resolved into water and bromide of iodine. (Löwig.)

IODINE, CHLORIDES OF. Iodine unites directly with chlorine, forming a protochloride and a trichloride, and perhaps also a pentachloride. There is also a tetrachloride produced by decomposition of the protochloride.

Protochloride. ICl .—Of this compound there are said to be two modifications, one liquid at common temperatures, the other solid; but the differences observed are perhaps due to the presence of small quantities of foreign substances, or to slight variations in the proportions of the chlorine and iodine. It is obtained:—1. By passing dry chlorine gas over dry iodine till the whole is liquefied, but no longer.---2. By distilling iodine with chloride of potassium, oxygen being then evolved, the protochloride distilling over, and a mixture of chloride, iodate, and perchlorate of potassium remaining behind (Berzelius):

The protochloride of iodine obtained by either of these processes is described as a reddish-brown oily liquid, and nothing is said about its solidification (*Gmelin's Handbook*, ii. 346). According to J. Trapp also (*J. pr. Chem.* lxxiii. 108), the liquid protochloride obtained as above does not solidify. But P. Schützenberger (*Zeitschr. Chem. Pharm.* 1862, p. 1) by passing dry chlorine in the cold over dry iodine (100 grms.) till it was liquefied, then adding more iodine (50 grms.), distilling between 100° and 102° , and rectifying between the same limits, obtained a liquid which crystallised in long needles when cooled to 10° in an open vessel, but if sealed up in a flask before it had time to solidify, retained its fluidity for 24 hours even when cooled to between 2° and 3° , and when the flask was opened, solidified suddenly, with rise of temperature; like a supersaturated solution of Glauber's salt. The crystals when exposed to the air, melted at 30° and solidified again at 25° . A similar result was obtained by introducing 31 grms. of iodine into a flask containing 8.7 grms. of chlorine (quantities proportional to the atomic weights). The whole of the chlorine was rapidly absorbed, and a liquid was formed which remained unaltered for many hours at 5° or 6° , but ultimately solidified completely.—By distilling iodine with chlorate of potassium, Schützenberger likewise obtained a dark-coloured liquid which quickly crystallised.

Trapp (*loc. cit.*) has also obtained the protochloride of iodine in the solid state by strongly heating iodine in a retort till it melted, and passing a stream of dry chlorine into the iodine-vapour till all the iodine had disappeared; the upper part of the retort then became filled with a thick red-brown vapour, and the solid protochloride of iodine collected in the receiver in large, hyacinth-red, transparent prisms and tables, which melted at 25° to a red-brown oily liquid.

Protochloride of iodine is very volatile; has a pungent odour of chlorine and iodine; attacks the eyes strongly; tastes slightly acid, strongly astringent and biting; stains the skin deep-yellow, and produces smarting. It decolorises indigo and litmus, but does not give a blue colour with starch. It deliquesces in the air, and according to Gay-Lussac, dissolves easily in water without decomposition; according to Schützenberger, on the other hand, it is decomposed by water, yielding iodic and hydrochloric acids, with separation of iodine, and formation of an iodised compound, which remains dissolved in the water, but may be extracted therefrom by ether. The protochloride dissolves in alcohol and in ether, forming yellow solutions.

Protochloride of iodine sometimes decomposes spontaneously into the tetrachloride and free iodine: $4\text{ICl} = \text{ICl}_4 + \text{I}^2$ (Kämmerer, *J. pr. Chem.* lxxiii. 83).—When heated, it gives off the trichloride, leaving a residue of pure iodine: $3\text{ICl} = \text{ICl}_3 + \text{I}^2$ (Kane, *Phil. Mag.* [3] x. 430). Sulphurous and sulphydric acids decompose it with separation of iodine. With aqueous solutions of the fixed alkalis it yields a chloride and iodate and free iodine:

the iodine however dissolving in excess of the alkali in the form of iodide and iodate,

—With aqueous or alcoholic ammonia, it yields various iodamides (the so-called iodides of nitrogen (p. 289), according to the proportions used and the manner in which the reaction takes place, e.g.:

Mercuric chloride added to a concentrated aqueous solution of protochloride of iodine throws down mercuric iodide, leaving trichloride of iodine in solution (Kane):

Stannous chloride added in small quantity to the concentrated aqueous solution, precipitates iodine, and is converted into stannic chloride: but on adding a larger quantity of the stannous chloride, the iodine disappears, and stannous iodide separates in brilliant orange-coloured needles (Kane):

Protochloride of iodine acts very readily on many organic compounds, the chlorine taking up an atom of hydrogen to form hydrochloric acid, and the iodine taking its place. In this way, many iodine-substitution-compounds may be obtained which could not be formed by the action of iodine alone; e.g., iodopyromeconic acid, $\text{C}^8\text{H}^3\text{IO}^3$, from pyromeconic acid, $\text{C}^8\text{H}^4\text{O}^3$ (J. Brown, Edinb. Phil. Trans. xxi. [1] 49); mono- and di-iodophenic acids, from phenic acid, $\text{C}^6\text{H}^4\text{O}$ (Sengenwald, Compt. rend. liv. 197). On the alcoholic hydrides, hydride of heptyl for example, protochloride of iodine acts in a manner opposite to that just mentioned, converting them into chlorides, with elimination of hydriodic acid (Schorlemmer, p. 144). In some cases, chloride of iodine unites directly with an organic compound, with ethylene, for example, forming chloriodide of ethylene, $\text{C}^2\text{H}^4\text{ClI}$ (Maxwell Simpson, Proc. Roy. Soc. xii. 278). According to Geuther, however (Ann. Ch. Pharm. cxxiii. 123), when dry coal-gas is passed over fused protochloride of iodine, the ethylene contained in it is converted into dichloride of ethylene:

From iodised organic compounds it sometimes takes away one or more atoms of iodine, replacing them by chlorine; thus it converts iodide of ethyl into chloride of ethyl (Geuther):

di-iodide of ethylene into chloriodide of ethylene (Maxwell Simpson):

or into dichloride of ethylene (Geuther):

Benzene, C^6H^6 , is violently attacked by protochloride of iodine, yielding chiefly crystalline chlorinated products of high boiling point, together with iodated bodies and free iodine.

Trichloride. ICl^3 .—This compound is produced:—1. By treating iodine at a gentle heat with excess of chlorine gas.—2. By introducing finely divided iodine anhydride into dry hydrochloric acid gas; the mass then liquefies and boils, and on cooling deposits trichloride of iodine in long needles (Serullas):

Also by mixing the crystallised iodic acid or anhydride with strong hydrochloric acid, the trichloride then crystallising out. (Soubeiran.)

Trichloride of iodine is orange-yellow, and crystallises on cooling after fusion in long needles (Serullas). It acts on other substances in the same manner as the protochloride (Kane); decolorises solution of indigo (Gay-Lussac); does not turn starch blue, except on the addition of an aqueous solution of stannous chloride, or other dechlorinating substance, which sets the iodine free.

It melts at a temperature between 20° and 25° , evolving chlorine gas, which it again absorbs on cooling (Serullas). In contact with a very small quantity of water, it is partly resolved into an insoluble yellowish portion (probably a mixture of trichloride of iodine and iodic anhydride), and a solution of protochloride of iodine and hydrochloric acid (Serullas):

Trichloride of iodine is less readily dissolved by water than the protochloride; the

saturated solution may be regarded either as aqueous trichloride of iodine—which is the more probable supposition; or as a mixture of hydrochloric acid and iodic acid containing free iodine; or as a mixture of hydrochloric acid and an acid of iodine which contains 2 atoms of oxygen (iodous acid):

Iodic acid.

Iodous acid.

A similar solution is obtained on passing chlorine gas to saturation, through 1 pt. of iodine diffused in 4 pts. of water, the mixture being kept cool, and the excess of chlorine afterwards removed by a current of atmospheric air. The solution, when saturated with chlorine as completely as possible, has a bright yellow colour and contains rather more than 3 atoms of chlorine to 1 atom of iodine, because the water gives rise to the formation of a small quantity of hydrochloric acid and iodic acid (Soubeiran). Solution of trichloride of iodine may also be prepared by precipitating an aqueous solution of the protochloride with mercuric chloride, and distilling the liquid after decanting it from the precipitated iodide of mercury.

When an aqueous solution of trichloride of iodine is gradually mixed with sulphuric acid, and the vessel kept cool, the trichloride separates in the form of a white curdy mass, which afterwards assumes an orange-yellow colour; on heating the mixture, it dissolves, but separates again as the liquid cools; on distilling the mixture, the trichloride passes over (Serullas). Ether does not separate trichloride of iodine from an aqueous solution (Dumas); but if protochloride of iodine is also present, the ether takes up the trichloride in company with it, provided the solution is not too dilute (Serullas). An aqueous solution of trichloride of iodine neutralised with a fixed alkali, yields a chloride, an iodate, and a precipitate of iodine, which redissolves in an excess of alkali in the form of iodide and iodate (Liebig):

On mixing the aqueous solution with an aqueous solution of neutral iodate of potassium and then adding alcohol acid iodate of potassium is precipitated (Serullas). An aqueous solution of trichloride of iodine agitated with a small quantity of oxide of silver, yields chloride of silver and iodic acid; when a larger quantity of oxide of silver is used, the chloride of silver is mixed with iodate (Serullas), and iodide of silver is probably formed at the same time:

Silver-leaf is converted by aqueous trichloride of iodine into chloride and iodide of silver (Serullas). When aqueous trichloride of iodine is mixed with a small quantity of a solution of stannous chloride, a precipitate of iodine is obtained, soluble in excess of the tin-salt. (Kane.)

Trichloride of iodine unites with metallic chlorides. (Filhol.)

Tetrachloride. ICl^4 .—Produced by spontaneous decomposition of the liquid protochloride, $4\text{ICl} = \text{ICl}^3 + \text{I}^2$. Crystallises in red octahedrons, the free iodine separated at the same time remaining dissolved in the mother-liquor. (Kämmerer, J. pr. Chem. lxxiii. 83.)

Pentachloride. ICl^5 .—Not known in the free state. Dry iodine cannot be made to combine with 5 atoms of chlorine (Liebig). Iodine diffused in 4 pts. of water does not absorb much more than 3 atoms of chlorine, and the yellow solution obtained yields a precipitate of iodine when saturated with alkalis (Soubeiran). The same results are obtained when the quantity of water is 8 or 10 times as great as that of the iodine. If, however, the iodine be diffused through a still larger quantity of water, 20 pts. for instance (Soubeiran), the iodine combines with 5 atoms of chlorine; the solution in this case is colourless, or merely coloured yellow from excess of chlorine, which may be removed by a current of air; it exhibits all the properties of a solution of hydrochloric and iodic acids (Liebig, Soubeiran, L. Thompson):

A solution of the same kind is obtained on mixing dilute hydrochloric and iodic acids. It smells strongly of chlorine and slowly decolorises a solution of indigo (Gay-Lussac). Strong sulphuric acid precipitates trichloride of iodine from it and liberates chlorine. (Soubeiran.)

IODINE, DETECTION AND ESTIMATION OF. Iodine in the free state is easily recognised by the violet vapour which it gives off when heated, and by its reaction with starch. The starch for this purpose should be perfectly colourless; it

may be prepared by boiling potato-starch or arrow-root with water and leaving it to cool. To obtain a delicate reagent, Béchamp (Zeitschr. Analyt. Chem. i. 466), recommends the following mode of preparation. Gelatinous starch is boiled with a quantity of concentrated potash-ley equal to $\frac{1}{10}$ of the weight of the dry starch contained in it, till it has become perfectly fluid; the liquid is then diluted with water, supersaturated with acetic acid, and precipitated with alcohol; and the bulky precipitate is boiled first with alcohol of 60 vol. per cent. then washed, first with alcohol acidulated with sulphuric acid, then with pure alcohol of the same strength, and dried. For use, the dried preparation is to be suspended in hot water.

When iodine exists in solution in the form of hydriodic acid or a metallic iodide, it may be separated by the addition of chlorine-water, sulphuric acid, or nitric acid, and will then give the blue colour with starch. When chlorine-water is used, care must be taken not to add an excess, as a chloride of iodine will then be formed which will not exhibit the starch reaction. (See IODINES, p. 287.)

The methods of detecting iodine in insoluble iodides, and in presence of oxygen, sulphur, phosphorus, &c., are the same as those employed when it is to be estimated quantitatively.

Quantitative Estimation.—Iodine in the free state is best determined by means of a standard solution of sulphurous acid (see ANALYSIS, VOLUMETRIC, i. 265). When it occurs in the solution in the form of hydriodic acid or a metallic iodide, it may either be set free by chlorine-water and estimated volumetrically in the same manner; or it may be precipitated by nitrate of silver in the same manner as chlorine and bromine (i. 677, 903). 100 pts. of iodide of silver correspond to 54.128 pts. of iodine.

It may also be precipitated as iodide of palladium, by mixing the solution with chloride or nitrate of palladium. A black precipitate then falls, which settles down slowly but completely, and when ignited, leaves metallic palladium, 100 pts. of which are equivalent to 239.62 pts. of iodine.

This last method of precipitation serves also to separate iodine from bromine and chlorine. If the chlorine is also to be estimated, the precipitation must of course be made with nitrate of palladium, not with chloride. If bromine is present without chlorine, the iodine must be precipitated with chloride of palladium, because the nitrate would precipitate bromine as well as iodine; the precipitation of the bromine may however be prevented by the addition of a soluble chloride. To estimate the chlorine and bromine in the filtered liquid, the excess of palladium is removed by sulphydric acid and the excess of the latter by means of nitric acid or a ferric salt. The bromine and chlorine may then be precipitated by nitrate of silver, and the precipitate treated in the manner already described (i. 903). Iodine may also be estimated in presence of chlorine by the method already described (i. 678) for the estimation of bromine, viz., by precipitating the two elements with nitrate of silver and heating the silver precipitate in a stream of chlorine. The quantity of iodine is equal to the loss of weight

multiplied by $\frac{127}{127 - 35.5} = 1.28$.

A precisely similar method may be applied to the determination of iodine in presence of bromine, the precipitate of iodide and bromide of silver being ignited in bromine-vapour, and the loss of weight multiplied by $\frac{127}{127 - 80} = 2.70$.

For other methods of estimating iodine in presence of chlorine and bromine, see i. 678.

The method of decomposing insoluble iodides, so as to obtain the iodine in solution, are similar to those adopted for insoluble bromides (i. 678).

Iodates and periodates are reduced to iodides by the action of sulphurous or sulphydric acid. To decompose them by ignition would not give accurate results, as a portion of the iodine would be driven off.

The compounds of iodine with phosphorus, arsenic and antimony may be decomposed and analysed by treating them with water or aqueous alkalis, whereby the iodine is converted into hydriodic acid, and may then be precipitated with nitrate of silver from a solution acidulated with nitric acid. The iodides of sulphur are most readily analysed by heating them in a combustion-tube with nitrate of potassium and carbonate of sodium, whereby the iodine and sulphur are converted into metallic iodide and sulphate. (Guthrie, Chem. Soc. J. xiv. 59.)

Iodine in organic compounds may be estimated in the same manner as chlorine (i. 247). In the more easily decomposable compounds, such as the iodated organic acids, the iodine may also be determined by decomposing the compound with water and sodium-amalgam, then acidulating the solution with nitric acid, and precipitating with nitrate of silver. The same method may be applied to the corresponding bromine- and chlorine-compounds. (Kekulé, Ann. Ch. Pharm. Suppl. i. 338.)

Atomic Weight of Iodine.—The earlier attempts to determine the atomic weight of this element, by Proust, Davy, Gay-Lussac and Berzelius, gave results varying from 84 to 126, that is to say, considerably below those obtained by more recent determinations. Millon, by igniting iodate of potassium and iodate of silver, and weighing the remaining iodides, obtained the number 126.47; but the result is not quite exact, because the iodides themselves are partly decomposed by ignition.

The most exact determinations have been made by Marignac (Bibl. univ. de Genève, xlii. 367) and Dumas (Ann. Ch. Pharm. cv. 93). Marignac determined the quantity of iodide of potassium required for precipitating a known quantity of silver from the nitrate, and found, as the mean of five closely agreeing experiments, that 100 pts. silver are precipitated from the solution of the nitrate by 153.74 pts. iodide of potassium; whence the proportion $100 : 153.74 = 108 : x$ gives 166.04 for the atomic weight of iodide of potassium; and this diminished by 39.2, the atomic weight of potassium, gives for that of iodine the number 126.84.

In another set of experiments, Marignac determined the quantity of iodide of silver precipitated by iodide of potassium from a known weight of silver dissolved in nitric acid. As the mean of three closely agreeing experiments, he found that 100 pts. of silver give 217.511 pts. AgI: hence the atomic weight of iodide of silver is $\frac{217.511 \times 108}{100} = 234.91$, which, diminished by 108, gives for iodine the number 126.91.

Dumas decomposed pure iodide of silver by ignition in a stream of chlorine, and weighed the chloride of silver thus produced. In one experiment 3.620 grms. iodide of silver gave 2.149 chloride; in another 7.011 iodide gave 4.281 chloride. Both these results give for iodine the atomic weight 127, which is the number now adopted.

IODINE, OXIDES AND OXYGEN-ACIDS OF. The series of oxidised compounds of iodine is not as yet so complete as that of chlorine. The following have been described and analysed with more or less accuracy:

Acids.	Oxide or Anhydride.
Hypo-iodous acid HIO	Millon's Sub-hypo-iodic acid . . . I ⁰ O ⁰
	Periodic oxide (Millon's Hy- po-iodic acid) . . . IO ² or I ⁰ O ¹
	Intermediate Iodic oxide . . . I ⁰ O ¹
Iodic acid HIO ³	Iodic anhydride I ⁰ O ²
Periodic acid HIO ⁴	Periodic anhydride I ⁰ O ³

Of these, the only compounds whose composition has been established with certainty are iodic and periodic acids, with their corresponding anhydrides and salts. The existence of hypo-iodous acid and of periodic oxide has been rendered probable by experiments which will be presently described. The remaining oxides, I⁰O¹ and I⁰O², are of very doubtful constitution: the substances analysed were perhaps impure periodic oxide, or the last may have been iodic anhydride containing excess of iodine.

Hypo-iodous acid. HIO?

An oxygen-acid of iodine corresponding to hypochlorous acid appears to exist, but neither the acid nor its salts have yet been obtained in definite form. According to Magnus and Ammermüller, disodic periodate gives off part of its oxygen when ignited, and yields a residue, the solution of which in cold water possesses bleaching properties (p. 310). Mitscherlich (Pogg. Ann. xi. 162; xvii. 481), by dissolving iodine in moderately strong soda-ley, till the liquid began to show colour, and evaporating at a low temperature, obtained a salt consisting of Na²I⁰O². 10H²O, which however might have been a mixture composed of iodide and iodate of sodium: NaI.NaIO³. 10H²O; in fact the salt when treated with alcohol is resolved into soluble iodide and insoluble iodate. Wöhler (Pogg. Ann. viii. 96), by distilling iodine with anhydrous peroxide of barium, obtained a yellow liquid which he regarded as hypo-iodous acid, or rather anhydride. (Vid. Gm. ii. 252.)

According to Schönbein (J. pr. Chem. lxxxiv. 385), when 1 at. iodine is dissolved in an aqueous solution of 1 at. potash, the formation of iodate of potassium does not take place immediately, but is preceded by that of hypo-iodite of potassium, just as in the case of chlorine; the solution, which has the odour of saffron, and exhibits properties similar to those of the hypochlorites, is however very unstable, the hypo-iodite being resolved, gradually at ordinary temperatures, and instantly at the boiling heat, into iodide and iodate: $3\text{KIO} = 2\text{KI} + \text{KIO}_3$. Schönbein also finds that hypo-iodite of ammonium is formed by the action of iodine on excess of ammonia.

According to Lenssen and Löwenthal (J. pr. Chem. lxxxvi. 216), hypo-iodous acid is contained in the solution formed by the action of carbonate of sodium (or other

alkaline liquid) on trichloride of iodine, which is yellow, reddens benzene, colours starch blue, and contains a salt having the composition NaI^{O} or NaIO_2 ; that is, hypo-iodite of sodium with 2 atoms of free iodine, on the removal of which, either by excess of alkali, sulphurous acid, benzene, or other reagents, the hypo-iodite of potassium is immediately resolved into iodide and iodate. The alkaline solution of hypo-iodous acid is decomposed by iodide of potassium, yielding free alkali and free iodine, according to the equation:

The subject requires further examination.

Periodic oxide, IO^2 , and Oxides nearly allied to it in composition.

Periodic oxide is obtained, according to Millon, by treating with dilute alcohol the powder (p. 299) produced by the action of fuming nitric acid on iodine, regarded by Kämmerer as nitroso-iodic anhydride, $\text{I}^{\text{O}}(\text{NO})^2$.

When iodic anhydride is heated with 5 pts. of strong sulphuric acid, till a few bubbles of oxygen are given off, a scaly sulphur-yellow substance is formed, which appears to consist of $4\text{I}^{\text{O}} \cdot 2\text{IO}^2 \cdot \text{SO}^2 \cdot \text{H}^2$. If the boiling be continued, the evolution of oxygen goes on, and crystals are formed, having a much deeper yellow colour than the preceding, and apparently consisting of $2\text{I}^{\text{O}} \cdot \text{IO}^2 \cdot \text{SO}^2 \cdot \text{H}^2$. Water decomposes both these compounds into sulphuric acid, iodic acid, and iodine. By continuing the action of the sulphuric acid till iodine begins to escape as well as oxygen, two other compounds are formed, to which Millon assigns the formulæ $2\text{IO}^2 \cdot 2\text{SO}^2 \cdot \text{H}^2 \cdot \text{O}$ and $\text{I}^{\text{O}} \cdot \text{IO}^2 \cdot 10\text{SO}^2 \cdot \text{H}^2 \cdot \text{O}$. These substances, subjected to the action of moist air, appear to yield the compounds IO^2 and $\text{I}^{\text{O}} \cdot \text{IO}^2$ in the free state. To the latter, Millon gives the name *sub-hypo-iodic acid* [anhydride].

When sulphurous anhydride is allowed to act upon iodic anhydride longer than is required to form the compound $5\text{I}^{\text{O}} \cdot \text{SO}^2$ (p. 299), a large quantity of iodine is separated, and a lumpy adhesive mass is formed, which, if left for a day standing over water in a bell-jar, then washed with alcohol and with water, leaves an oxide of iodine containing $\text{I}^{\text{O}} \cdot \text{IO}^2$, contaminated with a small quantity of sulphuric acid. It is a brown-yellow powder which does not decompose in the air, but absorbs a small quantity of water from it. Dilute nitric acid dissolves it, with separation of iodine; fuming nitric acid converts it into iodic acid. When heated to 100° , it splits up into iodine and iodic anhydride: $5\text{I}^{\text{O}} \cdot \text{IO}^2 = 13\text{I}^{\text{O}} + \text{I}^{\text{O}} \cdot \text{IO}^2$. Water decomposes it slowly at ordinary temperatures, quickly at 100° , into iodine and iodic acid.

Aqueous alkalis act in the same manner; but alcoholic alkalis do not act upon it at ordinary temperatures. This circumstance distinguishes it from the oxides IO^2 and $\text{I}^{\text{O}} \cdot \text{IO}^2$ above-mentioned, which, according to Millon, form with alcoholic potash, brick-red easily decomposable salts. Absolute alcohol, ether, acetic ether, and sulphide of carbon are likewise without action on the oxide $\text{I}^{\text{O}} \cdot \text{IO}^2$, even at the boiling heat. (Kämmerer, J. pr. Chem. lxxxiii. 72.)

Iodic acid, Anhydride and Salts.

Iodic Acid. HIO^2 . (Gm. ii. 253.)—This acid is produced by the action of oxidising agents upon iodine in presence of water or alkalis. According to Pectenkofer (Jahresber. 1857, p. 581), it is sometimes found in commercial nitric acid (the iodine being doubtless derived from the Chili saltpetre used in the preparation). According to Riche (Compt. rend. xlv. 348), it is produced by the electrolysis of aqueous hydriodic acid or aqueous iodine; in the former case, the hydriodic acid is simply oxidised to HIO^2 by oxygen evolved by the decomposition of the water; in the latter the iodine is first converted into hydriodic acid, which is then oxidised in the manner just mentioned. It is also produced by the action of iodine on chloric or bromic acid. (Kämmerer, J. pr. Chem. lxxxv. 452.)

Preparation.—1. Small quantities of iodic acid are conveniently prepared by heating iodine with the strongest nitric acid free from nitrous acid in a wide glass tube, and leaving the liquid to cool. Iodic acid is then deposited in crystals (Connel). Jacquelin (Ann. Ch. Phys. [3] xxx. 332) recommends this as the best mode of preparing iodic acid in all cases. He heats 5 grms. of dry iodine in a flask with 200 grms. nitric acid of specific gravity 1.6 to 60° for an hour; decants the supernatant liquids (the upper consisting of nitric acid containing pernitrilic oxide, the lower of a red-brown solution of iodine in nitric acid) from the separated iodic acid; distils these liquids down to one-sixth; and gently heats the residue, together with the crystallised iodic acid, in a vessel in which it is protected from dust; iodic anhydride then separates in nacreous crystals.—2. For preparing larger quantities, Liebig's method is, however, generally preferred. It consists in suspending an ounce or two of pulverised iodine in a pound of water, and passing a stream of chlorine through the liquid, till the iodine is completely dissolved:

The brown strongly acid liquid is then slightly supersaturated with carbonate of sodium, whereby a considerable quantity of iodine is precipitated, which may be collected on a filter, then suspended in water, and treated with chlorine as before. The filtered solution contains iodate and chloride of sodium, with a trace of carbonate, which may be neutralised by hydrochloric acid. On afterwards adding chloride of barium to the filtered liquid as long as a precipitate is formed, the whole of the iodic acid is thrown down as iodate of barium, which may be collected on a filter, dried, and then decomposed by boiling it for half an hour with 2 pts. of oil of vitriol diluted with 10 or 12 pts. of water. The iodic acid thus liberated dissolves in the water, and the solution filtered from the sulphate of barium and evaporated at a gentle heat, yields the acid in the form of a crystalline mass. Kämmerer (J. pr. Chem. lxxix. 94) dissolves iodine in hot saturated baryta-water; filters the solution of iodide of barium from the separated iodate; passes chlorine through the filtrate (which at first precipitates iodine, but in a state of very fine division, so that it is very quickly oxidised), and thereby converts the whole of the iodide of barium into iodate, from which the iodic acid may then be separated by sulphuric acid.—3. Another very good method of preparing the acid is to digest 4 pts. of iodine with 7.5 pts. of chlorate of potassium in 40 pts. of water acidulated with 10 pts. of nitric acid, and heat the liquid sufficiently to cause rapid evolution of chlorine. In a short time the iodine is completely oxidised, and the iodic acid thus formed may be precipitated by baryta, and separated again by sulphuric acid. The largest crystals are obtained when the solution contains a slight excess of sulphuric acid.

The crystallised acid, HIO^3 or $\text{I}^3\text{O}^5 \cdot \text{H}^2\text{O}$, when exposed to a heat of 130° , or digested in absolute alcohol, is partly resolved into water and iodic anhydride, which remains combined with the iodic acid, forming the compound $\text{I}^3\text{O}^5 \cdot \text{HIO}^3$ or $3\text{I}^3\text{O}^5 \cdot \text{H}^2\text{O}$:

which at 170° suffers further decomposition, yielding water and iodic anhydride.

Iodic anhydride, I^3O^5 , crystallises in forms belonging to the trimetric system, and often reduced to the tabular form by the predominance of two parallel faces αP . For P the ratio of the principal to the secondary axes is $1:0.7586:0.7122$. Angles P:P in the terminal edges = $99^\circ 22'$, and $105^\circ 12'$; in the lateral edges = $125^\circ 7'$; $\alpha\text{P}:\alpha\text{P} = 93^\circ 37'$. The pyramidal faces occur sphenoido-hemihedrally. Cleavage perfect parallel to $\text{P}\infty$; imperfect parallel to $\text{P}\infty$ (Schabus, *Bestimmung der Krystallgestalten in chemischen Laboratorien erzeugter Produkte*, Wien, 1855; *Jahresber.* 1854, p. 310). Specific gravity of the crystals = 4.250 (Filhol, *Ann. Ch. Phys.* [3] xi. 415). At the temperature of boiling olive-oil, the anhydride is completely resolved into iodine and oxygen. It dissolves in water, forming iodic acid.

Pulverised iodic anhydride is reduced at ordinary temperatures by a small quantity of sulphurous anhydride, yielding sulphuric anhydride and free iodine; by continued action of sulphurous anhydride at 100° , it is converted into a light yellow granulo-crystalline mass, consisting of an iodosulphuric anhydride, $5\text{I}^3\text{O}^5 \cdot 8\text{SO}^3$. This compound is quickly decomposed by contact with air and water, with separation of iodine. By absolute alcohol or ether, it is resolved into I^3O^5 and SO^3 ; and by alcoholic potash it is converted into iodate and sulphate of potassium. Strong sulphuric acid does not act upon it at common temperatures; hydrochloric acid dissolves it, with evolution of chlorine and formation of chloride of iodine. By still longer exposure to the action of sulphurous anhydride, the iodic anhydride is completely decomposed, yielding a large quantity of iodine, and an adhesive mass containing an oxide of iodine, I^4O^{10} (p. 288).

Nitro-iodic anhydride, $\text{I}^3\text{O}^5(\text{NO})^2$?—Millon (*Ann. Ch. Phys.* [3] xii. 330), by triturating iodine with strong nitric acid, obtained a yellow powder which he regarded as a compound of nitric acid with periodic oxide, IO^3 ; it was resolved by water into nitric acid, iodic acid, and iodine, and when treated with dilute alcohol yielded a small quantity of periodic oxide, IO^3 (Millon's *hypo-iodic acid*). Kämmerer (J. pr. Chem. lxxiii. 72) has obtained the same substance by Millon's method, also by treating iodine with a mixture of fuming nitric and strong sulphuric acids, and assigns to it the composition above given. He finds that it is decomposed by drying over lime, with evolution of nitric oxide, and that, when dried in an atmosphere of carbonic anhydride, it splits up into nitric oxide and periodic oxide. It is decomposed by water and by aqueous acids and alkalis; hydrochloric acid dissolves it, with evolution of chlorine and formation of chloride of iodine. Alcohol, ether, and acetic ether are violently attacked, often with incandescence, even by small quantities of the compound. By exposure to moist air at common temperatures, it is decomposed into iodine, iodic acid, and nitric acid; in dry and very cold air it remains unaltered for a long time. It dissolves slowly, and without decomposition, in strong sulphuric acid, and sometimes separates from the solution spontaneously, but is easily precipitated on scratching the sides of the vessel with a glass rod, or adding fuming nitric acid to the solution. The sulphuric acid solution, when boiled, gives off a large quantity of nitric oxide.

Iodic acid, HIO^3 , crystallises from a strong aqueous solution in transparent six-sided tables without water of crystallisation (Serullas, Marignac). According to Rammelsberg (Pogg. Ann. xc. 12) the crystals are trimetric, the ratio of the brachydiagonal, macrodiagonal, and principal axis being = 0.58905 : 1 : 1.1903. They exhibit the faces ∞P , $\text{P}\infty$, oP , with $\frac{1}{2}\text{P}\infty$ and $2\text{P}\infty$ subordinate. In the brachydiagonal principal section $\infty\text{P} : \infty\text{P} = 119^\circ 0'$; $\text{P}\infty : \text{P}\infty = 80^\circ 4'$. The crystals are transparent and have a vitreous lustre; they are generally either tabular, by predominance of oP , or elongated in the direction of the brachydiagonal; cleavage distinct parallel to oP , less distinct parallel to ∞P . According to Marignac (Jahresber. 1856, p. 296, 1857, p. 124) iodic acid crystallises from aqueous solution at 50° — 60° for the most part in the form determined by Schabus for the anhydride,* less abundantly in the form just described as determined by Rammelsberg. Marignac finds, however, different values for some of the angles, viz., $\infty\text{P} : \infty\text{P}$ in the brachydiagonal principal section = $114^\circ 46'$; $\text{P}\infty : \text{P}\infty$ in the same = $79^\circ 38'$. Kämmerer (J. pr. Chem. lxxxv. 452) has obtained a hydrate of iodic acid, $2\text{HIO}^3 \cdot 9\text{H}_2\text{O}$, which crystallises at 17° in beautiful hexagonal tables.

Iodic acid is very soluble in water, slightly soluble in alcohol. The aqueous acid bleaches litmus paper after first reddening it. It is easily decomposed by *deoxidising agents*, yielding in the first instance hydriodic acid, which then, with the remaining iodic acid, forms water and free iodine:

Hence aqueous iodic acid, though it does not of itself impart a blue colour to starch, produces this colour immediately on the addition of hydriodic, sulphuric or sulphurous acid, stannous chloride, vegetable acids, or other deoxidising agents. In some cases however an excess of the reducing agent converts the free iodine into hydriodic acid and destroys the blue colour: thus with sulphurous acid:

Nitric oxide gas reduces aqueous iodic acid at ordinary temperatures (Kämmerer). The acid heated in sealed tubes with *sulphide of carbon* is reduced to hydriodic acid, in like manner iodate of potassium to iodide (Schlagdenhauffen, J. Pharm [3] xxxiv. 175). *Ferrous sulphate* does not of itself appear to reduce iodic acid, but on addition of caustic soda and subsequent supersaturation with sulphuric acid, iodine is set free. In this case, it may be supposed that the ferrous sulphate first separates iodine, which is taken up by the soda-ley, forming iodide and iodate of sodium, and that, on addition of sulphuric acid, iodic and hydriodic acids are set free, which act upon each other in the way above mentioned, yielding free iodine (Hempel, Ann. Ch. Pharm. cvii. 97). Aqueous iodic acid yields by *electrolysis*, oxygen at the positive, and iodine at the negative pole, the separation of the latter being due to the action of nascent hydrogen resulting from the decomposition of the water. According to Buff (Ann. Ch. Pharm. ex. 267), the iodic acid is resolved by the current into H and IO^3 , which latter is decomposed by the water, yielding HIO^3 and free oxygen.

Iodates. Iodic acid is monobasic, like chloric and bromic acids, the general formula of its normal salts being

But there are likewise acid iodates, or more properly anhydro-iodates, which may be regarded as compounds of the normal iodates with one or more molecules of iodic anhydride: thus there are three iodates of potassium, having the following formulæ:

The normal iodates are obtained: 1. By bringing iodine in contact with an alkali and water, and removing the metallic iodide formed at the same time, by digestion in alcohol.—2. By direct mixture of iodic acid with a salifiable base.—3. By bringing the aqueous acid in contact with metals.

Most iodates are insoluble or sparingly soluble in water, the only easily soluble iodates being the ammonium-, potassium-, and sodium-salts. The solutions of these salts give with somewhat concentrated solutions of strontium- and calcium-salts, and with dilute solutions of barium-, lead-, and silver-salts, white crystalline, granular precipitates. The silver-precipitate is easily soluble in ammonia, very slightly soluble in nitric acid.

The normal iodates, when heated, either give up 3 atoms of oxygen, but no iodine, and are converted into metallic iodides (e.g. $\text{KIO}^3 - \text{O}^3 = \text{KI}$), or they part with their

* The crystals examined by Schabus probably consisted of the acid, not of the anhydride.

iodine and 5 atoms of oxygen, and are reduced to metallic oxides (e.g. $\text{BaO} \cdot \text{I}^{\text{O}} - \text{O}^2 - \text{I}^2 = \text{BaO}$), accordingly as the metal has greater affinity for iodine or for oxygen. Some iodates detonate when heated with combustible bodies, e.g. on red-hot coals,—sometimes even when merely struck; but the detonation is much weaker than that produced by chlorates or nitrates. The aqueous solution of an iodate mixed with sulphurous acid yields iodine and sulphuric acid, part of which combines with the base (Gay-Lussac). With sulphydric acid, the solution of an iodate yields hydriodic acid, water, sulphur, and a sulphate (H. Rose); with hydriodic acid, or with a dissolved iodide mixed with an acid to liberate the hydriodic acid, it yields a metallic iodide, iodine, and water:

Iodides and iodates containing weak bases may also decompose one another in solution without the intervention of an acid, yielding an oxide and free iodine: thus with the zinc-salts:

With hydrochloric acid, the iodates form water, a metallic chloride, trichloride of iodine, and free chlorine; and the metallic chloride thus produced often enters into combination with the trichloride of iodine (Filhol):

Arsenious acid, with the aid of heat, and likewise dichloride of tin, separate iodine from aqueous solutions of the iodates (Simon). Dilute sulphuric acid at a boiling heat separates the iodic acid from these salts (Gay-Lussac). When an aqueous solution of an iodate is heated with nitric acid, that acid at first takes hold of the base, either wholly or in part; but when the solution is evaporated to dryness and more strongly heated, the less volatile iodic acid drives out the nitric acid. (Penny, Ann. Pharm. xxxvii. 203.)

Iodates heated with strong hydrochloric acid and mercury, or with strong sulphuric acid and ferrous-ferrie oxide, impart a blue colour to starch, in consequence of the liberation of iodine.

Iodate of Aluminium. A solution of moist hydrate of alumina in iodic acid evaporated to a syrup and then left over sulphuric acid, yields deliquescent crystals.

Iodate of Ammonium, $(\text{NH}^4)\text{IO}^3$, is produced by saturating caustic ammonia or carbonate of ammonium with iodic acid or chloride of iodine, and separates as a crystalline powder if the solutions are moderately concentrated. By spontaneous evaporation it is generally said to be obtained in small shining cubes. According to Marignac, however (Ann. Min. [6] ix. 1), the crystals are dimetric, exhibiting the combination $\text{oP} : \infty\text{P}\infty$, often with $\text{P} \cdot 2\text{P}$, ∞P , $\text{P}\infty$ and $2\text{P}\infty$ subordinate. Angle $\text{oP} : \text{P} = 124^\circ 54'$; $\text{oP} : 2\text{P} = 105^\circ 14'$; $\text{oP} : \text{P}\infty = 134^\circ 37'$; $\text{P} : \text{P}$ in the terminal edges = $109^\circ 7'$. That the crystals are not monometric, is also shown by the observation of Marbach (Jahresber. 1855, p. 146), that they act upon polarised light. It decomposes with a hissing noise at 150° , giving off equal volumes of oxygen and nitrogen together with iodine and water. It detonates on glowing coals, and is decomposed by hydrochloric acid, yielding a compound of sal-ammoniac and trichloride of iodine, together with water and free chlorine (Filhol). It dissolves in 38.5 pts. of cold water at 15° , and in 6.9 pts. of boiling water. (Rammelsberg.)

Iodate of Barium, $\text{Ba}(\text{IO}^3)^2 \cdot \text{H}^2\text{O}$.—This salt is precipitated when iodine is dissolved in baryta-water, iodide of barium remaining in solution. It may also be prepared by saturating an aqueous solution of trichloride of iodine with carbonate of barium or baryta-water, or by precipitating a concentrated solution of chloride of barium with iodate of sodium. The hydrated salt forms a granular powder. From a solution in hot nitric acid, however, it is deposited on cooling or on addition of ammonia, in small crystals (Rammelsberg), which, according to Marignac (*loc. cit.*), are monoclinic and isomorphous with bromate and chlorate of barium, exhibiting the combination $\infty\text{P} : (\text{P}\infty) : -\text{P}\infty$. Angle $\infty\text{P} : \infty\text{P}$ in the clinodiagonal principal section = $82^\circ 0'$; $(\text{P}\infty) : (\text{P}\infty)$ in the same = $76^\circ 42'$; $-\text{P}\infty : \infty\text{P} = 119^\circ 4'$. The water of crystallisation escapes at a temperature below 200° . On heating the salt more strongly in a porcelain retort, vapour of iodine and oxygen gas are evolved, and a residus is obtained, consisting of basic periodate of barium (Rammelsberg):

It does not detonate on ignited charcoal, but sometimes exhibits phosphorescence (Gay-Lussac). Hydrochloric acid dissolves it readily, even in the cold, the liquid assuming a dark-yellow colour (probably arising from the formation of a double chloride of iodine and barium) and evolving chlorine. It dissolves with difficulty in warm nitric acid (Rammelsberg). It is soluble in 3,323 pts. of water at 18° , in 625 pts.

of boiling water (Gay-Lussac), in 1,746 pts. of water at 15°, and in 600 pts. of boiling water (Rammelsberg); the anhydrous salt dissolves in 8,018 pts. water at 18.6°, and in 661 pts. boiling water. (Kremers, Pogg. Ann. xciv. 265.)

Iodate of Bismuth, $2\text{BiI}^{\text{O}}\cdot\text{H}^{\text{O}}$.—Iodate of sodium added in excess to a solution of bismuth which is no longer precipitated by water, throws down the whole of the bismuth as iodate. The precipitate is nearly insoluble in nitric acid. When ignited it leaves trioxide of bismuth mixed with iodide.

Iodate of Calcium, $\text{Ca}(\text{IO}^{\text{O}})^2\cdot 5\text{H}^{\text{O}}$.—Crystallises slowly from the mixed solutions of iodate of potassium and chloride of calcium in water (Pleischl), a large proportion of the salt, however, remaining dissolved (Rammelsberg). The crystals are rendered anhydrous by heat. The dry salt gently ignited in a porcelain retort evolves 14.786 per cent. of oxygen and 54.072 of iodine, leaving a residue amounting to 31.143 per cent., and consisting chiefly of pentabasic periodate of calcium; but when heated more strongly, it evolves a still larger amount of oxygen (in the whole 17.176 per cent.) and of iodine (in the whole 62.478 per cent.), and leaves 20.346 per cent. of a mixture of pentabasic periodate and much free lime, which may be separated by water (Rammelsberg, Pogg. Ann. xlv. 576). Iodate of calcium detonates violently on ignited charcoal (Gay-Lussac). When treated with concentrated hydrochloric acid, by which it is readily dissolved, it yields an orange-coloured liquid, smelling of trichloride of iodine, and similar to that yielded by iodate of potassium; it does not, however, give crystals of the double chloride of iodine and calcium (Fihol). The hydrated salt forms four-sided prisms, which effloresce in the air, with partial loss of water, and become anhydrous at a temperature below 200° (Rammelsberg). From a solution acidulated with nitric acid, it separates in trimetric crystals, $\infty\text{P} \cdot \infty\text{P}^{\infty}$. $3\text{P} \cdot \text{P} \cdot \text{O} \cdot 3\text{P}^{\infty} \cdot 4\text{P}^{\infty}$. Ratio of axes, $a : b : c = 0.4537 : 1 : 0.5231$. $\infty\text{P} : \infty\text{P}'$ in the brachydiagonal = $132^{\circ} 55'$; $\infty\text{P} : \text{P} = 127^{\circ} 22'$; $\infty\text{P} : 3\text{P} = 104^{\circ} 17'$ (Senarmont, Marignac, Jahresber. 1857, p. 125). The crystals dissolve in 464 pts. of water at 18°, and in 102 pts. of boiling water (Gay-Lussac); in 253 pts. at 16°, in 75 pts. of boiling water, and much more copiously in nitric acid. From the latter solution the salt is precipitated by ammonia in prisms (Rammelsberg). Alcohol separates the salt from an aqueous solution. (O. Henry.)

Iodate of Cerium, $\text{Ce}(\text{IO}^{\text{O}})^3\cdot\text{H}^{\text{O}}$, is a white precipitate which gives off its water at 200°, and leaves pure ceric oxide when ignited.

Iodate of Cobalt, $\text{Co}(\text{IO}^{\text{O}})^2\cdot\text{H}^{\text{O}}$, is obtained by dissolving recently precipitated carbonate of cobalt in hot aqueous iodic acid, and separates partly on cooling, partly by evaporation, in violet-red crystalline crusts. Dissolves in 148 pts. of cold and 90 pts. of hot water. Gives off its water of crystallisation at 200°. At a red heat, it gives off iodine and oxygen and leaves cobaltoso-cobaltic oxide, $\text{Co}^{\text{O}}\text{O}^{\text{O}}$. Alcohol added to a solution of this salt in sal-ammoniac, throws down a pale-red double salt.

Iodate of Copper.—Iodate of sodium forms with sulphate of copper (after some time only if the solutions are dilute) a greenish-blue precipitate, consisting of $2\text{Cu}(\text{IO}^{\text{O}})^2\cdot 3\text{H}^{\text{O}}$, which gives off its water at 200° (Rammelsberg). According to Millon, iodic acid forms, even in very dilute solutions of copper-salts, a blue crystalline precipitate composed of $\text{Cu}(\text{IO}^{\text{O}})^2\cdot\text{H}^{\text{O}}$, and the same compound is obtained by digesting recently precipitated hydrate or carbonate of copper with iodic acid at ordinary temperatures. When hydrated cupric oxide is washed with boiling water and covered with a sufficient quantity of solution of iodic acid, an olive-coloured powder is obtained which has the same composition as the blue crystals, but requires a temperature about 40° higher to dehydrate it completely. Ignited cupric oxide shaken up with aqueous iodic acid, forms a basic salt, $3[\text{Cu}(\text{IO}^{\text{O}})^2\cdot\text{CuO}]\cdot\text{H}^{\text{O}}$, which however is converted into the olive-coloured salt when the mixture is boiled.

Iodates of Iron.—*Ferric Iodate*, $\text{Fe}^{\text{O}}\cdot 2\text{IO}^{\text{O}}\cdot 8\text{H}^{\text{O}}$ or $2\text{Fe}^{\text{O}}\cdot (\text{IO}^{\text{O}})^2\cdot \text{Fe}^{\text{O}}\cdot 24\text{H}^{\text{O}}$, is a yellowish-white precipitate obtained by adding iodate of sodium to ammonio-ferric sulphate. The precipitate when dry becomes heavier and assumes a reddish tint. It is soluble in nitric acid, and leaves pure ferric oxide when ignited.

Ferrous Iodate is produced on mixing ferrous sulphate with iodate of potassium, as a white precipitate, which dissolves readily in excess of the ferrous sulphate, but quickly turns brown and decomposes, with evolution of iodine, especially when heated. The brown precipitate dissolves in hydrochloric acid, with evolution of chlorine, and ammonia throws down from the solution a mixture of ferric hydrate and iodide of nitrogen.

Iodate of Lanthanum, $\text{La}(\text{IO}^{\text{O}})^3\cdot\text{H}^{\text{O}}$.—Precipitated as a crystalline powder on adding sulphate of lanthanum to aqueous iodic acid. From solution in hot water, it separates on evaporation in white crystalline scales. Gives off its water at a temperature above 110°. (Holzmann, J. pr. Chem. lxxv. 321; Hermann, *ibid.* lxxxii. 385.)

Iodate of Lead, $\text{Pb}(\text{IO}^{\text{O}})^2$.—White precipitate, very sparingly soluble in water and

in nitric acid. Gives off iodine and oxygen when heated, and leaves a mixture of oxide and iodide of lead, from which the oxide is easily dissolved out by acetic acid.

Iodate of Lithium, LiIO^3 .—Crystalline crusts, soluble in 2 pts. of water.

Iodate of Magnesium, $\text{Mg}(\text{IO}^3)^2 \cdot 4\text{H}^2\text{O}$.—Shining crystals soluble in 3 pts. of boiling and 9.43 pts. of cold water. They are monoclinic, exhibiting the combination, ∞P . $\infty\text{P}\infty$. $+ \text{P}$. $- \text{P}$. ∞P . $-\frac{1}{2}\text{P}\infty$. In the clinodiagonal principal section, ∞P : $\infty\text{P} = 78^\circ 20'$; $+ \text{P}$: $+ \text{P} = 91^\circ 53'$; $- \text{P}$: $- \text{P} = 120^\circ 30'$; further, ∞P : $\infty\text{P} = 100^\circ 40'$; ∞P : $-\frac{1}{2}\text{P}\infty = 155^\circ 32'$. The crystals cleave very distinctly parallel to $\infty\text{P}\infty$ (Marignac, Jahrb. 1857, p. 125). When heated they quickly become opaque and give off water, becoming completely anhydrous at 240° (Millon). At a red heat, the salt suffers decomposition and leaves pure magnesia.

Iodate of Manganese, $\text{Mn}(\text{IO}^3)^2$, is best obtained by precipitating a concentrated solution of acetate of manganese with iodate of sodium. It is pale red, soluble in 200 pts. of water, and when ignited leaves pure manganoso-manganic oxide. According to Berzelius, it contains 1 at. water [$\text{Mn}(\text{IO}^3)^2 \cdot \text{H}^2\text{O}$].

Iodates of Mercury.—1. *Mercuric Iodate*. Produced by digesting recently precipitated mercuric oxide in iodic acid. It is a white anhydrous powder, insoluble in water, but dissolving easily in hydrochloric acid, with evolution of chlorine. The solution mixed with stannous chloride yields a red precipitate of mercuric iodide, which by the further action of the tin-salt is reduced to yellow mercurous-mercuric iodide. Mercuric iodate when heated gives off oxygen and is converted into iodide.

2. *Mercurous Iodate*, $\text{Hg}^2(\text{IO}^3)^2$.—A solution of mercurous nitrate rendered as neutral as possible, yields with iodate of sodium a white precipitate, which is dissolved by hydrochloric acid, with evolution of chlorine, and yields a solution from which ammonia throws down iodide of nitrogen. It dissolves with difficulty in nitric acid, and is completely volatilised by heat, being at the same time resolved into mercuric iodide, mercury and oxygen.

Iodate of Nickel, $\text{Ni}(\text{IO}^3)^2 \cdot \text{H}^2\text{O}$.—Obtained by dissolving recently precipitated hydrate of nickel in iodic acid, or by evaporating to dryness a solution of 1 pt. sulphate of nickel and $1\frac{1}{2}$ pt. iodate of sodium, and dissolving out the sulphate of sodium from the residue with water. From a hot-saturated solution, it separates as a light-green crystalline powder. It dissolves in $77\frac{1}{2}$ pts. of boiling and 120 pts. of cold water. When ignited, it leaves pure oxide of nickel. Ammonia dissolves it readily, forming a blue liquid, from which alcohol throws down blue crystals, or a crystalline powder, consisting of iodate of nickel-diammonium, $\text{Ni}(\text{IO}^3)^2 \cdot 4\text{NH}^3 = \text{I}^2\text{O}^3 \cdot \text{N}_2 \cdot \left\{ \begin{array}{l} \text{N}^2\text{H}^4\text{N}^2 \\ \text{H}^2 \end{array} \right.$.

Iodates of Potassium.—1. *Mono-iodate or Normal Iodate*. This salt is prepared: 1. By adding iodine to solution of potash till a brown colour is produced, evaporating to dryness, and dissolving out the iodide of potassium formed at the same time with alcohol of specific gravity 0.81:

Should the iodate thus obtained contain carbonate of potassium, the latter must be decomposed by acetic acid, the whole evaporated, and the acetate of potassium removed by alcohol.

2. By dissolving trichloride of iodine in potash, the products being iodate, iodide and chloride of potassium:

The iodide and chloride are dissolved out by alcohol, as in the former process, but the latter, being less soluble, is more difficult to remove.

3. By melting iodide of potassium in a crucible, leaving it to cool till it becomes semifluid, and then gradually adding $1\frac{1}{2}$ pts. chlorate of potassium. The mass becomes fluid, swells up, and solidifies to a spongy mass of iodate and chloride of potassium. It is dissolved in hot water, the iodate left to crystallise, the crystals redissolved in hot water and the iodate precipitated by alcohol.

Mono-iodate of potassium forms small white cubic crystals (Gay-Lussac); $\infty\text{O}\infty$. ∞O (Marignac), but it is not easy to obtain distinct crystals. Specific gravity 3.979 (water at $17.6^\circ = 1$) (Kremers). It dissolves in 13 pts. water at 14° (Gay-Lussac); in 19.02 pts. water at 0.5° ; in 14.85 pts. at 9.4° ; in 10.77 pts. at 22.2° ; in 5.95 pts. at 45.8° ; and in 3.67 pts. at 69.2° . An aqueous solution of specific gravity 1.0741 at 19.5° contains 9.08 pts. KIO^3 , for every 100 pts. water. The saturated aqueous solution boils at 102° (Kremers, Pogg. Ann. xciv. 271; xcv. 121; xcvi. 5). More soluble in aqueous iodide of potassium than in water. Insoluble in alcohol of specific gravity 0.81. Soluble in warm sulphuric acid without decomposition of the iodic acid. (Berzelius.)

At a low red heat, the salt melts and froths up, and is converted, with loss of

22.59 per cent. oxygen into iodide of potassium (Gay-Lussac). If only part of the oxygen is expelled, the residue consists of iodide and iodate, without any periodate (Rammelsberg). It deflagrates with a purple light on glowing charcoal.

The aqueous solution exhibits with sulphydric acid and other reducing agents, the reactions already described for iodates in general (p. 301). From a solution of the salt mixed with iodide of potassium, the stronger acids precipitate iodine. With strong hydrochloric acid, it yields water, free chlorine, and chloride of iodine and potassium:

A solution of iodate of potassium in excess of boiling nitric acid yields crystals of iodic acid on cooling, while nitre remains in solution; if however it is evaporated to dryness, one half the nitre formed is decomposed, and there remains a mixture of 1 atom of nitrate and 1 atom of di-iodate of potassium. When greater heat is applied, all the nitric acid is decomposed into pernitric oxide and oxygen, and driven off, so that the residue consists merely of iodate of potassium. (Penny, Ann. Ch. Pharm. xxxvii, 203.)

Double-salt of Iodate and Acid Sulphate of Potassium, $\text{KIO}_3 \cdot \text{KHSO}_4$.—This salt separates after the tri-iodate (p. 306) from a solution of the mono-iodate mixed with sulphuric acid. It was first obtained by Serullas (Ann. Ch. Phys. [2] xliii, 113), who regarded it as a compound of the di-iodate with anhydrous di-sulphate of potassium. Millon (Ann. Ch. Phys. [3] ix, 497) supposed it to be a compound of mono-iodate and monosulphate of potassium, $2\text{KIO}_3 \cdot \text{K}_2\text{SO}_4$. The formula above given was determined by Marignac (Ann. Min. [5] ix, 1), who obtained it of the same composition, even when the proportions between the sulphuric acid, iodic acid and potash in the solution were varied. The crystals are monoclinic, exhibiting the combination ∞P . ∞P_2 . ∞P_3 . ∞P_∞ . oP . $-\text{P}$. $-\text{P}_2$. $-\text{P}_\infty$. $+\text{P}$ (predominating at the ends) $+8\text{P}_\infty$. (P_∞) . $(\frac{1}{2}\text{P}_\infty)$. Angle ∞P : ∞P in the clinodiagonal principal section = $54^\circ 53'$; ∞P_2 : ∞P_2 in the same = $92^\circ 10'$; oP : $\text{P} = 91^\circ 29'$; oP : $\infty\text{P}_\infty = 93^\circ 14'$; ∞P_∞ : $+\text{P}_\infty = 116^\circ 50'$; ∞P_∞ : $-\text{P}_\infty = 120^\circ 42'$ (Marignac). When heated to redness, they give off oxygen and iodine and leave sulphate and iodide of potassium.

Di-iodate, $2\text{KIO}_3 \cdot \text{I}_2\text{O}_5$ or $\text{K}_2\text{O} \cdot 2\text{I}_2\text{O}_5$.—Obtained—1. By mixing the aqueous solution of the mono-iodate with hydrochloric acid, and precipitating with alcohol.—2. By partially saturating an aqueous solution of trichloride of iodine with caustic potash or carbonate of potassium, whereupon the mixture becomes heated, and on cooling deposits a compound of the di-iodate with chloride of potassium (the mother-liquor saturated with potash still yields the mono-iodate). The solution of this compound, largely diluted with water, and evaporated in the air at 25° , yields the di-iodate in beautiful transparent right rhombic prisms, with dihedral summits, having a sour, astringent taste, and acid reaction.

According to Marignac (Jahresb. 1856, p. 297), the crystals contain $\text{K}_2\text{O} \cdot 2\text{I}_2\text{O}_5 \cdot \text{H}_2\text{O}$, and exhibit three essentially different forms, one trimetric, the other two monoclinic, the occurrence of which is independent of the temperature of crystallisation. The trimetric crystals, which separate only from solutions containing a small quantity of the mono-iodate, exhibit chiefly the combination ∞P . ∞P_∞ . ∞P_∞ . oP . $\frac{1}{2}\text{P}$. $\frac{1}{2}\text{P}_\infty$. $\frac{1}{2}\text{P}_\infty$. Angle ∞P : $\infty\text{P} = 82^\circ 10'$; P : P in the macrodiagonal principal section = $87^\circ 10'$; in the brachydiagonal = $101^\circ 40'$; oP : $\text{P} = 106^\circ 4'$; oP : $\frac{1}{2}\text{P}_\infty = 127^\circ 23'$; oP : $\frac{1}{2}\text{P}_\infty = 146^\circ 48'$. No cleavage. According to Schabus (Jahresber. 1854, p. 310), the combination is oP (predominant). P . $\frac{1}{2}\text{P}$. P_∞ . $\frac{1}{2}\text{P}_\infty$. ∞P . ∞P_∞ . ∞P_∞ . For P , the ratio of principal and secondary axes is 1 : 0.8973 : 0.7819. Angles P : P in the terminal edges = $111^\circ 13'$ and $121^\circ 2'$; in the lateral edges = $97^\circ 2'$; ∞P : $\infty\text{P} = 82^\circ 4'$. Cleavage imperfect parallel to oP .—The second form, which is monoclinic, separates, according to Marignac, chiefly from solutions containing a slight excess of acid. According to Schabus, the predominant combination is ∞P_2 . ∞P_∞ . oP . $+\text{P}$. $-\text{P}$. The principal axis, clinodiagonal and orthodiagonals, are in the proportion 1 : 1.7307 : 0.8627. Angle of the inclined axes = $87^\circ 16'$. ∞P_2 : ∞P_2 in the clinodiagonal principal section = $78^\circ 48'$; oP : $-\text{P} = 129^\circ 22'$; oP : $+\text{P} = 128^\circ 9'$. The crystals are often joined as twins, the face of combination being apparently parallel to $+\frac{1}{2}\text{P}_\infty$. Marignac has also measured these crystals, viewing them in a different direction, so that the faces oP , ∞P_∞ , ∞P_2 , &c. in the preceding determination, become respectively ∞P_∞ , oP , $(\frac{1}{2}\text{P}_\infty)$, &c. in that of Marignac. Regarded thus, the crystals exhibit the faces oP . P_∞ . ∞P_2 . $-\text{P}$. (P_∞) . $(\frac{1}{2}\text{P}_\infty)$, with several subordinate clinodiagonal domes and hemipyramids. ∞P_2 : ∞P_2 in the clinodiagonal principal section = $120^\circ 17'$; $-\text{P}$: $-\text{P}$ in the same = $87^\circ 48'$; oP : $(\text{P}_\infty) = 116^\circ 53'$; oP : $(\frac{1}{2}\text{P}_\infty) = 127^\circ 20'$; oP : $\infty\text{P}_\infty = 91^\circ 56'$. The crystals are almost always intersecting twins, with the face of combination $-\text{P}_\infty$; rarely contact-twins joined by the face oP . Cleavage parallel to oP .—The third form, which accompanies the other two, is also monoclinic,

the crystals being mostly aggregated, and exhibiting the combination $\alpha P : \alpha P : + P\infty$. $-P\infty$. $-\frac{1}{2}P\infty$. $(P\infty)$. $(2P\infty)$. $-P$. Angle $\alpha P : \alpha P$ in the clinodiagonal principal section = $99^\circ 30'$; $\alpha P : -P = 122^\circ$; $\alpha P : \alpha P = 96^\circ 40'$; $\alpha P : -P\infty = 129^\circ 28'$; $\alpha P : +P\infty = 117^\circ 16'$ (Marignac). Rammelsberg, who formerly regarded the crystals as anhydrous, found, by a later determination (Jahresb. 1857, p. 125), that they contain $2(K^{\cdot}O \cdot 2I^{\cdot}O^{\cdot}) \cdot 3H^{\cdot}O$ [? in which form].

Di-iodate of potassium is soluble in 75 pts. water at 15° , insoluble in alcohol (Serullas). When heated, it gives off oxygen and vapour of iodine, and is converted, first into the mono-iodate, then into iodide. It deflagrates on glowing charcoal.

A double salt, consisting of *di-iodate and chloride of potassium*, $2KCl \cdot 2KIO^{\cdot} \cdot I^{\cdot}O^{\cdot}$, is obtained when an aqueous solution of trichloride of iodine is not quite saturated with potash, and the solution is left to evaporate:

or by heating mono-iodate of potassium with dilute hydrochloric acid:

It forms shining transparent prisms and elongated four-sided tables with truncated terminal edges (Serullas, Ann. Ch. Phys. [2] xliii. 121). According to Millon (*ibid.* [3] ix. 407) and Marignac (Jahresb. 1856, p. 298) the crystals contain 1 at. water. According to Rammelsberg (Pogg. Ann. xcvii. 92), who also finds them to be anhydrous, they are trimetric, exhibiting the combination $\alpha P : \alpha P\infty$. $\alpha P\infty$. $P\infty$. $\frac{1}{2}P\infty$. αP . $P2$. Angle $\alpha P : \alpha P$ in the macrodiagonal principal section = $82^\circ 8'$; $P\infty : P\infty$, in the same = $97^\circ 0'$; $\frac{1}{2}P\infty : \frac{1}{2}P\infty$, in the same = $132^\circ 16'$. Proportion of brachydiagonal, macrodiagonal, and principal axis = 0.8713 : 1 : 0.7709. The crystals are efflorescent, soluble in 19 pts. water at 15° (Serullas). Cold alcohol dissolves out the chloride of potassium, leaving the di-iodate. (Filhol, J. Pharm. xxv. 506.)

Di-iodate with Di-sulphate of Potassium, $K^{\cdot}S^{\cdot}O^{\cdot} \cdot K^{\cdot}I^{\cdot}O^{\cdot}$?—This, according to Serullas, is the composition of the double salt obtained, after the separation of the tri-iodate, when a solution of the mono-iodate is mixed with sulphuric acid. But, according to Millon and Marignac, this salt contains, not the di-iodate, but the mono-iodate of potassium (p. 303).

Tri-iodate, $2KIO^{\cdot} \cdot 2I^{\cdot}O^{\cdot}$ or $K^{\cdot}O \cdot 3I^{\cdot}O^{\cdot}$.—This salt is obtained by mixing aqueous iodic acid with a small quantity of potash, or by adding a solution of the mono- or di-iodate to aqueous sulphuric, phosphoric, hydrochloric, nitric, or silicic acid. When a solution of the mono-iodate is heated with a large excess of dilute sulphuric acid, and left to evaporate at 25° , the tri-iodate crystallises out, leaving in solution a compound of iodate and acid sulphate of potassium.

The tri-iodate forms large transparent crystals—triclinic, according to Rammelsberg and Marignac—which, even when free from sulphuric acid, assume a reddish colour after a while. According to Serullas and Rammelsberg, they are anhydrous; according to Millon and Marignac, they contain 2 at. water: $K^{\cdot}O \cdot 3I^{\cdot}O^{\cdot} \cdot 2H^{\cdot}O$. The salt when melted gives off $\frac{1}{3}$ of its iodine, leaving iodide of potassium. It dissolves in 25 pts. water at 16° . (Serullas, Ann. Ch. Phys. [2] xliii. 117.)

Basic Iodate?—According to Gay-Lussac, a solution of the mono-iodate mixed with potash deposits a salt containing excess of potash; but, according to Rammelsberg, nothing but the mono-iodate crystallises out.

Iodate of Silver, $AgIO^{\cdot}$, obtained by precipitating nitrate of silver with iodic acid or iodate of sodium, is white, insoluble in water, nearly insoluble in dilute nitric acid, easily soluble in ammonia, the solution yielding by spontaneous evaporation, pure iodate of silver in monoclinic crystals, which, according to Marignac (Ann. Min. [6] ix. 1), exhibit the faces αP . $\alpha P\infty$, inclined to one another at an angle of 127° , and a number of other faces at the ends of the prism, extending in a direction parallel to the orthodiagonal. Sulphurous acid passed into the solution of the salt in ammonia, is converted into sulphuric acid, and throws down iodide of silver. Hydrochloric acid decomposes it readily, yielding chloride of silver, chloride of iodine, and free chlorine.

Iodates of Sodium.—The *mono-iodate*, $NaIO^{\cdot}$ or $Na^{\cdot}O \cdot I^{\cdot}O^{\cdot}$, is obtained: 1. By passing chlorine gas to saturation through 10 pts. of water containing 1 pt. of iodine diffused through it; neutralising the liquid with carbonate of sodium; passing chlorine again through it, in order to dissolve the iodine thus thrown down; again neutralising with the carbonate; redissolving the iodine thus separated by means of chlorine, and so on. The liquid is then evaporated to $\frac{1}{10}$ th its bulk, mixed, while still warm, with half its volume of alcohol, and the compact crystalline mass, consisting of eight-sided prisms, produced on cooling, is freed from adhering chloride of sodium by washing with alcohol (Liebig, Pogg. Ann. xxiv. 362). An excess of carbonate of sodium must be avoided; otherwise, basic periodate of sodium will be formed (Magnus and Ammermüller). According to Duflos (Schw. J. lxi. 390), the addition of alcohol is unnecessary, as the less soluble iodate can be separated from the chloride of sodium

by crystallisation.—2. By partially saturating aqueous trichloride of iodine with caustic soda or carbonate of sodium, precipitating with alcohol, washing the precipitate with the same liquid, and recrystallising from hot water. (Serullas.)

Mono-iodate of sodium separates from an aqueous solution left to evaporate in moderately warm air (Rammelsberg), or from a hot concentrated solution on cooling (Penny), in crystals containing 1 at. water: $\text{NaIO}^3 \cdot \text{H}^2\text{O}$. This hydrate forms tufts of fine silky needles, which, if the temperature falls below 5° , while they are still immersed in the liquid, are converted into the pentahydrated crystals. They give off all their water at 180° (Rammelsberg, Penny). The pentahydrated salt, $\text{NaIO}^3 \cdot 5\text{H}^2\text{O}$, obtained by spontaneous evaporation below 5° , forms octagonal prisms of the trimetric system, with pyramidal summits, the combination being $\infty P \cdot \infty P \infty \cdot \infty P \infty \cdot P$, with $P \infty$ subordinate. Axes $a : b : c = 0.9534 : 1 : 0.6607$ (ii. 144). Angles $P : P$ in the terminal edges = $119^\circ 56'$ and $123^\circ 30'$; in the lateral edges = $87^\circ 30'$; $\infty P : \infty P = 92^\circ 45'$ and $87^\circ 15'$. The crystals are prismatically elongated in the direction of the principal axis, the faces ∞P being almost always unequally developed. When exposed to the air, they give off 4 at. water and are converted into the monohydrated salt (Rammelsberg, Pogg. Ann. xlv. 548; xc. 12). According to Millon (Ann. Ch. Phys. [3] ix. 400), crystals containing 2, 3, 6, and 8 at. water are also obtained, under special circumstances. Penny (Ann. Ch. Pharm. xxxvii. 203), by cooling a somewhat dilute solution, obtained crystals containing $\text{NaIO}^3 \cdot 3\text{H}^2\text{O}$.

The anhydrous salt, obtained by drying the crystals at 150° , dissolves in 13.8 pts. of water at 14.5° , but is insoluble in alcohol (Gay-Lussac). According to Kremers (Pogg. Ann. xcvi. 5, 8), it dissolves in 38.76 pts. water at 0° , in 11.03 pts. at 20° , in 6.95 pts. at 40° , in 4.79 pts. at 60° , in 3.61 pts. at 80° , and in 2.95 pts. at 100° . The saturated solution boils at 102° . A solution of specific gravity 1.0698 at 19.5° contains 8.13 pts. of the anhydrous salt for every 100 pts. of water. (Kremers, Pogg. Ann. xcix. 444.)

Mono-iodate of sodium melts when heated, and while still below redness, gives off 24.45 per cent. oxygen, together with iodine, leaving a mixture of iodide of sodium and soda (Gay-Lussac). According to Liebig, it leaves a hypo-iodide of sodium, containing $2\text{Na}^2\text{O} \cdot \text{I}^2\text{O}$ or $\text{Na}^2\text{I}^2\text{O}^2$; when heated to redness, it yields 24.21 per cent. of oxygen, and 75.79 of iodide of sodium (Benckiser). It detonates on glowing charcoal, and slightly when mixed with sulphur and struck (Gay-Lussac). It is decomposed by concentrated hydrochloric acid into water, chlorine, and a yellow liquid, which probably contains trichloride of iodine and sodium, $\text{NaCl} \cdot \text{ICl}_3$, but does not yield this compound in a crystalline form (Filhol, J. Pharm. xxv. 440). Heated with a little nitric acid, it yields di-iodate, and with a larger proportion, tri-iodate of sodium in the anhydrous state (Penny). When dissolved hot in a mixture of equal quantities of sulphuric acid and water, it gives, by evaporation, crystals which, when placed on bibulous paper and nearly dry, become all at once fluid and tenacious. (Liebig.)

Double Salts of Mono-iodate of Sodium.—1. With bromide of sodium, $2\text{NaBr} \cdot \text{NaIO}^3 \cdot 9\text{H}^2\text{O}$.—Obtained by dissolving the iodate in a hot strong solution of bromide of sodium. It crystallises, by cooling or spontaneous evaporation, in aggregations of extremely fine, colourless, transparent, six-sided laminae, apparently rhombohedral combinations. It is easily soluble in water. When heated, it gives off a large quantity of water, melts, gives off oxygen mixed with iodine, and leaves a mixture of bromide and iodide of sodium. Two-thirds of the water is given off over sulphuric acid. (Rammelsberg, J. pr. Chem. lxxxv. 436; Rép. Chim. pure, 1862, p. 251.)

2. With Chloride of Sodium, $3\text{NaCl} \cdot 2\text{NaIO}^3 \cdot 9\text{H}^2\text{O}$.—(1.) When chlorine is passed through a solution of iodate of sodium mixed with a rather large quantity of caustic soda as long as basic periodate of sodium (p. 310) continues to separate, the decanted liquid, when left at rest, deposits crystals of chloride of sodium, first combined with iodate of sodium, then by itself, and afterwards mixed with chlorate of sodium.—(2.) The mother-liquor obtained in the second mode of preparing mono-iodate of sodium (see above) deposits, at a higher temperature and greater degree of concentration, crystals of the compound of iodate and chloride. The crystals, which are large, colourless, and often transparent, belong to the triclinic system, and are sometimes triclinic pyramids having all their edges and summits truncated, frequently, also, modified by various pyramidal faces. They also form twins joined by the basal end-faces, and giving the crystal a tabular character. The axes a, b, c of the pyramid (c being the principal axis) are to one another as $1.1309 : 1 : 1.10436$. The inclinations of the principal sections are by direct measurement, $\infty P \infty : \infty P \infty = 97^\circ 16'$; $\infty P : \infty P \infty = 104^\circ 0'$; $\infty P : \infty P \infty = 100^\circ 63'$. Inclinations of the axes, by calculation, $b : c = 102^\circ 57'$; $a : c = 99^\circ 9'$; $a : b = 94^\circ 56'$. The crystals are not efflorescent, but when heated, they give off their water, and melt to a clear liquid which gives off nothing but oxygen gas, and when very strongly heated, leaves a mixture of iodide and chloride of sodium. Water extracts the chloride of sodium, leaving the iodate with 1 at. water. (Rammelsberg, Pogg. Ann. xlv. 548; cxv. 584.)

3. With *Iodide of Sodium*, $\text{NaI.NaIO}_3.10\text{H}_2\text{O}$ (Mitscherlich); $3\text{NaI}.2\text{NaIO}_3.19\text{H}_2\text{O}$ (Penny); $3\text{NaI}.2\text{NaIO}_3.20\text{H}_2\text{O}$ (Marignac).—This compound, discovered by Mitscherlich (Pogg. Ann. xi. 162; xvii. 481), is obtained by dissolving iodine in a cold and not very concentrated aqueous solution of caustic soda (or the carbonate, according to Penny) till it begins to turn brown, then leaving it in a cold place till it crystallises. Prisms of pure iodate of sodium then first appear, but afterwards redissolve, and are replaced by this compound (Mitscherlich). The same crystals are produced in a few days by immersing crystals of iodate of sodium in a strong solution of the iodide, and leaving the liquid to itself at a temperature not above 16° (Penny, Ann. Ch. Pharm. xxxvii. 202). The crystals are hexagonal tables, $\text{oR} : \infty\text{R}$, with $+ \text{R}$, $-\frac{1}{2}\text{R}$ and other faces. Angle $\text{oR} : \text{R} = 116^\circ 7'$; $\text{oR} : -\frac{1}{2}\text{R} = 133^\circ 10'$ (Marignac, Jahresb. 1857, p. 124). When heated they first give off water, then oxygen, with a trace of iodine. Cold water dissolves them without decomposition, but alcohol dissolves the iodide of sodium, leaving the iodate.

Acid Iodates of Sodium.—When an aqueous solution of trichloride of iodine is mixed, first with mono-iodate of sodium, then with alcohol, the di-iodate separates out, but this salt, if dissolved in water and evaporated, yields crystals of the mono-iodate, and an acid mother-liquor (Serullas, Ann. Ch. Phys. xlv. 59). By evaporating also a mixture of the iodate with excess of iodic acid, the neutral salt crystallises out first, and then the iodic acid (Rammelsberg). Penny obtained a di-acid and tri-acid salt, by treating the mono-iodate with nitric acid.

Iodate of Tin.—Iodate of sodium forms, with dichloride of tin, a precipitate which is white at first, but soon turns yellow, brown and grey, yielding tetrachloride and di-oxide of tin and free iodine.

Iodates of Uranium.—The *uranic salt*, $\text{U}^{\text{O}}_3.\text{I}^{\text{O}}_3.5\text{H}_2\text{O}$ or $(\text{U}^{\text{O}}_3)^+(\text{IO}_3)^-.5\text{H}_2\text{O}$, is obtained, by double decomposition, as a yellow precipitate which dissolves with difficulty in nitric acid, leaves uranoso-uranic oxide when ignited, and is decomposed by potash. *Uranous iodate* is obtained by precipitation from uranous chloride, as a greyish-green substance, which soon decomposes, being partially converted into the uranic salt.

Iodate of Yttrium.—Precipitable from concentrated solutions; remains as a crystalline crust on evaporation. It is anhydrous, dissolves in 160 pts. water, and when suddenly heated, decomposes with explosion and deflagration.

Iodate of Zinc, $\text{Zn}(\text{IO}_3)_2.2\text{H}_2\text{O}$.—To prepare this salt, a solution of sulphate of zinc and iodate of sodium in equivalent proportions is evaporated to dryness, and the resulting sulphate of sodium is dissolved out by water. Iodate of zinc then remains as a white powder, soluble in 75.9 pts. of hot, and 113.8 pts. of cold water, soluble also in nitric acid and in ammonia. The ammoniacal solution yields by spontaneous evaporation, or on addition of alcohol, a crystalline salt consisting of $3\text{Zn}(\text{IO}_3)_2.8\text{NH}_3$ or $3(\text{N}^+\text{H}_4^+/\text{Zn})(\text{IO}_3)_2.2\text{NH}_3$. It is decomposed by water, with separation of oxide of zinc.

Iodate of zinc leaves oxide of zinc when ignited.

Periodic Acid, Anhydride and Salts.

Periodic or Hyperperiodic acid. HIO_4 or $\text{H}^+\text{O}.\text{I}^{\text{O}}_4$, or according to Langlois, H^+IO_4 or $5\text{H}^+\text{O}.\text{I}^{\text{O}}_4$ (Magnus and Ammermüller, Pogg. Ann. xxviii. 514.—Benckiser, Ann. Ch. Pharm. xvii. 254.—Langlois, Ann. Ch. Phys. [3] xxxiv. 267; Jahresb. 1852, p. 345).—This acid, which was discovered by Magnus and Ammermüller (Pogg. Ann. xxviii. 514), is produced, in the form of a disodic salt, by the action of chlorine on a solution of iodate of sodium mixed with carbonate of sodium or caustic soda:

A good method of preparing it is to add 1 pt. of iodine to a solution of 7 pts. carbonate of sodium in 100 pts. water, and pass chlorine into the heated liquid as long as a precipitate continues to form. This precipitate, which consists of disodic periodate, is dissolved in nitric acid perfectly free from nitrous acid; nitrate of silver is then added; the resulting yellow precipitate of diargentate periodate is dissolved in hot dilute nitric acid; and the solution is concentrated at a moderate heat, till the monargentate periodate, AgIO_4 , crystallises out; this salt, separated from the mother-liquor, is treated with cold water, which extracts half the periodic acid, reproducing the diargentate periodate; and the filtered solution is evaporated: pure periodic acid then crystallises out (Magnus and Ammermüller). Another method is to precipitate the solution of the disodic salt in nitric acid with nitrate of lead, decompose the precipitate of per-

iodate of lead with somewhat less than an equivalent quantity of dilute sulphuric acid, and concentrate the filtrate by evaporation (Benckiser). According to Langlois, however, the acid thus obtained is always contaminated with iodic acid.

The acid may likewise be obtained by igniting iodate of barium, which then gives off iodine and oxygen, and is converted into pentabasic periodate of barium—and decomposing that salt with sulphuric acid. But this method is not advantageous, because a considerable portion of the iodic acid is completely resolved by the heat into iodine and oxygen.

The iodates of the alkali-metals give off the whole of their oxygen when heated, and are converted into iodides; consequently periodic acid cannot be prepared in the same manner as perchloric acid (i. 910).

Periodic acid separates from its aqueous solution by evaporation, at a gentle heat, in colourless crystals, apparently having the form of oblique rhombic prisms, which deliquesce quickly in moist air, melt at 130° , and at 160° give off their water, leaving a white mass of periodic anhydride, I^2O^7 , which, at 180° or 190° , gives off oxygen with great rapidity, leaving iodic anhydride (Benckiser). The crystals are rhombic prisms, having the composition $\text{H}^2\text{IO}^6 = \text{HIO}^4.2\text{H}^2\text{O}$ or $5\text{H}^2\text{O}.\text{I}^2\text{O}^7$. They melt at 130° , and between 200° and 210° , give off 5 at. water and 2 at. oxygen, and are reduced to iodic anhydride, I^2O^5 , which at a higher temperature is completely resolved into iodine and oxygen. (Langlois.)

Periodic acid dissolves very easily in water, sparingly in alcohol and in ether, in which solutions it is slowly reduced to iodic acid. It is likewise reduced by many other organic substances, and instantly by hydrochloric, sulphurous, or sulphydric acid. With hydrochloric acid it forms water, chloride of iodine, and free chlorine. Sulphur is not oxidised by it; but phosphorus is partly converted into phosphoric acid—for the most part, however, into oxide of phosphorus. Metals are oxidised by the solution, forming basic periodates. It forms a precipitate with tannic acid, a reaction which distinguishes it from iodic acid. The precipitate dissolves in potash and in ammonia, with dark red colour, arising from the oxidation of the tannic acid, the iodine at the same time uniting with the alkali-metal. (Langlois.)

Periodates.—Periodic acid is generally regarded as monobasic, like perchloric acid, the formula of its normal salts being MIO^4 or $\text{M}^2\text{O}.\text{I}^2\text{O}^7$. Only four of these anhydrous monometallic periodates are however known, namely those of ammonium, potassium, sodium, and silver. All other periodates contain a larger proportion of base, and may be derived from the crystallised acid H^2IO^6 , regarded as $\text{HIO}^4.2\text{H}^2\text{O}$, by the replacement of the water of crystallisation by a metallic oxide or hydrate, thus:

HIO^4	\cdot	H^2O	\cdot	H^2O	\cdot	Periodic acid.
$(\text{NH}^4)\text{IO}^4$	\cdot	H^2O	\cdot	H^2O	\cdot	Mono-ammoniac periodate.
NaIO^4	\cdot	NaHO	\cdot	H^2O	\cdot	Disodic periodate.
PbIO^4	\cdot	Pb^2O	\cdot	H^2O	\cdot	Triplumbic periodate.
CuIO^4	\cdot	Cu^2O	\cdot	CuHO	\cdot	Tetracupric periodate.
BaIO^4	\cdot	Ba^2O	\cdot	Ba^2O	\cdot	Pentabarytic periodate.

The existence of the monohydric acid HIO^4 must however for the present be regarded as hypothetical, the only hydrate whose constitution has been established by analysis being the pentahydric acid, H^2IO^6 , analysed by Langlois; and from this, regarded as a pentatomic molecule, $\left. \begin{matrix} \text{IO}^4 \\ \text{H}^2 \end{matrix} \right\} \text{O}^6$, the greater number of the periodates may be

derived by the partial or total replacement of the hydrogen by metals. The anhydrous periodates of potassium, silver, and sodium (MIO^4) may then be regarded as metaperiodates, bearing to the orthoperiodates, M^2IO^6 , a relation similar to that of metaphosphoric to orthophosphoric acid. There are a few periodates which cannot be included in either of the preceding formulae, viz. a barium-salt containing $5\text{BaO}.2\text{I}^2\text{O}^7$ or $3\text{BaO}.2\text{BaI}^2\text{O}^6$, a potassium-salt containing $2\text{K}^2\text{O}.\text{I}^2\text{O}^7$ or $\text{K}^2\text{O}.2\text{KIO}^4$, and a silver-salt containing $2\text{Ag}^2\text{O}.\text{H}^2\text{O}.\text{I}^2\text{O}^7$ or $\text{Ag}^2\text{O}.\text{HIO}^4$.

The monometallic periodates are resolved by heat into oxygen and metallic iodide; the polymetallic salts into a mixture of iodide and oxide or reduced metal. Most periodates are sparingly soluble or insoluble in water, but they all dissolve easily in dilute nitric acid. The solution of the monosodic salt, added to a solution of a barium-, calcium-, lead-, or silver-salt, precipitates the polymetallic or basic periodates of these bases, the liquid acquiring an acid reaction.

Periodate of Ammonium. $(\text{NH}^4)\text{IO}^4.2\text{H}^2\text{O}$, separates on mixing the solutions of ammonia and periodic acid. It dissolves in a large quantity of water, and the solution, evaporated at a gentle heat, yields crystals, apparently having the form of rhombic prisms. It has an acid reaction, and explodes when heated in a tube. (Langlois.)

Periodates of Barium.—The monobarytic salt is not known. A pentabarytic or

pentabasic salt, $\text{Ba}^2\text{I}^2\text{O}^{12}$ or $5\text{BaO} \cdot \text{I}^2\text{O}^7$, is obtained by igniting iodate of barium or a mixture of iodide and peroxide of barium, and dissolving out the iodide of barium from the residue with water. Its solution in nitric acid yields with nitrate of silver a yellow-brown precipitate of basic periodate of silver. (Rammelsberg, Pogg. Ann. xlv. 272.)

A salt containing half as much base as the last, viz. $\text{Ba}^2(\text{IO}^3)^2 \cdot \text{I}^2\text{O}^7$ or $5\text{BaO} \cdot 2\text{I}^2\text{O}^7$, is precipitated by ammonia from the solution of the pentabasic salt, or from a mixture of a soluble barium-salt with monobasic periodate of sodium dissolved in nitric acid; also on mixing nitrate of barium with dibasic periodate of sodium. The precipitate contains 5 at. water, which are given off at 100° ; by longer exposure to this temperature, the salt is completely converted into iodate of barium. (Rammelsberg.)

A *dibarytic* or *dibasic* salt, BaH^2IO^4 or $2\text{BaO} \cdot 3\text{H}^2\text{O} \cdot \text{I}^2\text{O}^7$, is obtained by adding baryta-water to a solution of the corresponding sodium-salt mixed with a few drops of nitric acid. It is a white precipitate which decomposes at a red heat, yielding the pentabarytic salt (Langlois):

Periodates of Calcium.—A *dicalcic* salt, CaH^2IO^4 or $2\text{CaO} \cdot 3\text{H}^2\text{O} \cdot \text{I}^2\text{O}^7$ (at 100°), is obtained by decomposing the sodium salt, NaH^2IO^4 , with nitrate of calcium, as a white precipitate, which appears crystalline under the microscope, and when heated gives off water, oxygen, and iodine, and leaves the pentacalcic salt, $\text{Ca}^2\text{I}^2\text{O}^{12}$ (Langlois). The latter is likewise obtained, but mixed with lime, by igniting iodate of calcium in a close vessel.

Periodate of Copper, Cu^2HIO^4 or $4\text{CuO} \cdot \text{H}^2\text{O} \cdot \text{I}^2\text{O}^7$, is precipitated by mixing the solutions of sulphate of copper and the monosodic salt—a considerable quantity, however, remaining in solution—or by the action of aqueous periodic acid in slight excess of hydrated carbonate of copper. (Langlois.)

Periodates of Iron.—Iron-salts (ferrous or ferric) form, with solution of periodate of sodium, yellowish white precipitates, easily soluble in nitric acid (Beuckiser). According to Langlois, periodic acid, in contact with ferrous oxide, is reduced to iodic acid, and ferric iodate separates out. Similar reaction with manganous oxide.

Periodates of Lead.—A *triplumbic* or *tribasic* salt, $\text{Pb}^3\text{H}^4(\text{IO}^3)^2$ or $3\text{PbO} \cdot 2\text{H}^2\text{O} \cdot \text{I}^2\text{O}^7$, is precipitated on mixing 1 at. of the disodic salt with 3 at. nitrate of lead, in microscopic crystals, which do not suffer any loss of weight between 120° and 130° , but, at a higher temperature, give off water, oxygen, and iodine, and leave an oxyiodide of lead containing $\text{PbI}^2 \cdot 5\text{PbO}$ (Langlois):

Periodate of Lithium, Li^2IO^4 ?—By treating carbonate of lithium with periodic acid and evaporating the solution at a gentle heat, a crystalline mass is obtained, which dissolves completely in water, and when dried in a vacuum, and then heated to redness, gives off successively water, oxygen, and iodine, but without undergoing complete decomposition. (Langlois.)

Periodate of Magnesium.—Magnesium-salts are not precipitated by solution of periodate of sodium. Carbonate of magnesium, immersed in aqueous periodic acid, is converted into insoluble periodate of magnesium, which dissolves, however, in excess of the acid. The salt consists of small prismatic crystals, which, when dried at mean temperatures, contain $2\text{MgH}^2\text{IO}^4 \cdot 9\text{H}^2\text{O}$ or $2\text{MgO} \cdot 3\text{H}^2\text{O} \cdot \text{I}^2\text{O}^7 + 9 \text{ aq.}$ give off 9 at. water, at 100° , and leave pure magnesia when ignited. (Langlois.)

Periodates of Potassium.—The *monopotassic* salt, KIO^4 , is precipitated in sparingly soluble crystalline grains on passing chlorine into a solution of the iodate mixed with potash or carbonate of potassium. Its aqueous solution, mixed with caustic potash, yields the *tetrapotassic* salt, $\text{K}^2\text{O} \cdot 2\text{KIO}^4$ or $2\text{K}^2\text{O} \cdot \text{I}^2\text{O}^7$, which is also sparingly soluble in water, and is converted by ignition into a mixture of potash and iodide of potassium. The neutral salt when ignited leaves the pure iodide. (Magnus and Ammermüller.)

Periodates of Silver.—Nitrate of silver added to a solution of disodic periodate, throws down a greenish yellow precipitate, which is a basic periodate of silver. By washing it with water containing nitric acid, then dissolving it nearly to saturation in warm nitric acid, and evaporating by heat, the *monoargentic* salt, AgIO^4 , is obtained in anhydrous orange-yellow crystals. This salt is decomposed by warm water, which dissolves out half the acid, leaving a blackish-brown residue of the *tetrargentic* salt, $2\text{Ag}^2\text{O} \cdot \text{I}^2\text{O}^7 \cdot \text{H}^2\text{O}$ or $\text{Ag}^2\text{O} \cdot 2\text{AgIO}^4 \cdot \text{H}^2\text{O}$, which turns red by trituration. Cold water decomposes the salt in like manner, but the residual salt is a yellow powder, consisting of $\text{Ag}^2\text{H}^2\text{IO}^4$ or $2\text{Ag}^2\text{O} \cdot 3\text{H}^2\text{O} \cdot \text{I}^2\text{O}^7$, and separates from a solution in dilute slightly warmed nitric acid, in straw-yellow crystals, which, according to Rammelsberg

310 IODINE, SELENIDE OF—IODOCINNAMIC ACID.

(Jahresb. 1857, p. 126), are rhombohedral, exhibiting the combination $R : \frac{1}{2}R : oR$. For R , the ratio of the secondary axes to the principal axis = 1:2:0653. Angle $R : R$ in the terminal edges = $74^{\circ} 0'$; $oR : R = 112^{\circ} 45'$. The crystals become darker-coloured by exposure to light. On pouring boiling water on these crystals or on the yellow powder, 2 atoms of water are removed, and the red salt above mentioned is produced. (Magnus and Ammermüller.)

Periodates of Sodium.—The monosodic salt, $NaIO^4$, is obtained by saturating the disodic salt with periodic acid, and evaporating. It is colourless, very soluble in water, anhydrous, crystallises readily, and is permanent in the air (Magnus and Ammermüller). The crystals are dimetric, $P : P_{\infty}$. For P , the ratio of the secondary axes to the principal axis is 1:1:59. Angle $P : P$ in the terminal edges = $99^{\circ} 30'$; in the lateral edges = $132^{\circ} 4'$. The crystals are colourless. (Rammelsberg, *loc. cit.*)

The disodic or dibasic salt, $Na^2H^2IO^4$ or $2Na^2O \cdot 3H^2O \cdot IO^4$, is obtained by passing chlorine gas into a hot solution of 1 pt. iodine and 7 pts. carbonate of sodium in 100 pts. water, or into a solution of 1 pt. iodate of sodium mixed with 3 pts. of caustic soda (Magnus and Ammermüller). Langlois uses equal weights of caustic soda and the iodate, and to obtain a solution as concentrated as possible, first dissolves the caustic soda in water, then adds the iodate, and surrounds the filtered solution with hot water while the chlorine is passing into it; the sodic periodate then separates in considerable quantity, as a crystalline powder, having the composition just mentioned. It is sparingly soluble in cold water, somewhat more in warm water, and may be obtained in the crystalline form from a boiling solution of the neutral salt mixed with caustic soda. At a white heat, it gives off 3 at. water and 8 at. oxygen, and leaves an oxyiodide of sodium:

At a low red heat, it loses only 3 at. oxygen, leaving a residue of *hypo-iodite* of sodium, $Na^2IO^2 = 2Na^2O \cdot IO^2$ (or perhaps a compound of iodide and *iodite* of sodium, $2NaI + 3Na^2O \cdot IO^2$ or $NaI \cdot Na^2O \cdot NaIO^2$). This compound is sparingly soluble in water, has an alkaline reaction, and bleaches vegetable colours, but loses this property when boiled with water, iodate of sodium being then formed, and the salt becoming easily soluble. On exposure to the air it turns moist, and gradually yields free iodine.

Periodate of Zinc.—Hydrated carbonate of zinc is converted by aqueous periodic acid into a granular powder of periodate of zinc, Zn^2HIO^4 or $4ZnO \cdot H^2O \cdot IO^4$, which dissolves readily in excess of the acid, forming a solution, which, when evaporated at a gentle heat, yields laminar crystals of another salt containing $3ZnO \cdot 7H^2O \cdot 2IO^4$, i.e.

a double per-iodic molecule, $Zn^2H^2IO^4 = \left(\frac{IO^4}{Zn^2H^2} \right)^2 O^2$. (Langlois.)

IODINE, SELENIDE, SULPHIDE, and TELLURIDE OF. See SELF-KIUM, SULPHUR, and TELLURIUM, IODIDES OF.

IODITE, IODOPYRITE, IODIC SILVER. Native iodide of silver. (See SILVER, IODIDE OF.)

IODOBENZOIC ACID. $C^6H^5IO^2$.—An acid produced by the action of hydriodic acid on diazobenzoylbenzamic acid:

It crystallises in needles, is heavier than water, easily soluble in alcohol; sublimes without decomposition; forms a white silver-salt, $C^6H^5AgIO^2$, insoluble in water and in alcohol; is converted by fuming nitric acid into nitro-iodobenzoyl acid. (Griess, Ann. Ch. Pharm. cxiii. 201.)

IOBORRUCINE. Syn. with Iodide of Brucine. (See BRUCINE, i. 683.)

iodo-CAOUTCHIN. See CAOUTCHIN (i. 787).

iodo-CHLORO-NITROHARMINE. Syn. with Di-iodide of Chloro-nitro-harmine. (See HARMINE, iii. 12.)

IODOCINCHONINE. See CINCHONINE (i. 979).

IODOCINNAMIC ACID. $C^6H^5IO^2$.—When cinnamic acid is melted with excess of iodine, and the dark brown mass is boiled with water till all the free iodine is volatilised, the liquid on cooling yields small colourless stellate crystals of iodocinnamic acid, which acquire a faint yellow colour on exposure to the air. The acid dissolves easily in hot water and in alcohol. (Herzog, N. Br. Arch. xx. 147.)

IODOCODINE. Syn. with Iodide of Codeine. (See *CODEINE*, i. 1068).

IODOFORM. CHI_3 . *Di-iodated iodide of methyl.* (Gm. vii. 330; Gerh. i. 609.)—This compound, which was discovered in 1824 by Serullas (Ann. Ch. Phys. xxv. 314), is produced by the action of iodine and alkalis or alkaline carbonates on wood-spirit, alcohol, or ether; in small quantity also by the action of the same substances on cane-sugar, glucose, gum, dextrin, and several albuminous substances. It has also been observed among the products obtained by heating glycerin with hydriodic acid. (Erlenmeyer, Jahresb. 1861, p. 668.)

Preparation.—1 pt. of alcohol is added to a solution of 2 pts. crystallised carbonate of sodium in 10 pts. water; the liquid is heated to 60° or 80°; and 1 pt. of iodine is added by small portions, till it is entirely dissolved, and the liquid has become colourless. Iodoform then makes its appearance towards the end of the operation and sinks to the bottom of the hot liquid, which must be filtered to collect this first portion of the product. The mother-liquor is then again heated to 60° or 80°; another portion of carbonate of sodium, equal to the former, is dissolved in it; a fresh portion of alcohol is added; and a current of chlorine is passed into the liquid, which must be continually agitated, so that the iodine which separates may mix well with it. When the process is so conducted that a slight excess of iodine is constantly present, iodoform is produced in abundance. When a considerable quantity has been deposited, the stream of chlorine is interrupted, the liquid is left to decolorise, and the second portion of iodoform is added to the first. The mother-liquor may then be treated with chlorine and a third portion of iodoform obtained. The process, when properly conducted, yields a quantity of iodoform weighing 40 or 50 per cent. of the iodine used. Care must be taken, throughout the operation, to avoid a great excess of iodine, as in that case the iodoform will not be produced at all. Borax may be used instead of carbonate of sodium, and will yield a product of equal amount. With phosphate of sodium the product is not so good. (Filhol, J. Pharm. [3] vii. 267.)

Cornelius and Gille (*ibid.* xxii. 196) prepare iodoform by adding hypochlorite of calcium to an alcoholic solution of iodide of potassium heated to 40°, continuing the addition till the liquid becomes colourless. It then on cooling yields a crystalline deposit, consisting of iodoform mixed with iodate of calcium, from which the iodoform may be dissolved by boiling alcohol. 8 pts. of iodide of potassium yield, by this process, 2 pts. of iodoform and 2 pts. of iodate of calcium.

Properties.—Iodoform crystallises in saccharous scales, friable, soft to the touch, having a sulphur-yellow colour and the odour of saffron. According to Rammelsberg and Kokscharow (Jahresber. 1857, p. 431), the crystals are hexagonal combinations of P. For P the ratio of the secondary axes to the principal axis is 0.9025 : 1. Angle P : P in the terminal edges = 133° 36'; in the lateral edges = 104°. Specific gravity about 2.0. Melts between 116° and 120°, and then vaporises, partly without alteration, partly resolved into iodine and hydriodic acid, with a residue of charcoal. With vapour of water it distils undecomposed. It is not perceptibly soluble in water, acids, or aqueous alkalis, but dissolves readily in alcohol, ether, and oils, both fixed and volatile.

Decompositions.—1. Iodoform heated in a sealed tube to 150°, either alone or with iodine, is resolved into di-iodide of methylene, and a number of brown substances not yet examined (Hofmann, Chem. Soc. J. xiii. 65).—2. Iodoform is acted upon by bromine, yielding bromiodoform, CHBr_2I .—3. With moist chlorine, it yields chloro-carbonic oxide, hydrochloric acid, and protochloride of iodine:

—4. Heated with *pentachloride of phosphorus*, it yields an oily liquid, perhaps chloroform, or according to Butlerow, di-iodide of methylene, CHI_2 .—5. Distilled with *chloride of mercury*, *lead*, or *tin*, it yields chloriodoform, CHCl_2I .—6. Distilled with *sulphide of mercury*, it yields a small quantity of an oily liquid, which, according to Bouchardat (J. Pharm. xxiii. 12) is sulphoform, C_2HS_2 ; but according to Eggert (Chem. Centr. 1857, p. 513) is nothing but disulphide of carbon.—7. With *cyanide of mercury* or *cyanide of silver* it yields a sublimate of iodide of cyanogen.—8. When *cyanogen gas* is passed into an alcoholic solution of iodoform, the liquid becomes heated and assumes a violet tint; and if then left at rest, deposits golden-yellow, prismatic crystals, from which alcohol extracts two substances having a strong metallic lustre; one with a greenish gold, the other with a violet colour; the latter appears to be *cyanide of di-iodo-methyl*, CHI_2Cy (St.-Evre, Compt. rend. xxvii. 533).—9. Heated with alcoholic solution of *sulphocyanate of potassium* to 100° in sealed tubes, it yields a gas and oily compound which has an odour of horse-radish, and forms a crystalline compound with ammonia, though not so readily as oil of mustard (Hlasiwetz, Ann. Ch. Pharm. cxli. 184).—10. *Mercuric oxide*, gently heated with iodoform acts energetically upon it, producing

water, carbonic anhydride, formic acid, and mercuric iodide.—11. Iodoform boiled with *aqueous potash* is partly converted into formate and iodide of potassium, a portion, however, volatilising with the watery vapour.—12. With *alcoholic potash* it forms a liquid which Brüning, who first obtained it (Ann. Ch. Pharm. civ. 187) regarded as C_4H_5IO , but which, according to Butlerow, is di-iodide of methylene, CH_2I_2 , together with iodide of sodium and aldehyde (Butlerow, Ann. Ch. Pharm. cvii. 110):

According to more recent experiments by Butlerow (*ibid.* cxiv. 204; cxviii. 325) it appears that acrylic acid, $C^2H^3O_2$, and ethyl-lactic acid, $C^2H^5O_3$, are likewise formed in this reaction.

14. Iodoform heated with *potassium* produces a violent explosion.

15. With *tri-thyl-phosphine*, iodoform unites directly, without the aid of heat, yielding the tri-iodide of formyl-nonethyl-triphosphonium (Hofmann, Proc. Roy. Soc. x. 189):

IODOLITE. A meteoric mineral mentioned by C. U. Shepard among a number of others which have been but imperfectly described. (Sill. Am. J. [2] ii. 377; vi. 402; xv. 363.)

IODOMECONE. $C^2H^4IO^3$. (J. Brown, Edinb. Phil. Trans. xxi. [1] 49.)—A substance formed by treating pyromeconic acid with excess of protochloride of iodine:

On adding potash to the yellow liquid thus obtained (after separation of a small quantity of iodypyromeconic acid) impure iodomecone is obtained as a black precipitate which redissolves on agitation. The addition of potash must be discontinued as soon as this precipitate exhibits a lighter colour, no longer redissolves on agitation, and is not increased by fresh additions; and by then collecting the precipitate, and washing it with cold water, and repeatedly crystallising it from boiling alcohol, iodomecone is obtained in the pure state. It may be obtained in the same manner from meconic or comenic acid, which differ from pyromeconic acid only by the elements of carbonic anhydride.

Iodomecone forms shining yellow hexagonal plates, having an odour which recalls that of saffron; it has neither an acid nor an alkaline reaction, sublimes below 100° ; is insoluble in water, soluble in alcohol and in ether, insoluble in hydrochloric acid, which does not decompose it even at the boiling heat. It is decomposed by strong nitric acid, and with aid of heat by strong sulphuric acid. Caustic potash, after long boiling, abstracts from it a small portion of iodine.

iodo-substitution compounds. Iodine, though generally speaking very similar in its action to chlorine and bromine, acts for the most part less energetically, and is much less disposed to form substitution-compounds by direct action. Some compounds containing hydrogen, indeed, are acted upon by iodine in the same manner as by bromine or chlorine, part of the hydrogen being abstracted to form hydriodic acid, and its place being supplied by an equivalent quantity of iodine; such is the case with ammonia (iii. 280), ethylamine (ii. 536), methylamine, and phenylamine. But iodated organic acids cannot, for the most part, be formed in this way; to produce them from the original acids it is necessary to use chloride of iodine instead of free iodine, so that the superior affinity of the chlorine for hydrogen may remove it, and enable the iodine to take its place (p. 294) *e. g.* :

On the other hand, Kekulé (Chem. Soc. J. xvii. 206) has lately shown that many iodo-substitution compounds are decomposed by hydriodic acid, iodine being set free and the original acid reproduced, *e. g.* :

It is evident that where this reaction takes place, it is impossible that an iodised compound can be produced by the direct action of iodine on an organic acid. [For an exception, perhaps only apparent, to this rule, see SALICYLIC ACID.]

The action of hydriodic acid on iodated organic compounds just noticed explains the reducing action which it exerts on certain organic acids (p. 285). The reaction takes place in two stages, an iodo-substitution compound being first formed, and subsequently decomposed in the manner above explained. *e. g.* :

IOLITE. Syn. with DICHROÏTE (ii. 320).

IONNAPHTHIN. This name is given by Carey Lea (Sill. Am. J. [2] xxxii. 211) to a colouring matter obtained in preparing naphthylamine from nitronaphthylene by the action of ferrous acetate (*Gmelin's Handbook*, xiv. 95, 5). If the mixture is heated before being treated with caustic potash, a faint red-coloured liquid distills over, which turns violet on addition of mineral acids, and if subsequently heated, assumes a dark purple-blue colour, and after a while yields a black crystalline precipitate, the quantity of which is increased by further heating; this is ionnaphthin. The crystals are black, with green metallic reflex, and dissolve in alcohol with blood-red colour, which, on addition of a very small quantity of sulphuric or nitric acid, changes to scarlet, and finally to purple-blue, is not altered by heating with sulphuric acid, but is changed to straw-yellow by hot nitric acid. From the brown mother-liquor, ammonia throws down dark-coloured flocks, which are insoluble in water and in alcohol, are blackened by dilute sulphuric acid and bichromate of potash, and then form a violet solution with dilute nitric acid.

IPECACUANHA. An emetic substance, the root of several plants growing in South America. All the kinds have nearly the same ingredients, but differ in the amount of the active principle (*emetin*) which they contain. The best is the annulated, yielded by *Cephalis Ipecacuanha*, a small shrubby plant of the rubiaceous order, native of Brazil and New Granada. It is found in commerce in pieces from 2 to 6 inches long and about the thickness of a straw, much bent or twisted, and sometimes branched, with a remarkably knotty character, owing to numerous circular depressions or clefts, which give the whole the appearance of a number of rings. It consists of a central axis called *medullullum*, and an external portion called the *cortical part*. Each of these contains emetin, but by far the greater portion exists in the cortical part.

The following are analyses of different kinds of ipecacuanha :

	a	b		c
		Cortical part.	Medi-tullium.	
Fatty matter	1.2	2	trace	2
Wax	1.2	6		
Resin	16.0	16	1.15	14
Emetin	2.4	10	2.45	16
Non-emetic extract	2.4		5.00	
Gum	53.0	42	20.00	18
Albumin	12.5	20	66.40	48
Starch	trace			
Woody fibre	11.3	4	5.00	2
Gallie acid ?	100.0	100	100.00	100
Loss				

a. Grey ipecacuanha, analysed by Barruch and Richard (the 2.4 per cent. gum includes saline matters). b. Blackish-grey, analysed by Pelletier. c. Reddish-grey, deprived of its medittullium, analysed by Pelletier. In an ash-grey variety, Pelletier found 9 per cent. fatty matter, 12 emetin, and 79 starch, gum, and woody fibre.

Another sort of ipecacuanha is obtained from the *Psychotria emetica*. This kind contains only 9 per cent. emetin; and the undulated or amylaceous ipecacuanha, the produce of *Richardsonia scabra*, contains only 6 per cent. emetin, with 92 per cent. starch. Besides these, the roots of numerous other plants are used in tropical countries as emetics, and often termed ipecacuanha. (Pelouze et Frémy, *Traité*, vi. 399.—*Penny Cyclopædia*, xiii. 17.—Rochleder, *Phytochemie*, s. 131.)

IPECUANIC ACID. An acid existing, according to Willigk (Ann. Ch. Pharm. lxxvi. 342), in the root of *Cephalis Ipecacuanha*. It is extracted from the root by boiling with alcohol, precipitating with basic acetate of lead, and decomposing the lead-salt with sulphydric acid. It is a reddish-brown, very bitter, amorphous mass, soluble in ether, more soluble in alcohol and water. It colours ferric salts green, the colour being changed to violet by ammonia. Its dilute solution does not precipitate neutral acetate of lead. When mixed with an alkali, it absorbs oxygen from the air and becomes coloured. It gives by analysis 56.22 per cent. C, and 6.23 H, whence Willigk deduces the formula $C^{14}H^{16}O^7$. Pelletier (Ann. Ch. Phys. iv. 172) regarded it as gallic acid.

IPOMEIC ACID. An acid produced by the action of nitric acid on rhodoretic acid, a derivative of jalap-resin (q. v.) It agrees with sebacic acid in all its properties excepting its melting point—which is 104° , whereas sebacic acid melts at 127° —and in some of its relations to bases (Mayer, Ann. Ch. Pharm. lxxxiii. 143). See SEBACIC ACID.

IRIDIUM. Ir. Atomic weight 198.26.—The black scales which remain when native platinum is dissolved in nitromuriatic acid were found by Smithson Tennant (Phil. Trans. 1804) to consist of an alloy of two metals, iridium and osmium, hence called iridosmine. The same alloy occurs in flat white metallic grains in native platinum. Iridium has also been observed in combination with about 20 per cent. of platinum, crystallised in octahedrons, which are whiter than platinum, and are said to have a greater density, namely 22.86.

The separation of the osmium and iridium is effected by the following methods:—
1. The iridosmine is mixed with an equal weight of common salt, and subjected to the action of a stream of chlorine in a porcelain tube heated to redness. Double chlorides of iridium and sodium, and of osmium and sodium, are then formed, and if the chlorine is moist, a certain quantity of osmic acid, which volatilises, and may be condensed in aqueous ammonia. The mixture of the double chlorides is detached from the tube and boiled with nitric acid. Osmic acid is then evolved, and may be condensed in an alkaline solution, while the chloride of sodium and iridium remains in the solution, and, when mixed with sal-ammoniac, yields a precipitate of chloride of iridium and ammonium, which, on ignition, leaves metallic iridium. (Wöhler, Pogg. Ann. xxi. 161.)

2. A mixture of 100 grms. of iridosmine and 300 grms. of nitre is placed in an earthen crucible, and heated to bright redness for an hour, the resulting mixture of osmate and iridiate of potassium poured out on a cold metal plate, then introduced into a tubulated retort, and distilled with a large excess of nitric acid. A large quantity of

osmic acid then volatilises and condenses in the receiver in beautiful white crystals. As soon as the evolution of osmic acid ceases, water is added, and the residue, consisting of oxide of iridium, with a certain quantity of oxide of osmium, is collected on a filter and boiled with nitromuriatic acid, which dissolves the two metals as chlorides. The solution is then mixed with sal-ammoniac, which precipitates chlorosmate and chloriridiate of ammonium; and the mixed precipitate is suspended in water and exposed to a current of sulphurous acid, whereby the chloriridiate of ammonium, NH_4IrCl_6 , is converted into chloriridite, $(\text{NH}_4)^2\text{Ir}^{2+}\text{Cl}_4$, which dissolves, while the chlorosmate of ammonium remains unaltered, and does not dissolve: this latter chloride yields pure metallic osmium by calcination. The solution of chloriridiate of ammonium leaves, when evaporated, beautiful brown crystals, which by calcination yield metallic iridium. (Frémy, *Compt. rend.* xviii, 144.)

Iridosmine generally, however, contains platinum as well as other metals of the same group, which are not effectually separated by the methods just described. The complete separation of the several metals of the platinum group has of late years formed the subject of several elaborate investigations, which will be more fully considered under PLATINUM; those more especially relating to iridium are the following:

3. The separation of iridium from platinum depends upon the ready convertibility of the chloriridiate of ammonium or potassium to a lower degree of chlorination by the action of reducing agents, and the easy solubility of the resulting double chloride. Mucklé and Wöhler (*Ann. Ch. Pharm.* civ. 368) treat chloriridiate of ammonium containing platinum with solution of cyanide of potassium, adding the solution cautiously and avoiding an excess, then digest it at a gentle heat till the undissolved portion has acquired a light yellow-brown colour. The chloriridiate of ammonium is thus converted into chloriridite of potassium, which easily dissolves, whereas the chloroplatinate resists the action of the reducing agent much longer, and remains undissolved. The completion of the process is plainly indicated by the change of colour of the undissolved salt, since the presence of a small quantity of the iridium-salt gives a deep red colour to the chloroplatinate.

The separation may also be effected by sulphocyanate of potassium, the action of which is similar to that of the cyanide, but somewhat more complex. It is better, however, to reduce the chloriridiate of ammonium by sulphydric acid, or by sulphurous acid, as in Frémy's method (see above), because metallic iridium may then be immediately obtained by simply evaporating the filtered solution of the chloriridite of ammonium, and igniting the residue. (Claus, *Ann. Ch. Pharm.* cvii. 129; *Jahresb.* 1858, p. 210.)

4. The iridosmine which remains after the complete exhaustion of platinum ore with nitromuriatic acid is a mixture of two substances, one of which is scaly and consists of osmium, iridium, and ruthenium, while the other, which is granular, contains but mere traces of osmium and ruthenium, but is very rich in iridium and rhodium. Now when this residue is heated to bright redness in a porcelain tube through which a current of air (freed from carbonic acid by passing through potash, and from organic matter by passing through oil of vitriol) is drawn by means of an aspirator, osmic acid and oxide of ruthenium are formed, the latter crystallising in the colder part of the tube, while the more volatile osmic acid is carried forwards (see OSMIUM and RUTHENIUM), and an alloy of iridium and rhodium remains behind. To separate these metals, the residue thus obtained is calcined in an earthen crucible with four times its weight of nitre, care being taken not to carry the process too far; and the product is exhausted with boiling water and filtered. The filtrate consists of an alkaline solution of osmite of potassium, the osmium never being completely removed by the previous roasting, while a copious precipitate containing the iridium and rhodium, together with potash, remains on the filter. On treating this precipitate with nitromuriatic acid for several hours, the iridium is converted into chloriridiate of potassium, which may be dissolved out by boiling water, the rhodium still remaining undissolved. (Frémy, *Compt. rend.* xxxviii. 1008.)

5. Iridosmine in fine powder (into which state it may be brought by calcining it in a crucible with four or five times its weight of zinc, till the flame no longer exhibits any trace of that metal) is mixed with 3 pts. peroxide and 1 pt. of nitrate of barium, and heated to redness for an hour. The black friable substance remaining in the crucible, and consisting of osmo-iridiate of barium containing ruthenium, is freed from osmic acid by prolonged boiling with nitromuriatic acid; the baryta is then precipitated by the exact quantity of sulphuric acid required (this quantity being known from the previous weighings); the dark red filtrate mixed with excess of hydrochloric acid is evaporated over the water-bath, and mixed, towards the end of the operation, with a large excess of solid sal-ammoniac; the residue, no longer smelling of acid, is washed, first with a concentrated solution of sal-ammoniac (which dissolves out the rhodium, together with metals not belonging to the platinum group) till the liquid no longer

runs away coloured, then with a more dilute solution of the same salt; the residue, chiefly consisting of chloriridiate of ammonium, is dried, heated to commencing redness (so as to decompose the ammonium-salts completely, the chlorides of the platinum metals imperfectly), then in a current of hydrogen to complete the reduction; and the resulting metallic sponge, in which the metals are not alloyed, but only mechanically mixed, is treated with nitromuriatic acid, which completely removes any platinum that may still be present, but leaves behind a certain quantity of osmium. The remaining pulverulent metallic mass is then fused with a mixture of nitrate and hydrate of potassium; and the unattacked portion of the metal, after being carefully freed from ruthenate of potassium by washing with water, is heated to whiteness in a crucible lined with charcoal, in which it bakes together; then placed in a vessel of lime and ignited in an oxy-hydrogen flame containing excess of oxygen, till every trace of the odour of osmium has disappeared; and lastly, fused at the strongest heat which the oxy-hydrogen flame is capable of producing. (Deville and Debray, *Ann. Ch. Phys.* [3] lvi. 385; *Rép. Chim. pure*, 1859, p. 541; *Jahresber.* 1859, p. 241.)

6. An intimate mixture of 100 pts. iridosmine or platinum-residues, 100 pts. nitrate of barium and 200 pts. caustic baryta, is heated in a red-hot earthen crucible; and the fritted mass, after being pulverised, is thrown by small portions into cold water, then mixed with nitric acid, and heated till all the osmium is driven off as osmic acid. A small quantity of hydrochloric acid is then added; the liquid is heated and filtered through gun-cotton; and the iridium is separated from the other metals contained in it, as in the preceding method. (Deville and Debray, *Compt. rend. liv.* 1138.)

7. Platinum-residue, finely pulverised and freed by levigation from the coarser grains of osmide of iridium, is gently ignited in a covered crucible, then mixed with 1 pt. finely granulated lead and $1\frac{1}{2}$ pt. litharge, and heated, with stirring, in a thick-bottomed hessian crucible till the mixture becomes perfectly fluid. By this means all the silicates and earthy minerals present are converted into a slag; the metals more oxidable than lead are oxidised; and the specifically heavier platinum-metals collect in the lead-regulus. The latter, after being freed from slag, is dissolved at a gentle heat in nitric acid diluted with $1\frac{1}{2}$ vol. water, which dissolves principally copper and palladium, leaving a residue which, when washed by decantation, consists of a fine black metallic powder of iridium, rhodium, and ruthenium, together with fine grains and scales of iridosmine, which must be separated by levigation. The black powder is immediately available for further treatment; the iridosmine, on the other hand (together with the coarser grains obtained by levigating the crude platinum-residue), is reduced to powder by fusing it in a charcoal crucible with twice its weight of granulated zinc, and then raising the heat to whiteness to drive off the zinc (p. 315). The finely divided iridosmine, is then heated in a stream of oxygen to expel the osmium, and the residue, together with the black powder of iridium, rhodium, and ruthenium above-mentioned, is mixed with an equal weight of chloride of sodium, and decomposed by Wöhler's method with chlorine gas (p. 314). The dark brown solution thus obtained is mixed with a little hydrochloric acid and one-fourth of its bulk of ordinary nitric acid, and distilled to one-third, the osmic acid which passes over being condensed by ammonia; the remaining liquid, which contains the double chlorides of iridium, &c., is mixed, while still warm, with an equal volume of a saturated solution of sal-ammoniac; and the red-brown precipitate, after standing for some days, is separated from the liquid, and washed with sal-ammoniac solution till the liquid runs off colourless. The wash-water contains the whole of the rhodium-salt, the mother-liquor consists chiefly of chloride of iron and ammonium, with traces of iridium, rhodium, and gold. The precipitate, consisting of chloriridiate of ammonium contaminated with platinum and ruthenium-salt, is mixed, after drying, with $1\frac{1}{2}$ pt. cyanide of potassium, and melted for 10 or 15 minutes in a capacious porcelain crucible; the cooled mass is dissolved in the smallest possible quantity of water; and the yellow filtrate (after the whole of the free cyanide of potassium has been decomposed by dilute hydrochloric acid) is precipitated by sulphate of copper. The resulting precipitate, consisting chiefly of platino- and iridio-cyanide of copper, is washed with boiling water, first by decantation, then on a filter, and finally decomposed with boiling baryta-water, whereby oxide of copper is separated, and the platinum and iridium are converted into platino- and iridio-cyanides of barium, which are easy to separate, the platinum-salt, which is much more soluble in hot than in cold water, separating out completely at first, and the white iridium-salt crystallising afterwards. The mother-liquor of the iridium-salt contains a small quantity of ruthenio-cyanide of potassium; any rhodium-salt that may be present may be precipitated by acetic acid. (C. A. Martius, *Ann. Ch. Pharm.* cxvii. 357; *Jahresber.* 1860, p. 202.)

8. The following process is given by Deville and Debray (*Ann. Ch. Phys.* [3] lxi. 5; *Jahresb.* 1861, p. 889) for obtaining iridium, pure or alloyed, from the substance

known in the Russian mint as "iridium-oxide"—a not quite uniform mixture containing iridium as oxide, and having the following average composition:

Volatile substances (and oxygen)	28.0
Soluble salts (NaCl and CaSO ⁴)	12.0
Platinum	3.8
Rhodium	1.8
Palladium	0.4
Copper	0.6
Iron	0.7
Iridium (and loss)	52.7
	<hr/> 100.0

The substance is ignited in a crucible lined with charcoal; and the residue is washed with water, heated with strong sulphuric acid to the boiling point of that liquid, and again washed with water, whereby all the soluble salts are removed, together with the copper and iron. If the amount of platinum is known, and the object is to prepare an alloy, the washed metal is heated to whiteness (to give it a compact texture), and then fused before the oxy-hydrogen blowpipe. To obtain pure iridium, the crude metallic powder, after treatment with sulphuric acid, is digested with nitromuriatic acid, the greater part of the iridium (with traces of rhodium) then remaining behind.

Metallic iridium is obtained from the chloride by reducing that salt with hydrogen at a red heat, or by exposing it alone to a very high temperature, or more easily by igniting the chloriridate of ammonium (p. 314), in the form of a grey metallic powder much resembling spongy platinum. It is the most refractory of all bodies excepting ruthenium and osmium; not being fusible in the flame of the ordinary oxy-hydrogen blowpipe. Children, however, by the discharge of a very large voltaic battery, succeeded in melting it into a globule which was white and very brilliant, but still a little porous, and had a density of 18.68; and Deville and Debray, by means of their powerful oxy-hydrogen blast furnace, have fused it completely into a pure white mass, resembling polished steel, brittle in the cold, somewhat malleable at a red heat, and having a density equal to that of platinum, viz. 21.15. By moistening the pulverulent metal with a small quantity of water, pressing it tightly, first between filtering paper, then very forcibly in a press, and calcining it at a white heat in a forge-fire, it may be obtained in the form of a compact, very hard mass, capable of taking a good polish, but still very porous, and of a density not exceeding 16.0. After strong ignition it is insoluble in all acids, but when reduced by hydrogen at low temperatures, it oxidises slowly at a red heat, and dissolves in nitromuriatic acid. It is usually rendered soluble by fusing it with nitre and caustic potash, or by mixing it with common salt, or better with a mixture of the chlorides of potassium and sodium, and igniting it in a current of chlorine, thereby it is converted into the soluble chloriridate of potassium or sodium.

IRIDIUM, ALLOYS OF. 1 pt. of iridium combines at a white heat with 4 pts. of copper, forming a ductile, pale red alloy, which is much harder than copper, and gives up its copper to nitric acid, the iridium remaining in the form of a black powder.

With gold, iridium forms a malleable alloy, having a colour very much like that of gold: nitromuriatic acid dissolves out the gold and leaves the iridium.

1 pt. of iridium and 8 pts. lead heated together to an intense red heat, form an alloy which is very ductile, but much harder and whiter than lead, and behaves with nitric acid like the copper alloy. On cupellation, the iridium is left as a soft black powder.

With mercury, iridium forms a viscid amalgam, which is obtained by immersing sodium-amalgam in an aqueous solution of chloriridate of sodium. When very strongly ignited, it leaves a black powder, from which boiling nitric acid extracts a small quantity of mercury, leaving a residue of pure iridium, soluble in boiling nitromuriatic acid. (Böttger, J. pr. Chem. xii. 252.)

The compound of iridium and osmium is not, properly speaking, an alloy, inasmuch as osmium is rather a metalloïd than a metal. (See IRIDOSMINE.)

Platinum and iridium easily melt together, and form alloys which, even when they contain 20 per cent. of iridium, are still malleable and capable of being worked, but are less easily attacked by chemical reagents than pure platinum. (Deville and Debray.)

Equal weights of the two metals form a brittle alloy capable of welding to a certain extent. The alloy of platinum with a few parts per cent. of iridium is ductile and much harder than pure platinum, and more capable of resisting the action of fire and of chemical reagents (Berzelius). An alloy made by fusing 1 pt. iridium and 10 platinum in the

flame of the oxyhydrogen blowpipe, is very malleable, susceptible of hardening, does not tarnish, and when laid on copper serves for metallic mirrors. (Gaudin, *J. pr. Chem.* xvi. 55.)

A native alloy of iridium and platinum called native iridium occurs in the Ural in cubo-octahedrons of specific gravity varying from 21.85 to 22.66 and 22.8, and in Brazil in white round grains of specific gravity 16.94. (Svanberg, *Gmelin's Handb.* vi. 392.)

	Pt.	Ir.	Rh.	Pd.	Os.	Fe.	Cu.	
Ural	19.64	76.85		0.89			1.78	= 99.16
Brazil	55.44	27.79	6.86	0.49	trace	4.14	3.30	= 98.02

1 pt. of iridium unites but imperfectly with 2 pts. of silver. (Vauquelin.)

1 pt. of iridium unites with 4 pts. of tin at an intense red heat, forming a dull white easily crystallisable, hard, malleable alloy. (Vauquelin.)

When iridosmine is fused with from 5 to 6 times its weight of tin, the alloy being kept for a long time at a red heat in the charcoal crucible, then slowly cooled and treated with hydrochloric acid, tin passes into solution, together with traces of iridium, and there remains a mixture (separable by a fine sieve) of finely pulverulent crystalline osmium, and large shining cubic crystals of an alloy of tin and iridium, which is not attacked by nitromuriatic acid, but when strongly ignited in an atmosphere of sulphydric acid, gives off the whole of the tin, amounting to 56.6 per cent., as sulphide, leaving 43.4 per cent. iridium.—By fusing tin with a mass containing platinum, iridium, and rhodium, and dissolving the excess of tin in hydrochloric acid, a crystalline residue is obtained, whose composition (if Pt denotes the platinum metals in general) is PtSn^2 . (Deville and Debray.)

An alloy of iridium and zinc, obtained as in Deville and Debray's first method of preparing an alloy of iridium and tin, is not crystallisable.

IRIDIUM, CARBIDE OF. When a coherent mass of iridium is held in the flame of a spirit-lamp, black masses appear on its surface, which are a carbide containing 19.83 per cent. carbon, or IrC^4 . The carbon burns off readily in the air.

IRIDIUM, CHLORIDES OF. Iridium appears to form four compounds with chlorine; but only two of them have been obtained in definite form.

The *dichloride*, IrCl^2 , is said by Berzelius to be formed when pulverised iridium is heated to low redness in chlorine gas. It is described as a dark olive-green powder, insoluble in water, slightly soluble in hydrochloric acid, and forming double salts with the chlorides of the alkali-metals. According to Claus, however (*Ann. Ch. Pharm.* lix. 255), the so-called dichloride of iridium is merely a mixture of the trichloride with metallic iridium. The dichloride appears, however, to exist in certain double salts (p. 322).

The *trichloride*, Ir^3Cl^3 , is prepared by dissolving the sesquioxide in hydrochloric acid, and evaporating; it also sublimes when iridium, either alone or mixed with nitre, is ignited in chlorine gas. It is black, deliquescent, and does not crystallise. It unites with the chlorides of the alkali-metals, forming double salts, called chloroiridites, which are prepared, either by mixing the solutions of the component chlorides in the required proportions, and evaporating, or by reducing the solutions of the corresponding chloriridates with sulphurous acid, sulphydric acid, alcohol, or ferrocyanide of potassium. Claus has obtained the compounds $6\text{NH}^+\text{Cl}^-\text{Ir}^3\text{Cl}^3$, $6\text{H}^2\text{O}$, $6\text{KCl}^-\text{Ir}^3\text{Cl}^3$, $6\text{H}^2\text{O}$, and $6\text{NaCl}^-\text{Ir}^3\text{Cl}^3$, $24\text{H}^2\text{O}$. They are olive-green, pulverulent salts, soluble in water; the sodium-salt is also soluble in alcohol; the other two are insoluble in alcohol. Berzelius obtained a potassium-salt containing $4\text{KCl}^-\text{Ir}^3\text{Cl}^3$.

Chloriridite of silver, $\text{Ag}^+\text{Ir}^3\text{Cl}^3 = 6\text{AgCl}^-\text{Ir}^3\text{Cl}^3$, is produced, on adding nitrate of silver to aqueous chloriridate of potassium, as a deep indigo-coloured flocculent precipitate, which, however, becomes paler in a few seconds, and finally loses its colour altogether. The reaction, which is attended with evolution of oxygen, is:

With a boiling solution of chloriridate of potassium, the same compound is formed immediately, without the intermediate production of a blue substance. The silver-salt is insoluble in water and in acids, and but slightly soluble in ammonia. When it is covered with strong aqueous ammonia and left to itself for a few days, one portion dissolves, and the remainder is converted into a crystalline modification of the salt composed of rhombohedrons having an adamantine lustre. (Claus, *Ann. Ch. Pharm.* lxiii. 338.)

The *tetrachloride*, IrCl^4 , is obtained by dissolving very finely divided iridium, or one of its oxides, or the trichloride, in nitromuriatic acid, and heating the liquid to the boiling point. On evaporating the solution, it remains in the form of a black, deliquescent, amorphous mass, translucent with dark red colour at the

algebra. It sustains a rather strong heat without decomposition, but at a higher temperature is reduced to the trichloride and ultimately to metallic iridium (Berzelius). It dissolves in water, forming a reddish-yellow solution. It unites with the alkaline chlorides, forming definite crystalline double salts called chloriridates, the general formula of which is $M^2IrCl_6 = 2MCl \cdot IrCl_6$. The ammonium-salt, $2NH_4Cl \cdot IrCl_6 \cdot H_2O$ or $(NH_4)_2IrCl_6 \cdot H_2O$, is obtained, on mixing the solutions of the component chlorides, as a very dark brown precipitate, which dissolves in boiling water and crystallises in octahedrons on cooling. It dissolves in 20 pts. of cold water, forming a dark red brown liquid, and imparts distinct coloration to 4,000 pts. of water. The red colour often exhibited by chloroplatinate of ammonium is due to small quantities of this salt. The aqueous solution supersaturated with ammonia forms a pale yellow mixture, which becomes perfectly colourless when exposed to light, but afterwards turns purple, then violet, and finally assumes a beautiful blue colour.

The chloriridates are easily converted, by the action of sulphurous acid, sulphydric acid, and other reducing agents, into the more soluble chloriridites, a reaction which affords the means of separating iridium from platinum, the chloroplatinates being but very slowly reduced under the same circumstances, and not converted into more soluble salts (p. 315).

The *potassium-salt*, $K_2IrCl_6 = 2KCl \cdot IrCl_6$, is precipitated on mixing the aqueous solutions of its component salts. It may also be prepared by passing chlorine gas over a gently ignited and intimate mixture of finely divided iridium and chloride of potassium; filtering from unaltered iridium; dissolving the unfused black-brown mass in hot water; mixing it with nitromuriatic acid and evaporating to dryness; extracting the excess of chloride of potassium by small quantities of cold water; dissolving the residuum in boiling water; adding a small quantity of nitromuriatic acid; and evaporating to the crystallising point. It crystallises in black octahedrons, yielding a red powder. It dissolves very slowly in cold water, but quickly in boiling water, forming a liquid which appears deep red in the mass, but yellow in thin films. It is insoluble in saline solutions and in alcohol, which precipitates it from solution in water. The aqueous solution, mixed with excess of potash, behaves in the same manner as the ammonium-salt with excess of ammonia. At a strong heat, it is converted into chloriridite of potassium, and at a still higher temperature, leaves metallic iridium mixed with chloride of potassium. The *sodium-salt*, $Na_2IrCl_6 \cdot 6H_2O$ or $2NaCl \cdot IrCl_6 \cdot 6H_2O$, is obtained, like the potassium-salt, by passing chlorine over a gently ignited mixture of iridium and chloride of sodium. It forms black tables and four-sided prisms with dihedral summits, isomorphous with the corresponding platinum-salt. When heated, they leave the anhydrous salt in the form of a brownish-grey powder. It is easily soluble in water, and the solution mixed with sal-ammoniac yields a precipitate of chloriridate of ammonium.

A *hexachloride* of iridium was obtained by Berzelius, in combination with chloride of potassium, by fusing iridosmine with nitre, distilling the product with nitromuriatic acid, and treating the residue with successive portions of water. A dark red solution was then obtained, which yielded a salt having the composition $6KCl \cdot IrCl_6$, but according to Claus, the salt thus obtained was really a ruthenium-compound, having been prepared by Berzelius from iridosmine containing ruthenium. Pure iridium fused with nitre and distilled with nitromuriatic acid, yields a salt containing dichloride of iridium.

IRIDIUM, DETECTION AND ESTIMATION. Iridium in its free state is easily distinguished from all other metals, excepting rhodium and ruthenium, by its insolubility in acids, not being attacked in the compact state by any acid whatever, and in the state of fine division, only very slowly by nitromuriatic acid. Its infusibility, even in the ordinary oxy-hydrogen blowpipe flame, serves also to distinguish it from all metals excepting rhodium, ruthenium, and osmium.

It may be distinguished from rhodium by fusing it in the finely divided state with acid sulphate of potassium. The iridium is then converted into sesquioxide, but does not dissolve in the acid sulphate or colour it red, as rhodium does. Another method of distinguishing iridium from rhodium, and likewise from ruthenium, is to mix it intimately with chloride of potassium or sodium, heat the mixture in a stream of chlorine, and dissolve the resulting double chloride in water: iridium thus treated yields a black-brown solution, rhodium a rose-red, and ruthenium an orange-yellow solution. (See RHODIUM and RUTHENIUM.)

All compounds of iridium are easily reduced to the metallic state by ignition in an atmosphere of hydrogen; the reduced metal may then be tested in the manner just described.

Iridic solutions (containing the dioxide or tetrachloride), which are those of most frequent occurrence, are of a dark brown-red colour; iridos solutions (containing the sesquioxide or trichloride) have an olive-green colour. The characters of an iridic solution are best observed with chloriridate of sodium, as all the other compounds are but very slightly soluble.

Caustic *potash* in excess decolorises the solution of an iridic salt, changing the dark red colour to a very faint greenish tint, and after some time throws down a slight black-brown precipitate of chloriridate of potassium. If the clear solution be heated, and then left in contact with the air, it first acquires a faint red and then a blue colour, gradually increasing in intensity from the surface downwards, and ultimately becoming as deep as that of an ammoniacal solution of copper. The solution evaporated to dryness, leaves a white mass, which, when treated with water, yields a colourless solution and an insoluble blue powder consisting, according to Claus, of iridic hydrate. This is the most characteristic of all the reactions of iridium. The presence of *palladium* interferes, however, with the production of the blue colour, and gives rise to the precipitation of iridic oxide. A solution of iridium containing *platinum* is likewise not coloured blue by potash, but is decolorised, and yields a red precipitate of chloroplatinate of potassium containing iridium; on heating the liquid, this precipitate redissolves, and another precipitate is formed consisting of platiniferous iridic oxides. If the solution contains *rhodium*, no alteration takes place at first; but subsequently, a light yellow precipitate of rhodic hydrate is produced; or if the solution is hot, the precipitate is of a dirty greyish-green colour, and the solution becomes colourless.

Ammonia in excess also decolorises iridic solutions, and forms a slight blackish precipitate. On boiling the solution for some time, till the greater part of the ammonia is expelled, the solution acquires a blue colour, especially if left exposed to the air; but the colour is neither so pure nor so deep as that produced by potash. The presence of *palladium*, *platinum*, or *rhodium* modifies the reaction with ammonia much in the same manner as with potash. *Carbonate of potassium* forms a red-brown precipitate, which gradually dissolves, the liquid afterwards turning blue when exposed to the air. *Carbonate of ammonium* imparts a blue colour to the liquid under the influence of the air. *Sulphydic acid* decolorises the solution at first, and afterwards forms a brown precipitate. *Chloride of ammonium* forms a dark cherry-red, pulverulent precipitate of chloriridate of ammonium. *Ferrocyanide of potassium* and *protosulphate of iron* decolorise the solution. *Dichloride of tin* forms a light brown precipitate. *Zinc* precipitates metallic iridium as a black powder.

Quantitative estimation and separation.—Iridium is completely precipitated from the solution of an iridic salt by treating the solution with chloride of ammonium or chloride of potassium, and then adding alcohol containing ether, in which the chloriridate of ammonium or potassium is quite insoluble. The precipitate may be collected on a weighed filter, washed with alcohol and ether, dried in the water-bath, and then weighed. The ammonium-precipitate contains 44.21 per cent., the potassium-precipitate 40.38 per cent. iridium. The ammonium-precipitate may also, after washing with ether-alcohol (not on a weighed filter), and drying, be carefully ignited in a tared platinum crucible, and the weight of the remaining iridium directly determined.

If the iridium exists in solution as sesquichloride, it must, before precipitation, be converted into dichloride by passing chlorine gas into it, or heating it with nitromuriatic acid.

The mode of precipitation just described serves for the separation of iridium from all metals excepting platinum, rhodium, ruthenium, and osmium; and from all these, except rhodium, it may be separated by reducing it to the state of sesquichloride, and then adding to the liquid an excess of a concentrated solution of sal-ammoniac. Chloriridate of ammonium, $6\text{NH}^+\text{Cl}.\text{Ir}^{2+}\text{Cl}^-$, is then formed, which is soluble in sal-ammoniac, whereas the double compounds of chloride of ammonium with the chlorides of the other platinum-metals (except sesquichloride of rhodium) are insoluble in excess of chloride of ammonium.

The reduction of dichloride of iridium in solution to sesquichloride may be effected by any of the reducing agents already mentioned (pp. 315, 316), but the most convenient for analytical purposes is *sulphydic acid*.

When, for example, iridium is to be separated from platinum, both being in the form of tetrachlorides, the mixture of these compounds, or rather their double salts with chloride of ammonium or potassium, may be treated with a small quantity of water, and solution of sulphydic acid added by small portions. The reduction of the iridic chloride then takes place immediately, a green liquid being formed, rendered milky by precipitated sulphur, and coloured brown by sulphide of platinum, if that metal is present in rather large proportion. Iridium is not precipitated from its solutions as sulphide by sulphydic acid at ordinary temperatures, unless the reagent is added in very large excess, and even then the precipitation takes at least 24 hours. The reduction of the iridium to trichloride being complete, sal-ammoniac is added in excess, and the liquid filtered. The platinum then remains undissolved, while the iridium passes into the filtrate, and may be reconverted into tetrachloride by means of nitromuriatic acid, and precipitated as already described.

The same method may serve to separate iridium from osmium, but the separation

of that metal from the other members of the group is generally effected by distillation with nitromuriatic acid, or by roasting in an atmosphere of oxygen. (See Osmium.)

Palladium is easily separated from iridium by precipitation with cyanide of mercury, which does not throw down iridium; also by fusion with acid sulphate of potassium, which dissolves the palladium, but merely oxidises the iridium.

The separation of iridium from rhodium may be effected, when the former is in the state of tetrachloride and the latter in the state of trichloride, by treating the solution with excess of chloride of ammonium, which forms, with trichloride of rhodium, a double salt soluble in excess of chloride of ammonium, whereas chloriridate of ammonium is insoluble in excess of that salt. Another mode of separation is founded on the fact that chloriridate of sodium is soluble, and chlororhodiate of sodium insoluble, in alcohol. The method of fusion with acid sulphate of potassium, whereby rhodium is dissolved while iridium is merely oxidised, serves for the qualitative distinction between the two metals (p. 319), but is not adapted for quantitative separation, because the solution of the rhodium takes place but slowly, and when a small quantity of it is mixed with a considerable quantity of iridium, not a trace of it is taken up by the fused acid sulphate. (See Rhodium.)

Atomic Weight of Iridium.—The only known determination of this number is that made in 1828 by Berzelius (Pogg. Ann. xiii. 435), and founded on the analysis of chloriridate of potassium, $2\text{KCl}.\text{IrCl}^4$. 100 parts of this salt ignited in a stream of hydrogen lost 29 pts. of chlorine. Now, as only 4 at. chlorine are given off, the chloride of potassium not being decomposed, we have, for determining the atomic weight of iridium (taking $\text{K} = 39.2$ and $\text{Cl} = 35.5$), the proportion

$$291.4 + \text{Ir} : 142 = 100 : 29$$

whence

$$\text{Ir} = 198.26.$$

IRIDIUM, IODIDES OF. (Oppler, *Ueber die Jodverbindungen des Iridiums* (Dissertation), Göttingen, 1857; Jahresb. 1857, p. 263).—Iridium appears to form three compounds with iodine, namely, IrI^2 , IrI^4 and IrI^6 .

The *di-iodide*, IrI^2 , or *Hypo-iridious iodide*, appears to be formed, as a brown powder, by passing sulphurous acid gas into water in which iridic iodide is suspended. By dissolving finely pulverised chloriridate of ammonium in a boiling concentrated solution of iodide of potassium, and leaving the liquid to stand for a few hours, *hypo-iridite of ammonium*, $(\text{NH}^4)^2\text{IrI}^4$ or $2\text{NH}^4.\text{IrI}^2$, separates as a black crystalline powder or in blackish-grey spangles.

The *tri-iodide*, IrI^4 , or *Iridious iodide*, separates as a black crystalline precipitate on adding chloride of ammonium to aqueous iodiridate of potassium, K^2IrI^6 (iodiridate of ammonium being probably formed in the first instance, and subsequently resolved into tri-iodide of iridium, iodide of ammonium, and free iodine). It is very sparingly soluble in cold water, somewhat more freely in hot water, insoluble in alcohol. It unites with alkaline iodides, forming double salts which may be called iodiridites. The *ammonium-salt*, $(\text{NH}^4)^3\text{IrI}^6.2\text{H}^2\text{O}$ or $6\text{NH}^4.\text{IrI}^3.2\text{H}^2\text{O}$, separates in crystalline needles from the mother-liquor of hypo-iridite of ammonium (see above) on repeated concentration, first together with the latter, afterwards alone. The *potassium-salt*, $\text{K}^6\text{IrI}^{12}$, separates on adding a concentrated solution of iodide of potassium to a solution of trichloride of iridium, as a fine crystalline powder, having a green lustre, insoluble in water and in alcohol, dissolving slowly in acids, easily in alkalis when heated. The *silver-salt*, $\text{Ag}^4\text{IrI}^{12}$, is obtained on adding nitrate of silver to a solution of iod-iridate of potassium, as a dark green amorphous precipitate, which afterwards turns brown. The reaction by which it is formed is similar to that of nitrate of silver on chloriridate of potassium (p. 318).

The *tetra-iodide*, IrI^4 , or *Iridic iodide*, is obtained as a soft black powder by adding iodide of potassium to a strong solution of tetrachloride of iridium, and boiling the brown-red liquid, mixed with a little hydrochloric acid. With alkaline chlorides it forms the iodiridates. The *ammonium-salt*, $(\text{NH}^4)^2\text{IrI}^6$, or $2\text{NH}^4.\text{IrI}^3$, separates after some weeks from a solution of chloriridate of ammonium in cold concentrated aqueous iodide of potassium, in dark brown shining crystals easily decomposed by heat. The aqueous solution, when gently heated, becomes turbid and black-brown, depositing hypo-iodiridite of ammonium, $(\text{NH}^4)^2\text{IrI}^4$, and iridic iodide. The *potassium-salt*, K^4IrI^6 or $2\text{K}.\text{IrI}^3$, separates after the iridic iodide itself, from a solution of iridic chloride mixed with iodide of potassium. It is formed also, though in small quantity only, by the action of iodine-vapour on an intimate mixture of iridium and iodide of potassium heated to 60° — 70° ; and in larger quantity, by adding iridic chloride to a solution of iodide of potassium, the latter being kept in excess; or by dis-

solving the iridic iodide in iodide of potassium, and leaving the solution to crystallise. It forms dark, metallic-shining, crystalline spangles, appearing as octahedrons under the microscope, easily soluble in water, insoluble in alcohol; it is dissolved by acids, and, with decomposition, by alkalis. The *sodium-salt*, $\text{Na}^2\text{IrI}^6 = 2\text{NaI}.\text{IrI}^6$, is obtained on adding a concentrated solution of iodide of sodium to iridic chloride, as a dark brownish-green crystalline powder, insoluble in alcohol and in cold water, sparingly soluble in hot water.

IRIDIUM, OXIDES OF. Iridium forms four compounds with oxygen, namely, IrO , Ir^2O^3 , IrO^2 , and IrO^3 . The *protoxide*, or *Hypo-iridious oxide*, IrO , is but little known. It is obtained by precipitating an alkaline hypochloriridite with caustic alkali in an atmosphere of carbonic anhydride (p. 323); but on exposure to the air it is quickly converted into a higher oxide. (Claus.)

The *sesquioxide*, or *Iridious oxide*, Ir^2O^3 , was formerly regarded as the most easily formed and most stable of the oxides of iridium; but, according to Claus, it has a great tendency to take up oxygen and pass to the state of dioxide. It may be prepared by gently igniting a mixture of chloriridite of potassium ($6\text{KCl}.\text{Ir}^2\text{Cl}^6$) with carbonate of sodium in an atmosphere of carbonic anhydride; on treating the product with water, the sesquioxide remains in the form of a black powder insoluble in acids (Claus, Ann. Ch. Pharm. lix. 251). It forms two hydrates, one containing 3 at., the other 5 at. water. The trihydrate, $\text{Ir}^2\text{O}^3.3\text{H}^2\text{O}$, is obtained by treating a solution of the olive-green sesquichloride, or one of its double salts, with potash and alcohol, as a black precipitate, which, when treated with hydrochloric acid, yields a small quantity of olive-green sesquichloride. The pentahydrate, $\text{Ir}^2\text{O}^3.5\text{H}^2\text{O}$, is obtained by mixing the solution of either of the double salts of trichloride of iridium with a small quantity of caustic potash, and leaving the liquid for some time to itself in well-closed and perfectly filled bottles. It is then deposited as a yellowish precipitate with a tinge of olive green; but it cannot be obtained pure, as it easily takes up oxygen, turning blue, and being partially converted into dioxide. It dissolves in the smallest quantity of potash.

Sesquioxide of iridium unites with bases, forming salts which may be called iridites. A solution of a chloriridite in excess of lime-water deposits, after standing for some time out of contact of air, a dirty yellow precipitate containing $\text{Ca}^2\text{Ir}^2\text{O}^6$ or $3\text{CaO}.\text{Ir}^2\text{O}^3$. (Claus, J. pr. Chem. lxxx. 282; Jahresh. 1860, p. 207.)

The *dioxide*, or *Iridic oxide*, IrO^2 , is, according to Claus, the most easily prepared and most stable of all the oxides of iridium, and is always deposited in the form of a bulky, indigo-coloured hydrate, $\text{Ir}^2\text{O}^2.2\text{H}^2\text{O}$, when a solution of either of the chlorides of iridium or their double salts is boiled with an alkali; but it always retains 3 or 4 per cent. of the alkali. The hydrate may also be obtained by dissolving the hydrated sesquioxide in potash and treating the solution with an acid. A greenish-blue precipitate is then formed, which gradually absorbs oxygen from the air and assumes an indigo-colour. The hydrate parts with its water when heated. It dissolves in acids, forming solutions which are dark brown when concentrated, reddish-yellow when dilute.

The *trioxide*, or *Periridic oxide*, IrO^3 , is formed, according to Claus, when iridium is fused for some time with nitre. The resulting blackish-green mass dissolves in water, forming a deep indigo-coloured solution of basic periridiate of potassium, leaving a black crystalline powder consisting of acid periridiate. This powder, when washed, is perfectly neutral and tasteless, and dissolves with indigo-colour in hydrochloric acid, giving off a very large quantity of chlorine. The quantity of potash in it is variable, but the iridium and oxygen (in the acid) constantly maintain the proportion of 1 to 3. (Claus, Ann. Ch. Pharm. lix. 249.)

IRIDIUM, OXYGEN-SALTS OF. Iridium, like the other platinum-metals, shows but little tendency to form oxygen-salts. The oxides dissolve in acids, but no definite salts are obtained in this way. The solution of iridic oxide in sulphuric acid has a dark brown colour, which is not modified by potash in the same manner as that of the tetrachloride, neither does it yield any blue precipitate on boiling.

The only definite oxygen-salts of iridium that have been obtained are double salts, containing sulphurous and hypsulphuric acids.

a. *Hypo-iridoso-potassic Sulphite*. $3(\text{K}^2\text{O}.\text{SO}^2).\text{IrO}^2.2\text{SO}^2 = (\overset{\text{SO}}{\text{IrK}})^4\text{O}^6.\text{SO}^2$.—This salt is obtained as a white powder when the mother-liquor obtained in preparing chloriridite of potassium by passing sulphurous anhydride through a solution of the chloriridiate (p. 318), is evaporated to a small bulk. It is somewhat crystalline, nearly tasteless, insoluble in water, but dissolves easily in hydrochloric acid, giving off sulphurous anhydride, and yielding a yellow prismatic salt, in which 3 at. SO^2 are replaced by 6 at. Cl. It dissolves in potash, forming a solution which is decomposed

by heat, with separation of blue iridic hydrate. The crystals contain 5 at. water, which is given off at 180° ; at a higher temperature, the salt is completely decomposed. (Claus, Ann. Ch. Pharm. lxiii. 352.)

β . Acid Hypo-iridious Sulphite with Chloride of Potassium, $6KCl \cdot IrO \cdot 2SO^2$.—Produced by treating the salt α with hydrochloric acid. The resulting yellow solution yields by evaporation, pale yellow prisms, very soluble in water, and having an astringent somewhat sweetish taste. At a red-heat it gives off sulphurous anhydride, and leaves a mixture of metallic iridium with chloride and sulphate of potassium. (Claus, loc. cit.)

γ . A salt containing $4KCl \cdot IrCl^2 \cdot (2K^2SO^2 \cdot IrSO^2 \cdot SO^2) \cdot 12H^2O$ is obtained by heating a solution of chloridite of potassium with acid sulphite of potassium till the green colour changes to red, and carefully evaporating. It forms minium-red crystals, yields protoxide of iridium when treated with carbonate of potassium in an atmosphere of carbonic anhydride, and is converted by prolonged heating with acid sulphite of potassium, into the white salt, α . (Claus, Ann. Ch. Pharm. cvii. 129.) In a former memoir (Ann. Ch. Pharm. lxiii. 344–348) Claus represented this salt by the formula $2(KO \cdot SO^2) \cdot 2KCl \cdot 2IrO \cdot S^2O^2Cl$, in which the protoxide of iridium was supposed to be combined with a chloro-hyposulphuric anhydride S^2O^2Cl . The same acid may be supposed to exist in the two following salts:

δ . $4KCl \cdot 2IrO \cdot S^2O^2Cl$.—Formed by treating the preceding salt with hydrochloric acid. Deep red prismatic crystals, easily soluble, with yellow colour, in water, insoluble in alcohol. The air-dried crystals contain 5 and 6 per cent. water ($=4H^2O$), which is given off at 180° . Alkalis slowly decompose the salt, and nitromuriatic acid converts it, after some time, into an iridic salt. Its composition might also be represented by the formula $2KSO^2 \cdot (2KCl \cdot Ir^2Cl^2)$; but it appears to contain a proto-rather than a sesqui-compound of iridium.

ϵ . $4(KO \cdot SO^2) \cdot IrO \cdot S^2O^2Cl$.—This salt is contained in the mother-liquor of δ , and separates as a translucent, amber-coloured, viscid mass, which dries up to an amorphous translucent substance, yielding a yellow powder. It is decomposed by water, part of it dissolving, while the rest is converted into the white salt α . (Claus, Ann. Ch. Pharm. lxiii. 351; see also *Gmelin's Hand-book*, vi. 388.)

IRIDIUM, SULPHIDES OF. Four of these compounds are described, analogous to the oxides, and obtained by precipitating the solutions of the chlorides with sulphydric acid. The *protosulphide*, IrS , obtained also by heating either of the higher sulphides in a close vessel, is grey or blackish-blue. According to Berzelius, it dissolves in nitric acid, forming hypo-iridious or iridious sulphate; and in sulphide of potassium more easily than sulphide of platinum. The *sesquisulphide*, Ir^2S^3 , is a brown-black precipitate, sparingly soluble in water [? when partially oxidised], and behaving like the protosulphide with nitric acid and sulphide of potassium (Berzelius). The *disulphide*, IrS^2 , is obtained by precipitation, also by igniting chloridite of ammonium with an equal weight of sulphur (Vauquelin); by igniting pulverulent iridium with sulphur and an alkaline carbonate, and exhausting the product with water (Fellenberg, Pogg. Ann. lix. 66); and by mixing a solution of tetrachloride of iridium in strong alcohol with sulphide of carbon, and leaving the mixture in a closed vessel for a week. It is then converted into a gelatinous mass, which is to be broken up, collected on a filter, washed with alcohol, then repeatedly boiled with water, filtered and dried. The product thus obtained is disulphide of iridium. It is a dark yellow-brown powder, which is decomposed by heat, leaving the protosulphide or metallic iridium according to the temperature to which it is raised. The disulphide obtained by precipitation behaves with nitric acid and with sulphide of potassium like the protosulphide. The *trisulphide*, IrS^3 , is obtained by decomposing the trichloride with sulphydric acid, but to complete the decomposition, the liquid saturated with sulphydric acid must be left for a considerable time in a closed vessel at 60° . It is a dark yellow-brown precipitate, which behaves like the preceding compounds with nitric acid and sulphide of potassium. (Berzelius.)

IRIDIUM-BASES, AMMONIACAL. *Ammonio-dichloride of iridium*, $2NH^4 \cdot IrCl^2$, or *Chloride of iridammonium*, $N^2H^4 \cdot Ir^2 \cdot Cl^2$, is prepared by heating tetrachloride of iridium till it is converted into dichloride, dissolving the brown resinous residue in carbonate of ammonia, and adding hydrochloric acid in slight excess. The compound then separates in the form of a yellow granular precipitate, insoluble in water. The oxide corresponding to this chloride has not been obtained in the free state. The *sulphate*, $N^2H^4 \cdot Ir^2 \cdot SO^2$, is obtained by heating the chloride with dilute sulphuric acid. It crystallises in large orange-yellow laminae, easily soluble in water.—*Tetrammonio-dichloride of iridium*, $4NH^4 \cdot IrCl^2$, or *Chloride of ammiridammonium*, $N^4H^4 \cdot (NH^4)^2 \cdot Ir^2 \cdot Cl^2$, is obtained as a white precipitate.

pitate, by boiling the compound, $N^2H^4Ir^{II}.Cl^2$, with excess of ammonia. Treated with moderately strong sulphuric acid, it yields the corresponding sulphate $(N^2H^4(NH^4)Ir^{II}.SO^4)$ in rhombic prisms; and, by decomposing this salt with nitrate of barium, or the chloride with nitric acid, the nitrate is obtained in yellow needles, which dissolve readily in water, melt when heated, and then suddenly decompose with flame.—

Chloronitrate of ammiridammonium, $N^2H^4(NH^4)Ir^{II}\left\{\begin{smallmatrix} (NO^3)^2 \\ Cl^2 \end{smallmatrix}\right\}$, or *Nitrate of ammochlori-*

ridammonium, $N^2H^4(NH^4)^2(IrCl^2).2NO^3$, analogous to Gros' platinum-nitrate, is obtained as a yellowish, crystalline, granular mass, by heating the chloride of iridammonium, $N^2H^4IrCl^2$, with strong nitric acid; when recrystallised from water, it forms shining, yellow, laminar crystals.—*Dichloride of ammiridammonium*, $N^2H^4(NH^4)^2Ir^{II}.Cl^2$, or *Chlo-*

ride of ammochloriridammonium, $N^2H^4(NH^4)^2(IrCl^2).Cl^2$, is obtained by treating the last-mentioned salt with hydrochloric acid, in the form of a violet precipitate, which dissolves readily in hot water, and separates from the solution in violet crystals. Nitrate of silver added to the solution throws down only half the chlorine. The nitrate, treated with dilute sulphuric acid, yields the chlorosulphate of ammiridammonium, in delicate greenish, needle-shaped crystals. (Skoblikoff, Ann. Ch. Pharm. lxxxiv. 276.)

The compound $10NH^3.Ir^2Cl^6$, or $N^2H^4(NH^4)^2Ir^{II}\left\{\begin{smallmatrix} Cl^6 \\ N^2H^2(NH^4)Ir^{II} \end{smallmatrix}\right\}$, is obtained by mixing a dilute

solution of chloriridite of ammonium, $(NH^4)Ir^4Cl^{12}$, with excess of ammonia, and leaving the mixture in a well-closed and completely filled bottle for some weeks in a warm place; heating the liquid, which has then acquired a rose colour, to expel the excess of ammonia; neutralising with hydrochloric acid, evaporating to dryness, and treating the greenish-yellow residue with cold water to extract the chloride of ammonium. A light flesh-coloured, finely crystalline powder then remains, which, when dissolved in boiling water acidulated with hydrochloric acid, yields on cooling, a crystalline precipitate of $10NH^3.Ir^2Cl^6$, mixed with trichloride of iridium. This compound, when dissolved in a boiling solution of ammonia, is partially decomposed, with separation of blue hydrated dioxide of iridium; when digested with water and oxide of silver, it yields a rose-coloured alkaline solution of the base $10NH^3.Ir^2O^3$. This solution, saturated with various acids, yields crystalline salts, soluble in water, namely, a carbonate, $10NH^3.Ir^2O^3.3H^2CO^3$, as a light flesh-coloured, finely crystalline, alkaline powder; a nitrate, $10NH^3.Ir^2O^3.3N^2O^4$, in indistinct, light flesh-coloured, neutral prisms; and a sulphate, $10NH^3.Ir^2O^3.3SO^4$, also neutral and of similar colour. (Claus, *Beiträge zur Geschichte der Platin-metalle*, Dorpat, 1854; Jahrb. 1854, p. 434.)

IRIDOSMINE. *Native iridium, Osmide of Iridium, Osmium-iridium, Iridosmium, Neujanskitz, Sisserskitz.*—This compound occurs, together with platinum, in the province of Choco in South America, in California, Oregon, Australia, and in the Ural mountains; also in the gold washings on the rivers du Loup and des Plâtes, Canada. It sometimes constitutes the principal part of platinum ore, especially of that from Katharinenberg, Slatoust, and Kischtin in the Ural. It occurs rarely in hexagonal prisms with replaced basal edges, commonly in irregular grains, flat or round, sometimes in very thin laminæ. It has a metallic lustre, tin-white or light steel-grey colour, and is slightly malleable. Hardness = 6 to 7. Specific gravity = 19.3 to 21.12.

The following are analyses of specimens from different localities:—1. By Thomson (*Gmelin's Handbook*, vi. 425).—2. By Claus (*Beiträge &c.*).—3. By Berzelius (*Pogg. Ann.* xxxii. 232).—4–8. Deville and Debray (*Ann. Ch. Phys.* [3] lvi. 385; *Jahrb.* 1859, p. 767).

	Os.	Ir.	Rh.	Pt.	Ru.	Cu.	Fe.
1. Brasil	21.55	72.90	260 = 100
2. Nischna Tagilsk, hexagonal plates	27.32	51.34	1.51	10.08	5.85	..	= 100
3. Katharinenberg, laminæ	49.34	46.77	3.45	0.74 = 100
4. Oregon, thin shining scales	17.20	70.40	12.30	0.10	6.00	..	= 100
5. round compact grains	35.10	57.80	0.63	..	6.37	0.06	0.10 = 100
6. California, cavernous nodules, sometimes filled with oxide of iron or chromic iron ore	43.40	53.50	2.60	..	0.80	..	= 100
7. Australia, extremely thin laminæ	33.46	58.13	3.04	..	5.22	0.15	= 100
8. Bornoo	38.94	58.27	2.64	0.15	= 100

Iridosmine has usually been regarded as consisting of definite osmides of iridium (the iridium being more or less replaced by rhodium, ruthenium, and platinum); No. 1 agreeing nearly with the formula Ir^2Os ; 2, with $IrOs$; and 3, with $IrOs^2$. But according to Deville and Debray, it is not a homogeneous substance, and cannot be regarded as a distinct mineral species.

Iridosmine, when heated in the air, gives off osmic acid, with greater facility as it is

richer in osmium, and becomes dull. When ignited for some time with nitre alone, or with nitre and caustic potash, it gives off part of the osmium as osmic acid, and forms osmate of potassium, together with iridiate of potassium (p. 314). According to Fischer (Pogg. Ann. xviii. 258) it is more easily decomposed by nitrate of calcium, and according to Deville and Debray (p. 316) by a mixture of peroxide and nitrate of barium. Nitromuriatic acid has scarcely any action upon it. [For the methods of analysing it, see IRIDIUM, pp. 316, 316, 320; also PLATINUM-RESIDUES.]

IRISINE. See CHINOLINE (i. 871).

IRITE. This name was given by Hermann, J. pr. Chem. xxiii. 276) to a black mineral from the Ural, crystallised in regular octahedrons and consisting of the protoxides of iridium, osmium, and iron, combined with the sesquioxides of iron and chromium. According to Claus (*ibid.* lxxx. 285) it is a very variable mixture, consisting chiefly of iridosmine and chrome-iron ore.

IRON. Synonyms: *Eisen*; *Fer*; *Ferrum*; *Mars*. Symbol: Fe. Atomic weight: 56. Equivalents: Fe = 28 (ferrous); $fe = 18\frac{1}{2}$ (ferric).

This metal, although the most abundant of the heavy metals, and most largely employed in the arts, is but little known in a state of absolute chemical purity. The iron met with in commerce always contains carbon, and generally some other foreign substances, altogether varying in amount from 0.5 to nearly 10 per cent. Probably all these admixtures exercise some influence on the characters of the metal; but it appears to be chiefly the amount of carbon contained in iron, which determines the remarkable differences of character presented by the several varieties of metallic iron known as malleable iron, cast iron, and steel.

Pure iron is described as resembling silver in whiteness, capable of receiving a very high polish, extremely tenacious, softer than ordinary malleable iron, and presenting a scaly, conchoidal, or sometimes crystalline fracture. Specific gravity, after melting 7.8439, in sheet or wire 7.75 to 7.60.

Iron obtained by electrolysis was found to have a specific gravity of 8.1393. Its malleability was not affected by heating to redness and rapid cooling, nor was it in the least degree hardened by this treatment. It was scarcely acted upon by acids at the ordinary temperature; but dissolved with the aid of heat, evolving hydrogen quite free from the peculiar smell observable in the hydrogen evolved during the solution of ordinary iron. (Percy, *Metallurgy*, ii. 2.)

The crystalline form of iron is either the cube, octahedron, or some other form belonging to the regular system.

The different kinds of iron employed in the arts may be comprised under three heads, viz. malleable iron, cast iron, and steel, the latter being to some extent intermediate in its characters between the other two, and combining some of the peculiarities of both. See STEEL.

The difference between these three kinds of iron is, however, by no means absolute, even as regards their characters, but more a difference in the degree in which particular characters are presented. Iron approaching nearest to a state of purity requires a very high temperature for its fusion, while cast iron melts at a comparatively low heat, but, not being sufficiently malleable, it cannot be wrought into any required shape. Malleable iron has a much higher degree of toughness or tenacity than cast iron, which on the other hand is much harder, while steel may be melted and forged, as well as rendered hard or soft at will, or as it is technically termed "tempered," by cooling suddenly or gradually; on account of these varied combinations of qualities, the different kinds of iron have a wide range of applicability to a great diversity of purposes.

Leaving out of consideration for the present all the other substances met with in iron except carbon, it appears that the greater or less approximation to the character of pure iron is so uniformly accompanied by very slight differences in the amount of carbon, that these two circumstances may be regarded as having a very intimate causal connection.

Karsten's observations lead to the conclusion that iron containing 0.65 per cent. carbon, and free from any other substance, becomes so much hardened by plunging it into water, while red-hot, that it may be regarded as steel. When the amount of carbon is as much as 1.4 or 1.5 per cent. the metal presents the maximum combination of tenacity with the capability of hardening by sudden cooling. Increase in the amount of carbon beyond this limit is accompanied by increased hardness, but the tenacity and malleability are less. With 1.75 per cent. carbon, the malleability of the metal is very slight, and with 1.9 per cent. it scarcely admits of being wrought. Iron with 2.3 per cent. carbon presents, when melted and gradually cooled, indications of graphite being separated during the cooling, and the other characters of cast iron, which may contain an amount of carbon varying from this minimum limit up to 5.75 per cent.

These limits, however, are somewhat different when iron contains other substances,

as is usually the case: thus, taking as the criterion between malleable iron and steel, the capability of acquiring, by sudden cooling, such a degree of hardness as to give sparks when struck with flint, this is generally found to obtain with iron containing 0.5 per cent. when it also contains small quantities of silicon, sulphur, phosphorus, &c.

Taking as the criterion which distinguishes cast iron from steel, the separation of graphite when the melted metal is slowly cooled, and the want of malleability in the cold, it is found, in like manner, that the relation between these characters and the amount of carbon is not strictly constant, but that it is to some extent modified by the nature and amount of other admixtures, not only by their rendering the metal less malleable, but also by their promoting the tendency to the separation of carbon.

Malleable Iron (*Schmiedeeisen*; *Stabeisen*; *Fer doux*).—Ordinary malleable iron has a grey colour, which varies in its shade according to the character of the iron, and has sometimes a bluish or blackish tinge.

The specific gravity varies between 7.3 and 7.9; that of the better kinds generally approximating to the mean of these two values. The specific gravity is affected to some extent by the alteration of internal texture produced mechanically. Thus a bar 4 inches wide and 1 inch thick with a specific gravity = 7.8010 acquired a specific gravity = 7.8621 when rolled out to very thin sheet, and iron of specific gravity 7.7938 acquired a specific gravity = 7.8425 when drawn into very thin wire. (Karsten.)

The specific heat of ordinary malleable iron is 0.113795, and is somewhat higher when the amount of carbon in the metal is large. (Regnault.)

The conducting power for heat is 374.3 compared with gold = 1000. (Despretz.)

The linear and cubical expansion by heat (see HEAT, iii. 68, 71) is less than that of most other metals. The linear expansion for each degree between 100° and 300° C. = $\frac{1}{8150}$. (Dulong and Petit.)

An iron bar expands $\frac{3}{800}$ when raised from a red heat to a white heat, and $\frac{7}{550}$ when heated from 20° C. to whiteness. (Ripman.)

The melting point of malleable iron has not been determined with any degree of certainty. It is between the melting point of cast iron and that of platinum, and is estimated at 1550° C. by Pouillet, and at 2000° C. by Scheerer, and there is no doubt that it is higher in proportion as the metal contains less carbon.

Pure iron is attracted by the magnet more powerfully than iron containing carbon, and it may be rendered magnetic; but it does not retain the magnetic condition so long as iron containing some carbon. Ordinary bar iron is also attracted more strongly than steel, and is more easily rendered magnetic, but loses the polar condition much sooner than steel does. It appears therefore that the presence of a certain amount of carbon is in some way necessary for the retention of the magnetic condition by iron. Bars of iron placed vertically or nearly so become, in course of time, magnetic. The magnetic condition of iron is very nearly destroyed by a red heat, and entirely so by exposure to a white heat.

The electric conductivity of iron is much less than that of copper. Taking this as = 100, that of iron is = 20 (Harris), 15.8 (Becquerel), 17.74 (Lenz). Matthiessen considers that the electric conductivity of electro-deposited iron is much higher than that of ordinary malleable iron.

	Conductivity at 0° C.	Percentage decrement in conductivity between 0° and 100° C.	Deducted conductivity of pure iron. at 0° C.
Electrotype iron	100	38.3	
	91.8	36.0	102.7
Plate iron.	72.8	34.1	102.1
	84.6	34.7	99.2

The hardness of malleable iron varies considerably; it is influenced by the presence of foreign substances, and reduced by increase of temperature. It is however but very slightly increased by sudden cooling of the red-hot metal; the less so the smaller the amount of carbon contained in it. A certain amount of carbon seems essential to the hardness of malleable iron. Absolutely pure iron is so soft that it offers but little resistance to friction.

The tenacity of iron also varies widely, and is influenced by the nature and amount of foreign admixture in the metal, as well as by its internal texture, by temperature, and by other conditions. Up to a temperature of 146° C., the tenacity of boiler plate is not sensibly diminished; but at a red heat it is reduced one fourth. The tenacity of good rivet iron at 190° C. is a third greater than at the ordinary temperature; but at a red heat it is reduced to nearly one half. (Fairbairn, *Useful Information for Engineers*.)

(See Kirkaldy, Trans. Instit. of Engineers in Scotland, 1858-9; and *Tensile Strength of Wrought Iron and Steel*, London, 1862.—Fairbairn, Brit. Assoc. Report, 1856.)

The malleability of iron is very considerable, though less than that of silver or gold. It is influenced by the presence of foreign substances which modify the hardness and tenacity, the degree of malleability being apparently determined by the relative hardness and tenacity, and to some extent also by its internal texture. The malleability of iron is increased in proportion as its temperature is raised, inasmuch as it then becomes softer without its tenacity being proportionally lessened. At a red heat it is sufficiently soft to be brought to any required shape by hammering or rolling, and at a white heat it becomes quite pasty, so that separate pieces may be, as it were, kneaded together into one mass; or, as it is termed, *welded*. This capability of being forged and welded, so important as regards the methods by which iron is wrought for various uses, is referable to the wide interval between the temperature at which the metal presents its ordinary degree of hardness, and that at which it becomes liquid; as well as to the fact that, at temperatures far below the melting-point, it acquires a soft plastic condition, which is retained in a greater or less degree through a considerable range of temperature.

Among the foreign substances influencing prejudicially the malleability of iron, the chief are sulphur, phosphorus, and silicon. The first communicates to it the character of being brittle while hot, or, as it is called, "red short" in forging. Phosphorus renders iron "cold short," or brittle and weak at the ordinary temperature. Silicon has a similar influence in a higher degree. Manganese seems to be beneficial rather than otherwise as regards the malleability of iron. The malleability of iron is considerably reduced by immersing it while red-hot in cold water, as well as by long continued hammering and by rolling, but it is again restored by heating the metal to redness, and allowing it to cool gradually.

The texture, or molecular structure of iron varies very considerably according to the treatment to which it has been subjected. After being melted, iron is decidedly crystalline or granular, and its fracture presents distinct indications of that condition. By hammering or rolling while hot, it acquires a fibrous or silky texture, becomes more tenacious, less susceptible of true fracture, and capable only of being torn asunder. In the usual method of producing malleable iron, it is not melted, but wrought mechanically while in a kind of doughy condition, and the uniform close fibrous texture which determines the quality of the metal depends much upon the nature of this treatment and the extent to which it is carried.

By hammering while cold, fibrous iron is rendered harder and brittle; when afterwards broken, it presents a granular or crystalline fracture, but opinions differ as to whether this crystalline condition be really a result of the hammering. This is also the case with regard to the influence of long continued pressure, vibration, or concussion action, in affecting the texture of iron, some maintaining that these conditions slowly destroy the fibrous texture, rendering the iron crystalline and thereby weaker. (Rankine, Proceedings of Inst. of Civil Engineers, 1843; Percy, *Metallurgy*, ii. 8.)

Malleable iron undergoes no change in dry air, or in water free from air; but in moist air, or in water containing air, it gradually becomes oxidised or rusted, from the surface inwards, until eventually the entire mass may be converted into oxide. The carbonic acid present in atmospheric air appears to contribute largely to the production of this change. The presence of saline substances in water also facilitates the oxidation of iron; while alkalis, and oily or resinous substances, retard the oxidation. (Mallet, *Action of air and water, &c., upon cast iron, wrought iron, and steel*, Brit. Assoc. Reports, 1838, p. 253; 1840, p. 221.) Contact with more highly electro-positive metals, such as zinc, also hinders the oxidation of iron within a certain distance around the point of contact.

At a temperature about 230° C., iron becomes capable of combining directly with atmospheric oxygen, and the polished surface at first becomes covered with an extremely thin film of magnetic oxide, of a yellow colour which gradually passes into red, blue, and grey. At a red heat this crust of oxide—*forge scale*—becomes thicker, and gradually passes at its outer surface into ferric oxide. At a white heat, iron burns

in the air, with production of magnetic oxide, and this combustion may be sustained for some time by directing a blast of air upon the metal.

At a temperature about 360° C. iron decomposes water-vapour, forming magnetic oxide and liberating hydrogen.

Pure iron dissolves completely in moderately dilute acids. Ordinary malleable iron dissolves completely in strong hydrochloric acid; but with dilute acid a carbonaceous residue remains undissolved. In both cases also the hydrogen evolved carries with it carbonaceous vapour, which communicates to it a peculiar smell.

Malleable iron generally contains from 0.25 to 0.5 per cent. carbon; sometimes the amount is much less. The smaller the amount of carbon, the softer is the iron, and

* The results to which this mark * is put are probably much too high. See *Estimation of Sulphur*, p. 372.

the larger the amount, the nearer does it approximate to the character of steel. The only iron that is probably quite free from carbon is that known technically as "burnt iron," which cannot be soundly welded. Hence it has been supposed that the capability of being welded is determined by the presence of carbon in iron. There are, however, no good reasons for this opinion; it is more probable that the peculiarity of "burnt iron" is only indirectly due to the absence of carbon, and is determined by the presence, in the metal, of a minute quantity of oxide, which could not have been introduced so long as it still retained any carbon.

Among the foreign substances, other than carbon, present in malleable iron, the most important are sulphur, phosphorus, and silicon, existing probably in combination with equivalent proportions of the metal, as sulphide, phosphide, and silicide.

Sulphur is generally present to some extent in malleable iron, and, even when amounting to only 0.034 per cent., has the effect of rendering it "red short," and liable to crack at the edges in forging. It has been considered that 0.01 per cent. is the highest amount consistent with the usefulness of the iron. (Karsten, *Handbuch der Eisenhüttenkunde*, 423.)

Phosphorus is also frequently present, and, when amounting to 0.75 per cent., renders the iron very weak and brittle at the ordinary temperature, or, as it is called, "cold short." In smaller amount, it is considered to be serviceable in rendering the iron more capable of being welded. (Karsten, *op. cit.*)

Silicon renders iron harder and lessens its tenacity, making it what is termed "rotten" in working, even when present to the extent of only 0.37 per cent.

Manganese is considered to render iron harder, but not to make it steely.

Copper is considered to render iron "red short," and to reduce the capability of being welded, without however affecting the tenacity of the metal.

It may, however, be safely said that the evidence upon which the above opinions, as to the influence of these admixtures upon the character of malleable iron, are founded, is much too slender, and it is very desirable that this subject should be more thoroughly investigated.

The characters of steel, and the methods of manufacturing it, will be treated of in a separate article.

Cast Iron, Pig Iron (*Roheisen*; *Gusseisen*; *Fonte*).—There are two essentially distinct kinds of cast iron, viz. grey and white.

Grey cast iron (*Graues Roheisen*; *Fonte grise*) varies in colour from pale to dark grey. It has generally some slight degree of malleability; but is harder and more brittle than malleable iron. Its texture is granular; sometimes very fine-grained, sometimes coarse-grained at the fracture, with minute particles of graphite visible throughout the mass.

White cast iron (*Weisses Roheisen*, *Fonte blanche*) varies in colour from that of tin to pale grey. It is very hard and brittle; of crystalline lamellar texture, and sometimes vesicular. The fracture is shining, and varies from lamellar to compact and conchoidal, in proportion as the colour varies from tin-white to grey. The most characteristic variety is called *specular iron* (*Spiegeleisen*; *fontes lamelleuses*).

The specific gravity of grey cast iron is, on the average, 7.1; that of white cast iron is, on the average, 7.5.

Grey cast iron melts at about 1600° C., and more easily in proportion as the amount of carbon it contains is greater. White cast iron melts at a lower temperature; but it does not become so liquid when melted as the grey cast iron, which passes suddenly from the solid to the liquid state, while the white cast iron remains in a pasty state for some time. Melted cast iron dissolves malleable iron, and is thus rendered tougher and stronger than originally (toughened cast iron). White iron, when cooled very gradually from the melted state, is converted into grey cast iron. Grey cast iron, on the contrary, when very gradually cooled from a melted state, is not altered except in becoming softer and more malleable; but when rapidly cooled, it is converted into white cast iron, more or less completely in proportion as the amount of carbon it contains is greater or less. On this account the outer surface of a casting has a hard crust or "skin," as it is called, in consequence of the more rapid cooling of that portion of the melted metal which comes in contact with the sides of the mould, and its conversion into white cast iron. This effect is often augmented, in practice, by lining the mould with iron plates, so as to facilitate the rapid cooling of the outer portions of the casting, and produce a layer of white cast iron, from $\frac{1}{8}$ to $\frac{1}{2}$ an inch thick, while the interior retains the condition of grey cast iron, thus combining the particular advantages of white cast iron as regards hardness, and of grey cast iron as regards strength.

It has been observed that in large masses of cast iron there is an inequality in the amount of carbon contained in the metal at the exterior and interior portions. In masses which have been gradually cooled from a melted state, the centre portion contains less carbon than the exterior portions. There is also a further difference as to the condition in which the carbon exists. At the centre, the relative proportion of graphitic carbon as compared with combined carbon, is greater than it is at the exterior

portions. This latter difference will be more marked in proportion as the melted metal is more rapidly solidified at the surface. In one instance of iron cast in an iron mould, referred to by Karsten, the following results were obtained:—

	Total quantity of carbon.	Combined carbon.	Graphite.
Cast iron before melting . . .	4.0281 . . .	= 0.7812 . . .	3.2469
Outer white portion of casting . . .	5.0929 . . .	= 5.0929	
Inner grey portion of casting . . .	3.8047 . . .	= 0.6106 . . .	3.1941

The main chemical difference between white and grey cast iron consists in the state in which the carbon they contain exists. In specular iron, the whole of the carbon is combined with iron, while in the most characteristic kind of grey cast iron, when solid, at least, the greater part of the carbon is merely mixed with the iron, in the state of graphite, and only a portion of it is in a state of combination. Between these two extremes there are a variety of intermediate states in which white and grey cast iron are mixed together in various proportions, constituting what is known as *mottled cast iron* (*halbirtes Gusseisen*; *fonte truitée*).

The hardness and strength of these varieties of cast iron differ considerably; as a rule, the grey is stronger than the white, and this again is harder than the grey. White cast iron is, however, too brittle to be used for structures, except for the purpose of coating the surface of castings with a hard crust or skin, by casting in moulds lined with metal (chill casting). (Rankine, *Civil Engineering*, p. 499.)

The tenacity of cast iron is very much less than that of malleable iron; but its capability of resisting crushing force is very much greater.

Kind of iron.	Direct Tenacity.	Resistance to direct crushing.	Modulus of rupture of square bars.	Modulus of Elas- ticity.
	In pounds per square inch.			
Cold blast . . .	from 12,694	56,455	36,693	14,000,000
	to 18,855	102,408	39,609	17,036,000
Hot blast . . .	from 13,434	72,193	29,889	11,539,000
	to 23,468	104,881	43,497	22,733,000
Toughened cast iron	from 23,461	129,876		
	to 26,764	119,457		

The strength of cast iron is increased by remelting, but reduced when the melting is repeated several times. At very low temperatures it becomes more brittle and weaker. (Fairbairn and Hodgkinson, *Report on the Application of Iron to Railway Structures*, p. 265.)

The specific heat of specular iron = 0.12983, that of ordinary white cast iron = 0.12728. (Regnault.)

The linear expansion of cast iron by heat is greater than that of malleable iron, amounting to $\frac{1}{800}$ between 20° and 560° C. (red heat), and $\frac{13}{880}$ between 20° and a white heat. (Rinman.)

Pieces of cold cast iron thrown into the melted metal sink to the bottom; but when they have a temperature near the melting point, they float on the surface of the melted metal. Hence it would appear that some degree of contraction takes place in the passage from the solid to the liquid state. This character of cast iron is important as regards its application to casting: for the increment of bulk attending solidification ensures the perfect filling of the moulds at that moment, and the production of sharp, well-defined castings. But the greatest amount of expansion and contraction takes place just below the melting point. On account of this contraction between a temperature near the melting point and the ordinary atmospheric temperature, it is necessary to make the moulds for castings proportionately larger than the castings are required to be. The contraction of grey cast iron amounts to about 1 per cent.; that of white cast iron is from 2 to 2.5 per cent. of the linear dimensions. The allowance generally made for this "shrinkage" in casting is $\frac{1}{80}$ or one eighth of an inch in a foot. Cast iron also undergoes a permanent increase of bulk under the long-continued influence of heat. (Percy, *Metalurgy*, ii. 872.)

White cast iron exposed to oxidising influences at the ordinary temperature, rusts much more slowly than grey cast iron, and this again, provided it does not contain much sulphur or other readily oxidisable substances, more slowly than malleable iron. Specular iron is but very little liable to oxidation.

At an elevated temperature, grey cast iron becomes coloured by oxidation sooner than malleable iron; white cast iron on the contrary becomes coloured even sooner

than steel. When cast iron is heated to redness in the air, the carbon it contains is first oxidised and the metal rendered more or less malleable; then a crust of magnetic oxide is formed at the surface and gradually increases in thickness as in the case of malleable iron. Grey cast iron is most slowly oxidised in this way, and becomes porous and friable after abstraction of its carbon. White cast iron is decarbonised more rapidly, and acquires a malleable steely character. Upon this fact is based the manufacture of malleable cast iron, which consists in heating to redness the castings, while imbedded in powdered chalk, charcoal, or oxide of iron, so as to be partially protected from the oxidising influence of the air.

Cast iron melted in contact with air becomes covered with a crust of oxide, and by removing this crust from time to time, it may be entirely converted into oxide. If the crust is allowed to remain in contact with the melted metal, this gradually becomes decarbonised, steely and less fusible. White cast iron heated in contact with air till it assumes the pasty condition, is decarbonised much more rapidly than by mere heating to redness, and passes from the steely condition to that of pure iron, without so great a degree of oxidation as takes place when the metal is melted. The most important method of manufacturing malleable iron is based upon this fact (puddling).

Cast iron melted under soda, potash, lime, or magnesia carbonates, is gradually decarbonised, and may be wholly converted into malleable iron, if the heat be raised as the iron becomes less fusible.

Atmospheric air forced into melted cast iron oxidises the carbon and silicon, as well as part of the iron, and converts the remainder into malleable iron. The temperature produced in this way is sufficiently high to determine the fusion of the wholly decarbonised iron. (See STEEL.)

White cast iron heated with concentrated hydrochloric acid is entirely dissolved; but grey cast iron, treated in the same way, leaves a residuum of graphite. In both cases the combined carbon enters into combination with a portion of the nascent hydrogen eliminated by the solution of the iron, forming volatile oily hydrocarbons, the vapour of which communicates a peculiar smell to the gas evolved. This oily substance, which appears to be of a nature analogous to petroleum, also collects as a thin film on the surface of the acid solution.

The action of dilute hydrochloric acid upon cast iron is somewhat different. Specular iron is acted upon very slowly at the ordinary temperature, but with the aid of heat, both it and grey cast iron are readily dissolved. The hydrogen evolved has the characteristic smell, but the amount of the hydrocarbons formed appears to be smaller than when concentrated acid is employed. White cast iron leaves a bulky dark-brown carbonaceous residue, which is soluble in potash, and, when washed and dried is very readily combustible, leaving a black residue containing silica (Daniell, *Journal of Science and the Arts*, ii. 278). Grey cast iron leaves a residue consisting partly of graphite, partly of a carbonaceous substance similar to that obtainable from white cast iron, and, partly of a black carbonaceous substance which is magnetic, takes fire by contact with the air, and leaves when burnt a residue of ferric oxide.

Cast iron is slowly acted upon by sea-water. Cannon balls that had been lying in the sea off the coast of Normandy since 1692, were found to have lost two-thirds of their original weight, contained no metallic iron, and were converted into a substance that could be cut with a knife (Deslongchamps, *J. Chim. méd.* xiii. 89). Cannon balls taken from vessels sunk fifty years before, near Karlsrona, were found to be partly converted into a grey porous graphite substance, which after exposure to the air for a quarter of an hour, became so heated that the adherent water was converted into steam (Berzelius, *Gmelin's Handbook*, v. 218). The substance remaining after the action of sea-water, appears to be similar to that remaining, mixed with graphite and the bulky carbonaceous residue, after dissolving grey cast iron by dilute hydrochloric acid, and which Karsten regards as a compound of iron with three equivalents of carbon. Berzelius considered this solution of cast iron by sea-water to be due to the conjoint action of carbonic acid and oxygen. The solution of cast iron takes place at places where it is exposed to the combined influence of fresh water and sea-water by tides more rapidly than in sea-water. (Mallet, *op. cit.*)

The solution of cast iron takes place at places where it is exposed to the combined influence of fresh water and sea water, by tides more rapidly than in sea water.

The maximum amount of carbon in cast iron is met with in specular iron, varying from 5.75 to 5.24 per cent. Bromeis and Percy consider that the manganese present, so far as is yet known, in all specular iron containing as much as 5 per cent. carbon, is in some way essential to this high proportion of combined carbon.

In grey cast iron the amount of carbon varies, as a general rule, between 2 and 4.65 per cent.; in white cast iron it is from 3.5 to 5.75 per cent; but the difference between white and grey cast iron is more intimately connected with the state in which the carbon exists, than with the amount of this substance.

Besides iron and carbon, cast iron always contains other substances, as indicated by the above analyses, especially silicon, sulphur, phosphorus, manganese, arsenic, copper. They probably exist, in combination with equivalent quantities of iron, as silicide, sulphide, phosphide, &c., and some of them appear to exercise considerable influence upon the quality and characters of the metal, although the mode in which it is exercised is but very partially understood, and the very nature of that influence is in some cases dubious.

Silicon is almost always present in cast iron to some extent, originating from the deoxidation of silica in the process of smelting. The amount varies very much. In white cast iron it is generally from 0.1 to 0.5 per cent. In grey cast iron the amount is much greater, and is seldom less than 0.5 per cent., sometimes exceeding even 3 per cent. Karsten found 3.46 per cent. to be the maximum amount. The greater amount of silicon in grey cast iron is considered to be due to the higher temperature at which it is produced. Iron produced with hot blast contains more silicon than that produced with cold blast.

It is generally considered that, within the ordinary limits as to the amount of silicon in cast iron, this substance does not exercise any prejudicial influence upon the quality of the metal; but, in the conversion of cast iron into malleable iron, the silicon must be as much as possible separated, since it is very detrimental to malleable iron as regards its tenacity. The greater the amount of silicon in pig iron, the greater also is the waste incurred in its conversion into malleable iron by the puddling operation.

Sulphur is almost always present in cast iron, but sometimes the amount is so small that it can hardly be estimated. It probably never reaches 0.5 per cent. in good cast iron. Iron smelted with mineral fuel always contains more sulphur than that smelted with charcoal, in consequence of the sulphur contained in the coal or coke being transferred to the iron. The presence of sulphur in cast iron renders it more fusible, but also more liable to solidify sooner when slightly cooled below the melting point, so as to become quite viscid while still red-hot.

When specular iron is melted with sulphur, carbon separates and collects upon the surface of the melted mass in the form of graphite, which differs from ordinary graphite in having no lustre. Grey cast iron melted with sulphur is converted into white cast iron, containing a greater amount of carbon than the original grey iron, as shown in the following results obtained by Karsten (*Eisenhüttenkunde*, i. 583):

	The grey cast iron contained in 100 pts.	The resulting white iron contained in 100 pts.
Combined carbon	0.6253	5.4878
Graphite	3.3119	
Sulphur	0.0286	0.4464

Hence it would appear that sulphur displaces carbon existing in combination with iron, but that up to a certain point, the carbon so displaced from combination with one portion of the iron, enters into combination with another portion, until no more can be taken up. The presence of sulphur in cast iron appears therefore to determine the existence of the carbon in the state of combination with the iron, and thus to be conducive to the production of white cast iron. (Janoyer, *Ann. des Mines*, 1851, iv. 20; Weston, *Percy's Metallurgy*, ii. 135.)

Phosphorus is frequently present in cast iron, sometimes to the extent of 1 or 2 per cent. When amounting to more than 0.5 per cent., it renders the iron brittle but more fusible, very liquid when melted, and capable of remaining longer in the liquid state. Within certain limits, therefore, the presence of phosphorus in iron intended for casting, is advantageous rather than otherwise.

Nitrogen.—It appears that cast iron sometimes contains a minute amount of nitrogen, and that it has a considerable influence on the character of the metal. Schaffhäutl estimated the nitrogen in several kinds of cast iron as follows (Precht, *Techn. Encyklop.* 1847, xv. 364; *Phil. Mag.* 1840, xvi. 44):

White cast iron (Maesteg, South Wales)	0.764 per cent.
Grey cast iron (Crenzot, France)	0.720 "
Specular iron	1.200 "

Marchand's experiments led him to doubt the existence of nitrogen in cast iron; and to infer that if it were present, it never amounted to 0.02 per cent., and that the indications of nitrogen obtained by analysis were generally referable to absorption of atmospheric nitrogen by the iron, and formation of cyanogen during the analysis.

Bou is (*Compt. rend.*, 1861, lii. 1195) on the contrary, considers that nitrogen is often present in cast iron, and has estimated the amount in a sample of very hard white cast

iron, containing much manganese, at 0.15 per cent. This subject, however, is far from having been satisfactorily investigated.

Arsenic.—There is much difference of opinion as to the influence of arsenic upon cast iron, and as to the frequency of its presence, but there are some well-established instances of cast iron containing a considerable amount of arsenic. Wöhler found it in four samples of pig iron, and Schafhäütl has stated that pig iron made at Alais from arsenical ore, contained from 2.5 to 4 per cent. of arsenic. Karsten never detected arsenic in pig iron. According to Berthier's analyses of some iron shells and shot from Algiers, they contained from 9.8 to 27 per cent. arsenic, constituting in fact a true alloy, and more recently a wrought shot from Sinope has been found to contain 16.20 per cent. arsenic by Dr. Noad. (Percy, *Metallurgy*, ii. 76.)

The presence of small amounts of arsenic in cast iron, is considered to have the effect, like phosphorus, of rendering the metal more fusible, brittle, and weaker.

Titanium appears to be frequently present in some kinds of cast iron, and it has been supposed to improve the quality of the metal. Several patents have been obtained for introducing it into cast iron intended for the manufacture of steel (Mushet's 13 specifications, March 1859 to December 1861), but it is very questionable whether this "invention" has any real foundation of known fact. The following analyses of titaniferous pig iron are by Mr. Riley.

Ore used Kind of Iron	Hæmatite and 7.57 % Ilmenite. No. 1 found- dry pig.	The same, with some Belfast aluminous ore.		Cornish hæmatite and Irish bog-ore, containing 6 to 9 per cent. manganese.		Cornish Irish bog- ore.

				0.06	0.04	0.06
	100.437	100.56	100.46	100.85	100.81	100.27

Vanadium has also been found in the pig iron made from the ores of Taberg in Sweden (Sefström, *Berz. Jahresb.* 1832, xi. 97), and in pig iron made from the Seend ore of Wiltshire. (Riley, *Journ. Chem. Soc.* [2] ii. 21.)

Chromium has been found in cast iron, but there is no evidence to show whether it has any influence on the character of the metal.

Manganese is very frequently present in cast iron, and it appears to have some influence in determining a high degree of carburization of the iron, as well as the existence of the carbon in a state of combination with the iron, so that its presence in the materials smelted, tends to effect the production of white cast iron (See *ante*, p. 331). Cast iron containing manganese appears to be especially suited for the production of steel or steely iron. (See STEEL.)

Copper is not unfrequently present in cast iron. When exceeding 0.2 per cent. it is said to render the metal harder, tougher, and stronger.

Zinc is sometimes present in cast iron smelted from ores containing zinc; and Karsten found cast iron containing traces of zinc to be very soft, but rotten and brittle. (*Eisenhüttenkunde*, i. 519.)

Aluminium, Magnesium, Calcium and Potassium are sometimes indicated by analyses as existing in minute proportion in some kinds of cast iron, but scarcely anything is known of their influence on the characters of the metal.

Occurrence. Although iron is one of the most abundant and widely distributed of the heavy metals, it is very seldom met with naturally in the metallic state. There are two species of native metallic iron, viz. telluric and meteoric iron.

1. **Telluric iron** is very rare; it occurs massive in plates and grains, is more malleable and ductile than ordinary iron; its specific gravity is from 7 to 7.8. It has been found associated with brown hæmatite and quartz in a lode near Grenoble (Schreiber, *Journ. de Phys.* July 1792); at Canaan, Connecticut, as a vein two

inches broad in mica slate (Shepard). This specimen contained 91·8 per cent. iron and 7 per cent. carbon. It is said to be mixed with the granular platinum of South America (John), and disseminated through some basaltic rocks (Andrews), also in the auriferous sand of Oláphian (Molnar). Native iron containing 6 per cent. of silicon and a little sulphur is said to have been found with galena, in the lodes at Leadhills, and in volcanic scorix at Gravenière in Auvergne.

2. *Meteoric iron* is met with, both as large compact masses, and as grains and splinters disseminated through earthy meteorites. Its colour is somewhat like that of platinum, and it is characterised by always containing nickel, sometimes also cobalt, copper, chromium and tin. The masses of meteoric iron found in South America and Siberia, and estimated to weigh several tons, are among the most remarkable that are known. Meteoric iron almost always contains particles of iron sulphide mixed with it, apparently neither magnetic nor ordinary pyrites. (Rammelsberg, Pogg. Ann. 1849, lxxiv. 442.)

Iron ores. Compounds of iron occur native in great numbers as minerals, and very widely distributed; there are indeed few natural bodies in which iron is not present to some extent; it exists in the ashes of most plants (see i. 417, ii. 680), and appears to be an essential constituent of the blood of animals (see *ante*, p. 2). Of the native compounds containing iron in large proportion, those which occur in greatest abundance are the oxides, disulphide, carbonate, phosphate, titanate, and silicate. But for the extraction of the metal the only minerals that are suitable are the several oxides and the carbonate, all of which occur as large masses, of a greater or less degree of purity, being generally mixed with varying amounts of siliceous or earthy substances, and smaller quantities of various other minerals. The most important varieties of these ores of iron are the following:—

Native magnetic oxide, Magnetic iron-ore; Magneteisen; Oxyde magnetique.—This is the richest of the ores of iron available for smelting; in its purest state it contains 72·41 per cent. iron. It is black and generally has a metallic lustre, and occurs both crystalline, granular and compact or even earthy, at well as in the state of sand. It exists abundantly in many localities as beds or veins, and sometimes forming entire mountain masses, associated with volcanic or schistose rocks, and chiefly in Norway, Sweden, Siberia, and North America. It is sometimes largely mixed with pyrites and other sulphuretted minerals. In this country magnetic iron-ore occurs in the West of England and at Rosedale in Yorkshire.

The mineral known as *Franklinite* appears to be a variety of magnetic iron ore in which ferrous oxide is replaced by zinc oxide.

forms large veins or beds, associated with quartz, calcspar, and heavy spar. Some kinds are hard, others soft and friable, and it generally contains varying amounts of earthy admixtures. The principal British deposits of hematite are in Cumberland and

Lancashire, the Isle of Man, Devonshire and Cornwall. On the Continent it occurs chiefly in the Hartz, Silesia, the Austrian provinces, and in Norway. A peculiar oolitic hematite occurs in the neighbourhood of Liège.

Red ochre is an earthy variety of ferric oxide containing a large admixture of clay.

Specular iron ore; Eisenglanz; Fer speculaire.—This also consists of anhydrous ferric oxide in a crystallised form. Its colour is iron grey or almost black. Specific gravity 4.8 to 5.3. The crystals of this mineral belong to the hexagonal system, $R.\infty R$ and sometimes $R.\frac{1}{2}P^2.\frac{1}{2}R$. It occurs chiefly in schistose rocks, in Norway, the Erzgebirge, in Russia, and several parts of the South of Europe, the most extensive deposit being that in Elba, which has been worked upwards of 3,000 years.

Specular iron ore often contains titanium, either in the form of rutile, or combined with the ferric oxide constituting ilmenite. This was formerly considered prejudicial to the ore; but quite recently it has been stated that the presence of titanium in iron ores, contributes in some way, not yet understood, to the production of good iron.

Native hydrated ferric oxide; Brown iron ore; Brauneisenerz; hematite brun.—This ore consists essentially of hydrated ferric oxide, which in the pure state contains 59.89 per cent. of iron and 14.44 per cent. combined water. It is sometimes indistinctly crystalline or fibrous; but more generally compact or earthy, and of various shades of colour from blackish-brown to yellowish-brown. This ore frequently contains a considerable amount of manganese, and a more or less considerable admixture of foreign earthy substances. It occurs abundantly in the Forest of Dean in Gloucestershire, in several parts of Devonshire and Northamptonshire, and Lincolnshire, as well as in Weardale, Durham, where it has originated chiefly by the alteration of spathic iron ore. On the Continent it is very abundant, and is one of the principal ores smelted in France and Germany.

A variety of this mineral occurs in many places under the name of bog iron ore (*Sumpferz; minerai des marais*), which has apparently been formed by deposition from ferruginous water under the influence of living organisms. Some kinds of this ore furnish very good iron—for instance, the lake ores of Sweden and Lower Canada; but generally it contains so large an amount of phosphorus as to be useless for smelting.

Yellow ochre is an argillaceous variety of hydrated ferric oxide containing more combined water than brown iron ore, and basic sulphate; sometimes also basic silicate, phosphate, and arsenate.

Native ferrous carbonate; Spathic iron ore; Späth-eisenstein; fer spathique.—This mineral consists essentially of ferrous carbonate, and in its purest state contains 48.27 per cent. of iron. It is generally crystalline, sometimes presenting distinct crystals (see i. 785), and sometimes in the form of fibrous nodular masses known by the name of sphærosiderite. It varies in colour from white to yellow or brown, and is very often found to have undergone more or less complete conversion into hydrated ferric oxide under the influence of atmospheric oxygen. Spathic iron ore occurs as veins and beds in the older rocks, and associated with limestone strata. It is worked in this country chiefly in Durham and Somersetshire; on the Continent it is of more frequent occurrence, the chief localities being Styria and Westphalia, where it constitutes entire mountains, and has long been famous under the name of "steel ore" for yielding very fine qualities of iron and steel.

IRON.

Sphatitic iron ore generally contains a considerable amount of manganese and small quantities of magnesia, and is sometimes associated with lead and copper ores, quartz, calcspar, heavy spar, &c., but is frequently quite free from any admixture of impurities that would be prejudicial to the iron made from it.

Ferrous carbonate mixed with clay often occurs with beds of coal, in sedimentary rocks, and is known under the name of argillaceous, sphaerosiderite, or clay iron ore. It is compact and earthy; of various shades of grey and brown, or sometimes quite black, owing to an admixture of carbonaceous substance, and occurs in lenticular masses or nodules. This ore is generally very abundant in the coal measures; but in some instances it is almost wholly wanting in those rocks, as for instance in the coal fields of Northumberland, Durham, Lancashire, and Belgium. The principal localities where it is worked in this country are the coal fields of Scotland, Staffordshire, Shropshire and Wales.

It is found to some extent in France and Germany, and abundantly in America, but is not worked there.

IRON.

A variety of this ore containing from 10 to 15 or even 30 percent of iron occurs as thin layers in the coal measures of Scotland, and some parts of North Wales, and is known under the name of "black band."

Both clay iron ore and carbonaceous iron ore are frequently accompanied by admixtures of metalliferous, sulphuretted, arsenical, and phosphatic minerals, sometimes in such amount as to detract from their value for smelting purposes; but generally they are sufficiently pure to furnish iron of good quality. Some kinds of the ore known as "coal brass" also contain a considerable amount of ferrous carbonate, though they were disregarded as iron ores, until attention was directed to their composition in 1853 by Messrs. Price and Nicholson.

Native iron Sulphides occur very frequently and in great abundance in some places. Of late years these minerals have been much used as a source of sulphur, and are largely imported from Spain and Norway for that purpose. The principal varieties are:

1. *Iron pyrites* (*Eisenkies*; *pyrite*), which has a yellow colour and metallic lustre. Specific gravity 4.9 to 5.1. It occurs crystalline, granular and compact, frequently disseminated through other minerals. In its purest state it contains 53.33 per cent. iron, and 46.67 per cent. sulphur.

2. *White iron pyrites* (*Strahlkies*; *pyrene*), is a variety of iron pyrites of a white colour; it is also of frequent occurrence.

3. *Magnetic pyrites* (*Magnetkies*; *pyrite magnetique*), has a bronze colour with metallic lustre, and is slightly magnetic. Specific gravity 4.5 to 4.7. It occurs both crystalline or granular, and compact. In its purest state it contains 60.49 per cent. iron, and 39.51 per cent. sulphur.

4. *Arsenical pyrites* (*Mispickel*; *Arsenkies*; *fer arsenical*), has a steel grey colour, and metallic lustre. Specific gravity 6 to 6.2. It occurs in the same states as iron pyrites, frequently associated with tin ores, and contains 34.35 per cent. iron, 10.96 per cent. sulphur, and 56.79 arsenic. This mineral frequently contains a considerable amount of silver. Both it and the other varieties of iron pyrites sometimes contain gold, and varying proportions of other metallic sulphides, especially copper pyrites, with which they are frequently associated.

The residue left after separating sulphur from iron pyrites by roasting, is smelted to extract the copper it contains; and attempts are being made to use it also for obtaining the iron from it.

Of other native compounds of iron that occur in large quantities, the most important are the *chromate* (see CHROME IRON ORE, i. 939); the *titanates iserine*, and *ilmenite* (see TITANATES); the *tungstate* (see WOLFRAM); the *silicates* (see GREEN EARTH, ii. 944, and SILICATES); the *ferrous* and *ferric phosphates*. (See PHOSPHATES.)

Preparation.—1. Pure iron may be obtained by heating pure ferric oxide in a current of hydrogen gas. If the reduction be effected at the lowest possible temperature, the iron is obtained in the state of a grey powder which is pyrophoric, and takes fire on contact with atmospheric air, being converted into ferric oxide. At a strong red heat the metal is obtained in a spongy state and is less readily oxidised.

2. A mixture of iron wire or iron filings, with one-fourth part of magnetic oxide, placed in a closely covered crucible, under a layer of powdered glass, free from heavy metallic oxides, and exposed to a white heat in a smith's forge, yields a button of iron containing only mere traces of carbon or other impurities.

Manufacture on the large scale.—Malleable iron may be obtained directly from iron ores by heating them with charcoal under the influence of a blast of air. Formerly, malleable iron was obtained by this method exclusively, but it is now practised almost only in Sardinia, the Pyrenees, India, some parts of America, Africa, and other countries where metallurgic art is less advanced than in the great iron-producing districts of Europe.

1. *Production of malleable iron direct from the ore.*—This is chiefly practised according to what is termed the Catalan method. It consists in heating the roasted ore with a charcoal fire urged by a blast, and in a manner very similar in its general character, to that adopted in working a smith's forge. The most important of the several arrangements for this operation, comprised collectively under the term "bloomery" (*Luppenfeuer, forge Catalan*), is the *hearth* (*Heerd; creuset*), which is a nearly cubical chamber built of stone, and lined with blocks of iron, *s, s, t, t*, at the back and front. It is placed against a wall *N, N*, through which the tuyere, *T*, of the blowing machine projects, as shown in *fig. 573*.

Fig. 573.

The ore to be reduced is broken to pieces the size of a nut, and is placed against the front of the hearth, *s, s*, while the remaining space *M*, between it and the back *t, t*, is filled with charcoal, and when the hearth is filled in this way, the upper part of the heap of ore forms a ridge at *d, f, g*, the surface *f, g*, being covered with a layer of closely packed charcoal dust (*brasque*). The fire is then urged by the blast and the ore becomes gradually deoxidised, while the gangue or earthy substance contained in the ore, combines with a portion of ferrous oxide, forming a fusible siliceous slag which collects at the bottom of the hearth. Fresh charcoal, and the finely divided ore, are constantly supplied to the fire meanwhile, and eventually the deoxidised mineral sinks down, in the state of malleable iron, to the bottom of the hearth, where a workman kneads together the fragments into a spongy mass, which is taken out of the fire, and rendered solid by hammering while still red-hot, so as to unite the metallic particles, and it is then drawn out into bars under a forge-hammer.

Only the richer kinds of ore can be treated in this way, and it always involves the waste of a large portion of the iron, which escapes reduction, and by entering into combination with the siliceous and earthy portions of the ore, forms a slag consisting chiefly of ferrous silicate. In the extraction of iron by this method, the reduction is effected, perhaps entirely, by carbonic oxide, and the carburization of the iron to such an extent as to determine the production of cast iron, is prevented by the want of an adequately high temperature.

2. *Indirect process.*—The production of malleable iron is now for the most part effected by operating upon cast iron so as to deprive it of the greater part of the carbon and silicon it contains, and at the same time to separate other admixtures that would be prejudicial to the quality of malleable iron. This operation is conducted in two ways, the one termed the charcoal finery, the other puddling. Both consist in a partial oxidation of the cast iron, and production of a fusible ferrous silicate, which reacts upon the carburet of iron and determines the oxidation of the greater part of the carbon and other substances contained in the cast iron.

The main distinction between these two modes of operating is that, in the one case charcoal is employed in contact with the cast iron; while, in the other, coal is used in a reverberatory furnace, so that the iron is acted upon in a separate chamber without actual contact with the fuel, but only by the flame and heated gases produced by its combustion.

White cast iron containing a small amount of carbon is most suitable for conversion into malleable iron, because it does not melt so readily at a moderate heat and is not so liquid when melted as grey cast iron, but softens before melting and remains for

some length of time in a viscous condition, which admits of its presenting a greater surface to the action of oxidising agents when stirred about. Its carbon is also more easily oxidised than the graphite of grey cast iron. When therefore grey cast iron has to be converted into malleable iron, it is in the first instance converted into white iron by a preliminary melting in the running-out fire (p. 349).

The production of malleable iron by the charcoal-finery, is practised in different places with a great number of minute variations, determined partly by the nature of the pig iron operated upon, partly by less important circumstances.

The charcoal-finery employed in Wales, and some other parts of the country, for manufacturing the sheet iron used for tin plates, which requires to be of very good quality, is represented in section by fig. 574. It consists of a quadrangular hearth lined with cast iron plates enclosed within brick walls and furnished with a blast apparatus. About 2 cwt. of pig iron, melted with coke in a similar kind of hearth, called a *melting finery*, is run into the hearth, covered with charcoal and stirred about, while the fire is urged by a blast of air until the iron becomes sufficiently decarburised to be malleable. Then it is collected in a *lump* (*Luppe; loupe*) at the end of an iron bar, and removed from the hearth for the purpose of being hammered into a prismatic slab about 2 inches thick. This is broken into pieces of about 25 lbs. each, called *stamps* (*schirbel; lopins*). About three of these stamps are piled upon the flattened end of an iron bar termed the *staff* or *portal*, and raised to a welding heat in a kind of reverberatory furnace termed the *hollow fire*, and again hammered into a slab about 3 inches thick, which is passed between rollers until it forms a sheet of the requisite thickness.

In Sweden the greater part of the best iron is made in a very similar manner, except that there, as well as in Germany and other parts of the Continent, the pig iron is melted in the same hearth in which it is converted into malleable iron. An ordinary form of the hearth employed is represented by fig. 575.

The pig iron is melted above the tuyere, so that it may not be exposed to the blast until it has become liquid, and the blast is regulated so as to retain the metal on the hearth in a proper state of fusion; the blast is then stopped, the slag run off, the iron raised off the hearth, and placed on the top of a fresh supply of charcoal, after which it is again melted. When the decarburisation has advanced far enough, which may be judged of by the consistence of the metal, it is again raised up, covered with charcoal, subjected to a strong welding heat to melt away the slag, and then hammered out to a short bar, which is cut into pieces that are again welded together, and drawn out into bars under a hammer.

In order to appreciate the chemical nature of the process that takes place in the charcoal-finery, it is necessary to consider the composition of the slags. They consist essentially of silica and ferrous oxide, but may be divided into two classes, viz. poor slag (*Rohschlacke*) and rich slag (*Gaarschlacke*).

The poor slag is formed during the first melting of the pig iron and the earlier stage of the operation. It consists essentially of ferrous silicate. It is very liquid and solidifies rapidly, is of a blackish-grey colour with metallic lustre, crystalline, frequently variegated, and sometimes porous. The crystals have the form of olivine or iron chrysolite, and the composition of the slag approximates to that of this mineral.

The rich slag is formed during the latter stage of the operation. It is less liquid, and solidifies less quickly than the poor slag. It forms an agglutinated mass; is heavier, of a grey colour, and has a compact fracture. Its composition varies much, and the amount of iron is greatest in that formed at the end of the operation.

In the charcoal-finery process, the separation of the carbon, silicon, phosphorus, and manganese from pig iron is effected by the oxidation of these substances, partly by the blast and partly by the ferrous oxide contained in the slag, formed at the end of the operation.

Cast iron melted with ferric oxide yields carbonic oxide and iron. Iron containing silicon, when heated with iron oxides, yields ferrous silicate. The ferrous silicate constituting poor slag is not reduced, either by pig iron or by carbon, at a red heat; it is only at a very high temperature that there is a reaction between the carbon and ferrous oxide, with elimination of iron. The more highly basic ferrous silicates, constituting rich

slag, on the contrary, are decomposed, even at a red heat, by pig iron, in such a manner that the excess of ferrous oxide is reduced, and a less basic ferrous silicate remains.

During the first stage of the process, the silicon of the iron, together with the oxidised iron, and any sand that may be present, contribute to the formation of poor slag; but as the oxidation of the iron continues, the slag gradually becomes richer in iron, and serves to a great extent as the medium by which the action of atmospheric oxygen upon the pig iron is exercised. Phosphoric acid and manganese also pass into the slag. The conversion of pig iron in this way must not be carried on too rapidly,

especially in the case of the less pure varieties, or the oxidation of the silicon, phosphorus, &c., and their consequent separation, will not be fully effected; nor must it be too much protracted, or there would be unnecessary waste of iron by oxidation.

Hot blast has been employed in the charcoal-finery; but since the object of that operation is not so much to obtain a high temperature as to separate all the impurities of the pig iron, the blast cannot be so much heated as in other cases.

3. *Puddling; Frischen im Flammöfen; affinage à la houille.*—This is at the present time by far the most important method of manufacturing malleable iron, especially in this country. The main difference between the operation of puddling and that of refining with charcoal, consists in the use of a reverberatory furnace for the purpose, in order that the decarburization of the iron may be effected in a chamber separated by a wall or bridge from the fire-place where the fuel is burnt. The metal is thus kept entirely out of contact with the fuel by which the furnace is heated, and it is acted upon only by the flame and hot gas passing over the bridge into the working chamber. This arrangement admits of the use of mineral fuel in place of charcoal, and is requisite for the sake of preventing the iron from becoming contaminated with the impurities always present in mineral fuel in far larger amount than in wood charcoal.

The construction of the puddling furnace is represented by *fig. 576* in elevation, and by *figs. 577* and *578* in vertical and horizontal sections. It is built of brick, and cased with

strong plates of cast iron, held together by iron bars. The fireplace is shown in the sections at *bb*, and the firing hole at *a* in the elevation; *c* is the bridge separating the fireplace from the working chamber *f*; *dd* the bed or hearth upon which the cast iron is melted and decarburized. This is now constructed of cast-iron plates covered with a layer of red iron ore, or some material

Fig. 576.

containing abundance of ferric oxide. The working door *g* has a small hole at the bottom, through which the workman stirs about the metal in the furnace. Just below this door, level with the surface of the hearth, is a small hole called the floss or tap-hole, that can be closed with a plug, and through which the slag is run out from the hearth. Sometimes the slag is allowed to run away from a hole *k* below the chimney. The door *h* is for introducing a fresh charge of pig iron. The chimney *i* is generally from 30 to 50 feet high, and is furnished at the top with a damper for regulating the draught, as shown in *fig. 579*.

The pig iron to be decarburized is piled up on the hearth of the working chamber, and when, after a few minutes, it begins to melt, about 25 per cent. of hammer- or mill-scale is added. The metal is then broken up and stirred about with an iron bar called a rabble, worked through the small hole in the door *g*. This is continued until the whole mass is reduced to a kind of sandy, half-melted condition. The heat is then increased, and soon after the whole of the metal

Fig. 577.

Fig. 578.

is melted, it begins to swell and heave as if boiling, while jets of blue flame issue from all parts of the mass. This is due to the formation of carbonic oxide by the reaction of the carbon in the metal with the ferruginous oxides present. As this reaction progresses, the iron becomes pasty, and in consequence of the oxidation of the silicon contained in the iron, and the formation of ferrous silicate, a liquid slag separates from it, and collects round the metal on the hearth, or flows away towards the floss *k*. When the separation of carbon from the metal has advanced to some considerable extent, the oxidising action of the atmosphere in the working chamber is lessened by lowering the damper and keeping the iron surrounded

by highly carbonaceous or smoky gas. When the iron has become so far decarburised as to be malleable, or as it is termed "come to nature," it is gathered together and worked into several lumps with an iron bar, ready to be removed from the furnace.

A modified form of this operation is adopted at some works, under the name of "pig-boiling." The furnace used for this purpose is constructed much in the same way as the puddling furnace, except that for "pig-boiling" the hearth is much deeper and more pan-shaped than in the puddling furnace. The hearth is also covered with a thick layer of red iron ore, or roasted slag from the puddling furnace, and the decarburisation of the pig iron is in this case effected probably more by the action of oxidised compounds of iron than by the direct action of atmospheric oxygen.

For detailed descriptions and drawings of the furnaces and machinery used in the manufacture of iron, see Truran, *Iron Manufactures of Great Britain*, London, 1862.

The presence of sulphur or of some metals, such as zinc, lead, and copper in the pig iron, retards the conversion into malleable iron, and in the case of pig iron that becomes very liquid when melted, is more difficult to bring it into a plastic condition than when it has the viscid character which good white cast iron, containing a small amount of carbon and a little sulphur, presents when melted. In puddling sulphury iron, there may be a very large waste, due to oxidation of the metal, in consequence of the greater time occupied in performing the last stage of the operation. It is the opinion of some that the presence of a certain amount of phosphorus in sulphury iron facilitates its working into balls.

The reactions that take place in puddling are essentially the same as those which take place in the charcoal refinery. Under the influence of the free oxygen in the atmosphere of the working chamber, a portion of the iron is oxidised, and at the same time the manganese, silicon, carbon, sulphur, and phosphorus present in the iron, are also oxidised, either by the direct action of air, or through the medium of the metallic oxides added to the pig iron, or formed during the process, the result being the production of a slag or cinder, consisting of ferrous and manganous silicates, and magnetic oxide, and containing the other earthy impurities present in the iron operated upon, as well as part of the sulphur and phosphorus, the one probably in state of sulphide, the other as phosphate. This will be evident from the following analyses of these slags.

The elimination of sulphur and phosphorus from pig iron appears to be always

attended with oxidation of the iron in a degree proportionate to the quantity of those substances separated from the metal. Consequently, in order that the waste of metal thus incurred in producing malleable iron of good quality may not exceed such a limit as would be tolerable in practice, it is essential that the amount of those substances in the pig iron operated upon should not be large. The smaller the amount of sulphur and phosphorus in the pig iron, the easier is its conversion into good malleable iron, and so far as the separation of those substances is concerned, the smaller is the waste experienced in this operation.

The manganese present in pig iron appears to be always separated almost entirely in the manufacture of malleable iron. The presence of manganese in pig iron appears to exercise, in some way not fully understood, a beneficial influence upon the quality of the malleable iron made from it by the operation of puddling. Experiments recently made by Caron (Compt. rend. xlv. 828) appear to show that sulphur may be separated from pig iron by the influence of manganese during the decarbonisation, but that phosphorus is not separable in the same way. He operated upon iron containing 1.15 per cent. of sulphur. By melting it three times without any admixture, the amount of sulphur was reduced to 0.96 per cent.; but by adding to it 6 per cent. metallic manganese, and by melting three times with access of air, the amount of sulphur was reduced to 0.8 per cent. The same iron melted with 10 per cent. ferric oxide showed a reduction in the amount of sulphur from 1.15 to 1.08 per cent., and by melting it with 10 per cent. ferric oxide and 6 per cent. manganese, the sulphur was reduced to 0.07 per cent.

The separation of silicon from pig iron in puddling, as in other modes of producing malleable iron, takes place very readily under the influence of oxidising conditions, with formation of ferrous silicate; and the chief importance attaching to its presence in pig iron employed for that purpose, relates more to the amount of malleable iron obtainable than to any special difficulty in the elimination of silicon. In the ferrous silicate constituting the slag of the puddling furnace, there is three and a half times as much iron as silicon; so that, if both the silica and the oxide of iron it contains originate from the oxidation of the pig iron operated upon, the waste of iron will be very considerable when the amount of silicon in the pig iron is large. Under the supposition that the slag is derived wholly from the metal by oxidation, the puddling of pig iron containing 5 per cent. of silicon would be attended with a waste of 15 per cent. of iron due to this cause alone, independently of that resulting from the separation of carbon, silicon, and other substances. Hence it is very desirable that the amount of silicon in pig iron intended for conversion into malleable iron should not be large.

In that modification of the method of producing malleable iron known as "boiling," the pig iron does not undergo any preliminary treatment, and the furnace is sometimes charged with the liquid metal run direct from the smelting furnace, so as to save the fuel requisite for remelting it. But in puddling, the practice is generally to submit the pig iron beforehand to an operation known as *refining* (*Feinen*; *mazéage*), which consists in melting the pig iron, in contact with coke and with the aid of an air-blast, in a hearth similar to a charcoal finery, but larger, and termed a *refinery* or *running-out fire* (*Feinherd*; *feu de finerie*). This operation, which, in fact, corresponds to the first melting of the pig iron under the blast in the charcoal-finery, has the effect of partially decarbonising the iron, and of removing from it the greater part of the silicon. At the same time grey pig iron is brought into the condition of white cast iron, which is most suitable for conversion into malleable iron by puddling. This change is facilitated by suddenly cooling the metal with water as it runs from the hearth. The composition of refined iron, or, as it is technically termed "*metal*" (*Feinesen*; *fine-metal*), and the change that takes place in the process, are shown by the analyses below.

The refinery or running-out fire, represented by *fig. 580*, consists of a rectangular hearth *n* about 2 feet deep, and rather longer than it is wide. It is lined with cast-iron plates constructed so as to admit of being cooled by water circulating through them, and has three blast tuyeres *t, t* supplying hot air on each side. The chimney *c* is supported upon iron columns, and the spaces between them are closed with cast-iron plates. (See *Truran, op. cit.*, p. 193, *et seq.*)

Fig. 580.

A quantity of coke is put into the hearth, and after the fire has been sufficiently raised, about one or two tons of pig iron is placed on the top, covered with coke, and the fire urged by the blast until the whole of the metal has melted and run down into the hearth, where, under the oxidising influence of the blast, the carbon and silicon it contains are oxidised, and a slag is formed which floats on the surface of the metal. Fresh coke is added, meanwhile, and the heat kept up until the action has advanced sufficiently far. A hole level with the bottom of the hearth is then opened, and the melted metal run into a cast-iron mould *n* cooled externally by water; and a quantity of water is thrown upon it in order to cool it suddenly and to render the slag discharged from the hearth with it, more easily separable. Sometimes the charge of iron is run into the refinery direct from the blast furnace, and in some cases a quantity of

Fig. 581.

hammer-scale or the slag from previous operations, is added to the charge, in order to facilitate the process of purification by which the silicon and other impurities are separated.

The slag produced in the operation of refining is vitreous, dark-coloured, black or bluish. It consists essentially of ferrous silicate, and generally contains the greater

part of the manganese, as well as some of the phosphorus and sulphur that were present in the pig iron operated upon, together with the ash of the coke used as fuel.

The quantity of slag produced in puddling depends very much on the kind of pig iron operated upon, and also upon whether it has been previously refined or not. Grey iron and unrefined pig, containing the most considerable amount of silicon, afford a more abundant and more liquid slag than refined metal, the slag from which is proportionately richer in ferrous oxide, and being consequently less fusible, accumulates in a thick layer on the bottom of the hearth. It may also contain ferric oxide, in consequence of partial oxidation of the ferrous silicate, or of the ferrous oxide produced in excess of that requisite to form the silicate.

The lumps of decarburised iron obtained as above described are termed *puddle-balls* (*Bällen*; *boules*), and consist of coherent spongy masses of malleable iron, intermixed with oxide and slag. In order to separate these admixtures and reduce the iron to a compact and uniform mass, the puddle-balls are removed from the working chamber of the puddling furnace while still at a welding heat, and either hammered or squeezed. This operation is termed "shingling" or blooming.

Fig. 582.

The hammers employed for this purpose, termed *forge hammers* (*Stirnhammer*; *mar-teau frontal*), are very powerful, and are either constructed of cast iron as shown at *fig. 582*, or are steam hammers. In the former a massive beam *c*, 8 or 10 feet long, resting at one end on a fulcrum *f*, and having at the other end a \perp shaped head *d*, is

lifted by the wipers *b, b* of the cam-wheel *a*, and, as that revolves, the hammer is let fall, at the rate of 70 or 80 strokes a minute, upon the anvil *c*, where the puddle-ball is placed. The *steam-hammer* (*Dampfhammer*; *marteau pilon*), consists of a block of iron, weighing several tons, attached to the piston of a steam-engine fixed above it, by which it may be lifted vertically in guides fitted to the frame work, and let fall upon the ball placed on an anvil.

The machines employed for compressing puddle-balls are of various forms, and are termed *squeezers* (*Quetscher*; *presse à charnière*). One of the most usual kinds, represented by *fig. 583*, consists of a lever, worked upon a fulcrum at the centre, by a crank

Fig. 583.

connected to one end, so that the jaws are alternately brought, at a rate of some 60 strokes a minute, nearer to the corresponding anvil-faces where the puddle-balls are placed to receive the pressure.

The puddle-ball, after having been hammered or squeezed, which occupies only a few seconds for each, is termed a *bloom* (*Luppe*; *loupe*), and is then drawn out into a bar by being rapidly passed several times, and while still red-hot, between grooved rollers, constituting what is termed a *forge-train* (*Streck-walzwerk*, *train de laminoir*), *fig. 584*. This consists of two pairs of rollers, *r, r*, fitted in frames and driven

Fig. 584.

by machinery. In one pair of rollers, called the *roughing-rolls* (*Cannelur-Walzen*; *cylindres dégrossisseurs*), there are corresponding V-shaped grooves round the surface. In the other pair of rollers, termed the *finishing rolls* (*cylindres finisseurs*), the grooves are flat, and in both they gradually decrease in size from one end of the rollers to the other, so that by passing the blooms successively through several pairs of grooves, they are reduced to bars of from 7 to 3 inches wide by from $1\frac{1}{2}$ to $\frac{1}{2}$ an inch thick. In this condition the iron is termed "puddle bar," or No. 1 iron.

After leaving the rolls, these bars, while still hot, are cut into short lengths by shears, and the pieces tied together by strong wire in a bundle is termed a *pile* (*Paket*; *trousse*), which is brought to a welding heat in a reverberatory furnace called the "re-heating or mill furnace" (*Schweissofen*; *four de chaufferie*), constructed somewhat like a puddling furnace, as shown by *fig. 585*. The hearth *a* of this furnace, on which the iron is placed, is made of sand, and slopes down towards the flue, so that any slag that is formed may run down and escape at the hole *b*, leaving the hearth quite dry.

The piles are raised as rapidly as possible to a full welding heat in the mill furnace,

and are then removed with tongs to mill-rolls, of a similar kind to those already described, but more highly finished, and drawn into bars which are again cut up, piled,

Fig. 585.

and then submitted to the same operations of heating and rolling several times, according to the required quality of the iron. Sometimes, after the first rolling of the iron into puddle bars, hammering is substituted in the place of drawing out between rollers. It is in this series of operations that the iron acquires its texture, and that close, uniform, and continuous fibre, upon which its strength and general good quality is considered to be chiefly dependent. The mode in which the pieces of iron are

arranged in the piles is considered to be of great importance as regards the result obtained; but notwithstanding the strong opinions expressed on this subject, little is known as to the rationale of the connection apparently existing between the quality of the iron and the mode in which it is wrought.

A certain proportion of slag is produced during the reheating of the piles in the mill-furnace, which has a composition very similar to that of the slag from the puddling furnace, but the silica it contains is derived mainly from the sand forming the hearth.

When all these successive operations have been completed, the iron is in the condition known as "merchant iron," and the different degrees of quality are indicated as No. 2, No. 3, &c., or as "common," "best" and "best best," as well as by particular brands.

Besides the waste of iron resulting from the formation of slag in refining, puddling, &c., there is always a further waste due to the oxidation of the iron during the shingling, hammering and rolling to which it is subjected. The product of this oxidation consists chiefly of magnetic oxide, which forms a crust on the surface of the hot iron, and falls off in scales, constituting what is known as "hammer-scale" or *mill-scale* (*Hammerschlag; battitures de fer*).

The total waste of iron in the conversion of pig iron into malleable iron, varies according to the kind of pig iron operated upon, and the amount of impurities in it, as well as upon the skill of the workmen. In South Staffordshire, the waste amounts to from 18 to 22 per cent. on the pig iron. In South Wales it sometimes amounts to from 26 to 28.5 per cent., though it is sometimes less than 13 per cent. Formerly the waste amounted in some cases to from 34 to 35 per cent. (T. R. U. R. A. *op. cit.* p. 215). The introduction of iron bottoms for puddling furnaces, in place of sand, has contributed largely to reduce the waste of iron due to the formation of slag, and the use of materials containing ferrous or ferric oxides, as admixtures in the puddling or boiling operation, in all probability tends to compensate the waste that would result from

atmospheric oxidation, inasmuch as the oxidation effected by these admixtures would be accompanied by an equivalent elimination of metal from them.

The greater part of this waste of iron takes place in the refining, amounting on the average to about 10 per cent. on the pig iron. In puddling refined metal, the waste is not more than from 4 to 7 per cent. In the mill-furnace the waste is much less, varying, according to the number of reheatings, and the size to which the iron is rolled, from 3.5 to 10 per cent. The consumption of iron in any stage of the manufacture, requisite to produce a ton of iron in a subsequent stage, is technically called the "yield," by a somewhat singular inversion of the meaning of the term.

The consumption of fuel in the various stages of the conversion of pig iron into malleable iron, varies according to the skill of the workmen, as well as the kind of fuel and iron used. In refining, from 6½ to 8 cwt. of coke per ton of metal made, is used when the pig iron has to be melted, and from 4 to 5 cwt. when the melted metal is run in from the blast furnace direct.

In "pig-boiling," the consumption of coal varies from 18 to 22 cwt. per ton of bar iron made, according as the coal is more or less bituminous and capable of burning with flame.

In puddling refined metal, the consumption is about 10 to 14 cwt. of bituminous coal, and from 17 to 18 cwt. of anthracitic coal per ton of iron made.

In heating the piles, the consumption of fuel is from 7 cwt. to 13 cwt. per ton of merchant bars, according as they are larger or smaller.

In connection with the consumption of fuel in the conversion of pig iron into malleable iron, it will be interesting to consider what amount of the heat, capable of being generated by the coal consumed, is really effective; how much of it is really used in heating the iron.

The temperature to which the iron requires to be heated in the puddling furnace may be taken as expressed by 1650° C.; and, assuming that the specific heat of cast iron increases above 350° C. in the same ratio that it does up to that temperature, it would, in that case, be about 0.26 at 1650° C.; accordingly, the quantity of heat requisite to raise iron from 15° C. to that temperature would be:

$$\begin{array}{l} \text{heat units.} \\ 424.84 = 1650 - 15 \times 0.26. \end{array}$$

A further quantity of heat would be consumed in melting the iron, and though the latent heat of iron has not been determined, it may be assumed as equal to 30 heat units. Thus the total heat requisite to heat cast iron up to 1650° C. and to melt it would be:

$$\begin{array}{l} \text{heat units.} \\ 454.84 = 424.84 + 30. \end{array}$$

and the quantity of heat requisite for one ton of iron would be:

$$\begin{array}{l} \text{heat units.} \\ 1,018,841.6 = 2240 \times 454.84. \end{array}$$

Taking the average calorific power of coal, expressed in heat units, to be 7,778, it appears from the foregoing calculation, that the quantity of heat actually communicated to the iron amounts to less than that capable of being generated by 131 pounds of coal. Thus:

Coal, lbs.	Calorific power, heat units.	Quantity of heat generated, heat units.	Quantity of heat required to heat 1 ton of iron from 15° to 1650° C. and to melt it, heat units.
131	7,778	1,018,918	1,018,841.6

Then, taking the quantity of coal consumed in puddling as being equal in weight to the pig iron worked, it appears that only 133 pounds out of every ton of coal burnt in the puddling furnace is really effective in heating the iron, or not more than one-sixteenth part. But though the quantity of heat actually communicated to the iron bears only this small proportion to the whole quantity generated by the combustion of the fuel used, it must be remembered that, under existing circumstances, this large consumption of fuel is unavoidable, since it is indispensable that, during the whole of the operation, the temperature should be maintained sufficiently high to keep the iron melted. For this purpose the rate of combustion must be high, and the intensely heated products of combustion must pass rapidly through the working chamber of the furnace. It has been estimated that in the ordinary puddling furnace, when the consumption of coal is at the rate of 240 pounds per hour, the volume of heated gas passing through the working chamber amounts to upwards of 72 cubic feet per second, or sufficient to fill the working chamber twice in a second, and that this is necessary in order to counteract the influence of conduction and radiation in reducing the temperature. (See Prideaux, *Elementary treatise on Fuel, particularly with reference to Reverberatory Furnaces.*)

It is in consequence of the extremely high temperature required to be maintained in puddling and mill furnaces, that only so small a fraction of the heat generated by combustion of the fuel consumed, is really effective in heating the iron (FUEL, ii. 729), inasmuch as it is only the heat corresponding to the difference existing at any moment between the temperature of the iron, and the higher temperature of the atmosphere in the working chamber of the furnace, that is available for maintaining or raising the temperature of the iron. So long therefore as the temperature of iron in a puddling furnace requires to be 1650°C. , the gas passing into the chimney must be at a temperature not less than that, and the whole of the heat corresponding to the quantity of gas discharged at that temperature into the chimney, will be without any other useful effect. A variety of arrangements have been contrived for turning this waste heat to account in raising steam for driving the machinery of iron works; and by far the most simple and convenient plan consists in doing away with the separate chimney to each furnace, and conducting the heated gas escaping from the working chamber of several puddling furnaces, into a spacious underground culvert, extending some distance away from the furnaces, and communicating with flues passing through and round a large Cornish boiler, along which the gas passes, and, after communicating its heat to the water, is then discharged into a lofty chimney capable of producing a draught sufficient for all the furnaces connected with it.

A great number of attempts have been made to introduce other improvements in the method of producing malleable iron by puddling; such, for instance, as the use of a blast of hot air, or of steam, or a mixed blast of air and steam, rotary puddling furnaces, &c., but excepting the admixture with the pig iron of materials containing ferruginous oxides, and the use of iron hearth-bottoms in the puddling furnace, none of these projects appear to have either any such scientific basis as to appear promising, or to have been attended with sufficient success to demand consideration.

The case is different as regards the application of gaseous fuel in the refinery, puddling furnace, and mill furnace. The gas used for this purpose is either the combustible gas evolved from the throat of the blast furnaces in which pig iron is made, or it is made specially from small coal and other inferior kinds of fuel, by burning them in such a manner that the carbonic acid generated by the combustion of one portion, is made to pass through a mass of incandescent fuel, so as to be converted into carbonic oxide, which, together with the hydrocarbon vapours driven off from the fuel, passes into the furnace to be heated, and is there burnt, much in the same manner as coal gas is burnt in a Bunsen's burner (See Bischof: *Die indirecte aber höchste Nutzung der rohen Brennstoffen*, 1848; also Scheerer, *Metallurgie*, i. 339). This method of using fuel has long been practised in Germany, and is now being introduced at some of the iron works in this country, where it is to be hoped it will eventually not only admit of coal being used in iron working, without those disadvantages arising from the presence of sulphur and other impurities, when it is in contact with the metal; but that it may likewise become an important means of economising fuel, and especially of turning to good account the vast quantities of small coal that have hitherto been almost entirely wasted. For descriptions of gas generators, and gas refining, puddling, &c., see the works above quoted, and Percy, *Metallurgy*, ii. 596, 674, 716; *Ure's Dictionary of Arts, Manufactures, &c.* ii. 573.

4. *Atmospheric process.*—Under this designation, an entirely new method of producing malleable iron from pig iron, has been proposed within the last few years as a substitute for the operation of puddling. It consists in submitting melted pig iron to the action of a current of air forced through it until it is sufficiently decarburised. The heat generated during this process, by the combustion of the carbon and silicon, and some portion of the iron, is sufficient to heat the metal above the melting point of malleable iron, so that, when the operation is ended, the decarburised iron is obtained in a liquid condition, and may be run into ingots, which are afterwards to be forged into bars. (Bessemer, specifications, 1855, Nos. 2321, 2768; 1856, Nos. 356, 630.)

The main principle of this method is to effect the conversion of pig iron into malleable iron, wholly by the direct influence of atmospheric oxygen, and independently of that reaction between the pig iron and the ferruginous or manganese oxides, or materials containing them, which takes place in the operation of puddling or boiling, and which, according to all experience, and to such scientific data as there are for forming an opinion, is so important a condition of the separation of sulphur and phosphorus from pig iron. The result of the trial of this new method of producing malleable iron affords a still further confirmation of the important influence of the reaction referred to as taking place in puddling. By the new method pig iron may be wholly decarburised, and the silicon it contains may be entirely eliminated with ease; but the case is very different as regards the sulphur and phosphorus: for these substances, which are so detrimental to malleable iron, far from being separated from the pig iron subjected to this new mode of treatment, are either wholly unacted upon,

or so little affected, that, relatively, they are augmented, the amount of phosphorus in the decarburised iron obtained by this method, being greater than it was in the pig iron operated upon, while the amount of sulphur is but little reduced, as will be seen by the following analyses:

Analyst	Pig iron, per cent.	Bessemer iron, per cent.
	Tookey.	
Carbon	3.309	0.218
Silicon	0.696	
Sulphur	0.485	0.402
Phosphorus	1.012	1.102

At the present time no means of obviating this defect are known; consequently, the application of this method is confined to the working of such kinds of pig iron as are practically free from sulphur and phosphorus; and hence, as regards the greater part of the malleable iron manufactured in this country, there is no possibility of the adoption of this method, although it admits of the decarburation of pig iron with much greater ease, and much more rapidly than the operation of puddling. In Sweden, on the contrary, where the pig iron produced is far less contaminated with sulphur and phosphorus than most of that made in this country, the new method is being worked with great advantage. In England, it is also being applied in working some of the better and more costly kinds of pig iron, but chiefly for the purpose of producing a kind of steel which bears a higher price than ordinary malleable iron. For this reason the further consideration of this method will be included in the article on STEEL.

5. Iron smelting.—In the extraction of iron from such of its ores as are suitable for metallurgic purposes, and as it is now chiefly practised in iron-producing countries, the metal is always obtained in the carburetted state, commonly known as cast iron, pig iron, or crude iron. The processes comprised in the smelting of iron are:—

1. The separation of water, carbonic acid, sulphur, and other volatilisable substances from the ore by the action of heat.

2. The reduction of the iron from the state of oxide, as it exists in the ore, to the metallic state, by the action of carbonic oxide.

3. The separation of the earthy substances, commonly present in iron ores, from the reduced metal, in consequence of the formation, at a high temperature, of fusible compounds of those substances; and

4. The carburation and melting of the reduced metal.

In smelting the richer kinds of iron ore, *calcination* or *roasting* (*Röstung; grillage*) is not always requisite for the removal of volatilisable substances; but with the majority of the iron ores used in that operation, it is very desirable that they should undergo this preparatory treatment, as will be seen by reference to the analyses of iron ores; and in all cases calcination is advantageous, inasmuch as it has the effect of rendering the ore more porous, and consequently more susceptible of being reduced.

The calcination of iron ores is effected by heating them to dull redness in contact with air, either in heaps, with layers of coal at the bottom and alternating with layers of the ore; or in kilns built of brick or masonry, from which the roasted ore can be drawn out at the bottom. The careful regulation of the heat applied is the most important requisite in the calcination of iron ores, and it should be only just sufficient to expel the volatilisable substances, without effecting, in the case of carbonaceous ores, the reduction of iron to the metallic state, or, in the case of siliceous ores, the formation of ferrous silicate and fusion of any portion of the ore, so as to render it more compact.

The changes effected by calcination consist chiefly in the separation of water, carbonic acid, and bituminous substance when the ores are carbonaceous. In this case there may be a partial deoxidation of the ore, attended with formation of ferrous or magnetic oxide; but more generally the calcination of iron ores has the effect of producing ferric oxide to a greater or less extent, if the iron is not already in that state.

The sulphur in iron ores, generally present in the state of pyrites, is also to a great extent separated from them by calcination, in consequence of the decomposition of the pyrites; one half of the sulphur being volatilised, while the residual iron sulphide is converted by oxidation into sulphate, which may be decomposed if the heat is sufficiently great. The entire separation of sulphur from iron ores in this way is seldom practicable.

An alteration of some kinds of iron ore similar to that resulting from calcination, especially as regards separation of sulphur, is effected by exposing them for a time to the atmosphere. In this process of *weathering* (*Verwitterung*), pyritic minerals are

oxidised and converted into sulphates, which may be washed out to some extent by rain, and this change, together with the peroxidation of the ore that takes place in some cases by contact with atmospheric air, has the effect of disintegrating the ore and rendering it more porous.

Sometimes the separation of the volatilisable constituents of iron ores, instead of being effected by a preliminary operation, takes place in the blast furnace, and is then the first stage of the process of smelting, the heat requisite for the purpose being derived from the current of gas ascending through the charge. It is probable that in some cases this plan may be attended with economy of fuel, and that if the height of the shaft could be increased, so that the upper part would serve as a substitute for the calcining kiln, the temperature of the gas discharged from the throat might be reduced to a minimum, and the whole of the heat generated in the furnace thus rendered effective. But there is a practical limit to the adoption of this plan, consisting in the friable character of some kinds of fuel and ore, and their liability to become crushed by the weight of a high column of materials in the shaft. In the Cleveland district, where the ore is used in large masses, and the fuel used is a very hard coke, furnaces have been built with this object 75 feet high, and the temperature of the gas has been reduced on the average to about 258°C . instead of 381°C . (I. L. Bell, *Industrial Resources of the Tyne, Wear, and Tees*, p. 107). But this saving is only partial, and since the calcination of ores in the blast furnace is attended with disadvantages as regards other modes of applying the waste heat of the gas discharged from blast furnaces (see p. 354), it yet remains to be seen whether that plan can be adopted so as to realise the greatest possible degree of economy in fuel.

The smelting of iron ores is conducted in a furnace consisting essentially of two parts, viz., the hearth, which is a circular chamber, built of stone and lined with fire-brick, where the combustion of the fuel and the melting of the reduced ore and flux take place, and the shaft, which is a wider cylindrical chamber, built above the hearth, and continuous with it, where the charge of ore, flux, and fuel continuously supplied at the top, is subjected to the action of the heated gas resulting from combustion, before reaching the hearth. The precise form and dimensions of this furnace, which is termed a *blast furnace* (*Hohofen*; *haut fourneau*) vary considerably (see Truran, *op. cit.* pp. 22, 124, *et seq.*; Percy, *Metallurgy*, ii. 350, 475, and 559). One of the most approved forms is represented by fig. 586. In this case, the distinction between the hearth, *a a'*, and the shaft, *b b'*, is less marked than it is in some furnaces where the hearth is not more than two or three feet wide, with its sides vertical and terminating in a decided angle at the junction with the lower part of the shaft, *b b'*, termed the *boshes* (*Rast*; *étalage*), which in the older form of furnaces, was more inclined than in the figure, while the *shaft* (*Schacht*; *cave*), *b b'*, was much more conical, and formed a decided angle at its junction with the upper part of the boshes, or widest part of the furnace, termed the *belly* (*Kohlensack*; *ventre*), so that the interior sectional contour corresponded to the dotted outline shown in the figure. In the furnaces of this form, the upper portion of the hearth is termed on the Continent the *Grstell*; *ouvrage*, and the lower portion, where the melted materials collect, the *Crucible* (*Heerd*; *creuset*).

At one side of the hearth, there is an opening formed by an arch, *t*, called the *tymp* (*Tümpel*; *tympe*), and below this arch the hearth is prolonged outwards somewhat beyond the plane of the tymp, as far as the block of stone *d*, called the *dam* (*Wallstein*; *dame*), over which the melted slag flows away to the "cinder fall," *s*, through a depression called the *cinder notch* (*Schlackentrift*), in the upper surface of the dam. Through the bottom of one side of the dam,

Fig. 586.

there is a channel, called the *tapping hole* (*Stichloch*; *trou de coulée*) communicating with the hearth, to admit of the melted metal collected at the bottom of the hearth being run out at intervals. This channel is stopped up with clay or sand, while the metal and slag are accumulating in the hearth. That side of the furnace towards which the hearth is prolonged, is called the *front* (*Arbeitsseite*; *partie antérieure*), while the opposite side is called the *back* (*Rückseite*; *partie postérieure*). At this side there is an arched opening, *a*, called the *tuyere hole* (*Form*), and there is generally a similar opening at each of the other sides. Opposite each of these openings an arch is turned in the outer brickwork of the furnace to admit of access to the tuyere holes. The upper extremity of the shaft is called the *throat* (*Gicht*; *guelard*), and is generally surmounted by a low wall or chimney, called the *tunnel head*, with openings at the side for introducing the materials into the furnace.

Air is supplied to the furnace through a series of pipes connected with a blowing engine, each pipe terminating with a conical tube called a *tuyere* (*Duse*; *tuyère*), surrounded with a hollow conical sheath, through which passes a stream of water to prevent the melting of the tuyeres, extending through each of the tuyere holes as far as the interior surface of the hearth.

In the working of a blast furnace, the shaft is kept nearly filled with the solid materials used; these are introduced at intervals into the upper end, and gradually sink down as the smelting progresses. Meanwhile a continuous supply of air is forced into the lower end of the furnace through the tuyeres, under a pressure of from $\frac{1}{2}$ to 2 lbs. per square inch in charcoal furnaces; and from 2 to 5 lbs. per square inch in furnaces worked with coal or coke, and in quantity proportionate to the size of the furnace and its rate of working, so as to maintain a rapid combustion of the fuel at that part of the furnace immediately above the level of the tuyeres. (See Truran, *op. cit.*, p. 115.)

The reduction of the ferruginous oxides in the ore is effected by the reaction taking place at a high temperature between these oxides and carbonic oxide, produced by the combination of carbonic acid, resulting from combustion of the fuel, with a further quantity of carbon equal to that it contains; and, since ferric oxide contains 30 per cent. of oxygen, the carbon and air requisite in these reactions for the reduction of a quantity of ferric oxide containing 1 pt. of iron will amount to:

		Parts by weight of carbon requisite in the state of carbonic oxide.		Parts by weight of oxygen requisite to form carbonic acid with half the carbon.			
Iron.	Ferric oxide.					Air.	
1	1.429	0.3214		0.4286		1.863	

or somewhat about 8 cwt. of coal, containing 80 per cent carbon, and 1 ton 17 cwt. 29 lbs. of air, or 54,443 cubic feet, per ton of iron made.

The reduction of the ferruginous oxide in the ore is not alone sufficient for the production of the metal in an available condition: for it is but seldom that iron ores do not contain a considerable admixture of earthy substances which require to be separated. They generally consist chiefly of silica, clay, or carbonate of lime, as will be seen by reference to the tabulated analyses of iron ores. These substances being intimately mixed with the ferruginous oxide, and consequently with the reduced metal, it is necessary that they should be melted as well as the metal itself, in order that they may separate according to their different densities in the liquid state. Any one of these substances alone is infusible at the temperature commonly produced in iron smelting, and they can be separated only by being converted into sufficiently fusible compounds. The double silicates containing two or more bases, are substances whose fusibility corresponds to the requirements of this case, and it is by the formation of such a vitreous silicate, termed *slag* (*Schlacke*; *laitier*), capable of being readily melted, that the separation of the earthy admixtures in iron ores is effected.

It is but rarely that these admixtures are of such a nature, and present in such relative proportions, as to produce, under the influence of heat, a silicate that would be suitable for the purposes of iron smelting. Hence it is necessary to mix with the ore some substance that will effect this result. The nature and proportion of this *flux* (*Zuschlag*; *castine*) will of course depend upon the composition of the ore to be smelted, and must be regulated in accordance with the general principles relating to the production of slags. (See METALLURGY.)

In smelting iron ores in which the earthy admixture is chiefly calcareous, clay or some siliceous material, such as forge cinder or the roasted slag from puddling furnaces, is added as a flux, or the ore may be mixed, in suitable proportions, with ores containing silica or clay. In the more frequent case of ores containing clay, or silica in some form, the material used as a flux is limestone or quicklime, in order to effect the formation of a double silicate containing alumina and lime as its basic constituents.

The fusibility of the double lime and alumina silicates varies according to the pro-

portion existing between the silica and the bases, as well as that between the two bases. The most fusible of them are those in which the oxygen of both bases amounts to two-thirds of that in the silica, and the oxygen of the lime equals that in the alumina.

In smelting iron ores with charcoal, the temperature of the furnace is generally lower than when they are smelted with coke or coal, and on that account the slag requires to be more fusible than in the latter case. In smelting iron ores with coke or coal, especially when hot blast is used, the temperature is so much higher than in furnaces worked with charcoal—not only where fusion takes place, but also at the upper part of the furnace—that the slag requires to be rendered less fusible by increasing the proportion of lime to such an extent, in relation to the silica and alumina in the ore, that fusion may not take place before the reduction of the ore has been completely effected, and that the fragments of the charge may not become agglutinated, but remain loose and porous while passing through that portion of the shaft where reduction takes place, and consequently more capable of being permeated by the reducing gas.

In the smelting of siliceous ores there is a further necessity for the addition of lime, even more important than that connected with the production of a suitably fusible slag. This arises from the circumstance that the double silicate, containing alumina and ferrous oxide as its basic constituents, is very fusible, and from the consequent tendency to the formation of this compound, the result of which would be that a considerable amount of the iron would escape reduction to the metallic state, and pass off in the slag, thus giving rise to considerable loss of iron, besides other serious inconveniences. This combination of ferrous oxide with the aluminous silicate in the ore does not take place in the presence of a sufficient amount of lime, and in order to prevent it as much as possible, the quantity of lime added to the ore is generally such as to form a slag in which the oxygen of the bases is equal to that in the silica.

The characters that are generally considered to be indicative of the formation of a suitable slag, consist in its being sufficiently liquid to separate perfectly from the metal, though as it flows from the furnace it is generally somewhat viscous. When sol. lifted, it should not be vesicular, but compact and homogenous, without being

either very vitreous or stony. The colour of slag from blast furnaces varies very much, but does not afford much indication of its character. When charcoal is used as fuel, the slag is lighter coloured than that from furnaces in which coal or coke is used.

The published analyses of blast furnace slags are very numerous; but comparatively few have any real value, from the absence, in most instances, of any statements as to the conditions under which the slags were produced. For the elucidation of the processes that take place in the smelting of iron ores, so far as the formation of slag is concerned, it is essential that the analyses of slags should not only be numerous, but that they should also be accompanied by descriptions of the kind of iron made, and the working condition of the furnace, as well as of the kind of ore, fluxes, and fuel employed. The analyses on pp. 359 and 360 will serve to illustrate the general character of the slag produced in iron smelting.

In some kinds of iron ore, the relation existing between the silica and alumina is very different from that generally obtaining in the clay iron ores of the coal measures, as will be seen from the following table and by reference to the analyses of ores.

	Low Moor.	Brierly.	Stanton.	Butterley.	Parkgate.	Cleveland.
Alumina . . .	23	24	20	26	24	25
Lime . . .	9	9	13	11	13	27
Magnesia . . .	8	7	17	9	19	14
Silica . . .	60	60	54	54	44	34
	100	100	100	100	100	100

In consequence of this difference, and the greater proportion of alumina in the ores of the Cleveland district, the slags produced in smelting them are much more stony and less vitreous than those produced in smelting other ores. An increased addition of lime would not remove this difference, which is due to the deficiency of silica in proportion to the alumina present, and is probably accompanied by a less degree of fusibility of the slags. This circumstance will perhaps serve to account for the apparent necessity of a very high temperature in the smelting of these ores, and for the failure of the attempts that have been made to smelt them with cold blast. (I. L. Bell, *loc. cit.* p. 95.)

The preceding analyses of slags from furnaces in which the Cleveland ores are worked, will illustrate the difference between them and the slags produced in other districts.

The precise mode in which the carburization of iron takes place in the blast furnace is not known. From the fact that iron becomes carburized when heated in contact with hydrocarbon gases, or even with carbonic oxide, and since these conditions obtain in the blast furnace, it is highly probable that carburization may take place before the reduced iron reaches that part where there is a temperature high enough for fusion.

The state in which the carbon exists in the iron obtained from the blast furnace appears to depend very materially upon the temperature at which fusion takes place. The lower the temperature, the greater is the proportion of the carbon combined with the iron, and any circumstance which tends to induce fusion at a low temperature is almost invariably attended with the production of white iron. This is the case when charcoal is used as fuel, when the ore is readily fusible, and also when it is highly refractory and has not a suitable admixture of flux to determine fusion. When a furnace is worked with a large amount of ore in proportion to the fuel, or, as it is termed, with a "heavy burden," and when sulphur is present to any large extent, there is from the same reason a tendency to the production of white iron.

The production of grey iron containing carbon in the graphitic condition appears to require a temperature far beyond that of mere fusion, and it is probable, on that account, the introduction of carbon in this form may be due to action more of a physical than chemical nature, and consist in solution of the carbon by the melted metal rather than actual combination. When sulphur is present in any of the materials used in smelting iron, it is necessary to employ a very high temperature in order to obtain grey iron, because the melting point of iron is considerably lower when it contains sulphur.

Besides the reduction of the ferruginous oxide in the ore and the separation of its earthy constituents by the formation of a suitable silicate, it is necessary to maintain a very high temperature at the lower part of the furnace for the fusion of these products. This is effected by the rapid combustion of fuel under the influence of a blast of air forced in through the tuyeres.

The kind of fuel employed in smelting iron ores has a great influence both on the quality of the iron produced and on the mode of working. With bulky porous fuel, such as charcoal, combustion takes place more readily than with the more compact and denser kinds of mineral fuel, and from the greater liability of charcoal to crumble under pressure, the furnaces in which it is used are generally much smaller than those worked with coal or coke. But the main difference between these two kinds of fuel, as regards the smelting of iron, consists in the relative freedom of charcoal from earthy substances, and its entire freedom from sulphur and phosphorus, which are so prejudicial to the quality of iron. Hence the greater purity of the iron smelted with charcoal, provided the ore used be free from deleterious admixtures.

The consumption of fuel requisite in smelting iron for the production of a sufficiently high temperature of fusion, far exceeds the amount requisite for the reduction and carburization of the metal, which, as already pointed out, is less than half the weight of the iron produced, whereas that consumed for melting may amount to from one to two or three tons per ton of pig iron made.

The consumption of fuel in iron smelting is one of the most important points with regard to the economical production of the metal, and it is exceedingly desirable to reduce it to the lowest possible limit. The amount of fuel consumed per ton of pig iron made varies considerably, not only according to the kind of fuel, its calorific power, combustibility, texture, etc., but also according to numerous other circumstances. Among these the shape of the furnace has an influence, in so far as it admits of the easy and uniform descent of the charge in the shaft, and less fuel is consumed in making white iron than in making grey or foundry iron; but probably the most important difference in the consumption of fuel is that resulting from the use of air at the ordinary atmospheric temperature, or air previously heated to a temperature considerably higher.

In charcoal furnaces, the consumption per ton of pig iron made, is from half a ton to two tons and upwards, according as hot or cold blast is used. In smelting with coal or coke, the consumption is from two to three tons and upwards with cold blast, and from 23 cwt. to two tons with hot blast.

The fuel is introduced into the furnace at intervals alternately with the mixture of ore and flux, and in uniform proportions, termed the *charge* (*Beschickung*; *lit de fusion*), and the relative proportion of fuel or of ore is termed in either case the "yield;" sometimes also in the case of the ore it is termed the "burden."

The total weight of the charge per ton of pig iron made, will vary, according to the kind of ore, flux, and fuel used, from four to five or seven tons and upwards, when the materials are used in the raw state; but by far the greater quantity of the material supplied to a blast furnace in smelting iron, consists of the air by which combustion is

supported: for taking carbonic oxide to be the ultimate though not the immediate product of the combustion, the quantity of air required would amount to at least five times the weight of the fuel burnt, taking the combustible portion of the fuel to be equal to 85 per cent. of carbon, and allowing for the carbon consumed in carburating the iron. Consequently the total quantity of air supplied to blast furnaces will be as follows, according to the consumption of fuel given above:

	tons. cwt.	tons.	tons.	
Fuel consumed . . .	23	2	3	} per ton of iron made.
Quantity of air . . .	5 15	10	16	
Cubic feet at 60°F. . .	168,038	292,240	438,360	

The greater part of this air is consumed in burning that portion of the fuel exclusively concerned in the production of a temperature high enough for effecting fusion; and that part which is consumed in the combustion of the fuel requisite for the reduction of the ore, does not amount to quite twice the weight of the iron made.

The temperature of the gaseous products of combustion discharged from blast furnaces differs according to the kind of materials used and their condition, the height of the shaft, and the mode of working. In the case of charcoal furnaces, the gas has generally a temperature of from 300° to 400° C., while that from furnaces worked with coke or coal, is from 550° to 1000° C., according to circumstances. The whole of the heat corresponding to the temperature of the gas discharged is waste heat, and although it has served, at an earlier stage of the process, to produce the high temperature necessary for fusion of the metal and slag, it is still available for any purpose to which it can be applied.

The great extent to which the heat generated in the smelting of iron ores is thus dissipated, without producing the full useful effect of which it is capable, may be judged of from the fact that the weight of the gas discharged from a blast furnace is more than equal to the entire quantity of both air and fuel consumed, or from 8 to 17 tons per ton of pig iron made.

But besides the waste of heat due to the high temperature of the gas discharged, there is a further and more considerable loss of heat, due to the fact that it contains a large amount of carbonic oxide, together with some hydrocarbons and hydrogen, and is in all ordinary cases sufficiently combustible at the temperature at which it is discharged, to take fire on coming in contact with atmospheric air at the top of the furnace. This waste is proportionate to the extent to which carbonic oxide is produced. Taking the average consumption of fuel in iron smelting to be represented by a quantity of carbon equal to twice the weight of the pig iron produced, if that portion only which is requisite for the reduction of ferric oxide be ultimately discharged from the furnace in the state of carbonic acid, the quantity of fuel fully utilised in producing the entire heating effect of which it is capable, will be only about one-sixth part of the whole.

Quantity of heat generated by perfect combustion of carbon. parts by weight				
2	:	0.3214		
Heat units . 16160	:	2596	=	6.225 : 1

Then, since the calorific power of carbon burnt to carbonic oxide is only about one-third of its calorific power when burnt to carbonic acid, or as

$$2473 : 8080 = 1 : 3.223,$$

the heating effect produced by the remaining five-sixths of the fuel consumed, so far as regards its ultimate condition when discharged from the furnace, will be less than one-third the effect it is capable of producing:

Quantity of heat capable of being generated by com- bustion of 1.6786 car- bon to carbonic acid. heat units.		Quantity of heat generated by com- bustion of 1.6786 car- bon to carbonic oxide. heat units.		Difference.	
12584	-	4151.1778	=	1.6786 x 2473	= 9413

the difference representing the heating effect capable of being produced by the carbonic oxide, and amounting to no less than 58.25 per cent. of the whole heating effect capable of being produced by the fuel consumed.

So far, therefore, as regards the condition in which the products of combustion are discharged from a blast furnace, the only portion of the fuel consumed so as not to be further available as a source of heat, is that equivalent to the reduction of the iron in the ore, and, supposing the metal to be contained in the ore in the state of ferric oxide, it would be only about one-third the weight of the iron made, or 16 per cent.

of the fuel consumed. The greater part of the heat corresponding to the remaining 84 per cent. of fuel consumed, leaves the furnace in some form or other in the gas, as sensible heat, or as heat capable of being generated by combustion, and is still available for heating purposes.

But, notwithstanding this large difference between the amount of fuel fully utilised and that which still remains available as a source of heat, after its combustion in the blast furnace, it must not be supposed that the large amount of fuel consumed in iron smelting, as compared with the amount which is fully utilised, does not, in the blast furnace, exercise its full heating power. For though only a small portion of the whole heat generated is rendered latent by the fusion of the metal, &c., the whole of it is required for producing the temperature at which those changes take place; that part which passes off in the gas does not indicate a useless consumption of fuel, and can only be regarded as waste heat, in so far as it is allowed to escape without being turned to such further advantage as it is still capable of.

In the immediate neighbourhood of the tuyeres, the fuel is burnt, under the influence of the blast, to carbonic acid, generating the full amount of heat corresponding to its calorific power, and producing there the greatest increase of temperature it is capable of producing when burnt with atmospheric air. (See FUEL, ii. 726.)

It is at this part of the furnace that, while the fuel is being consumed, the reduced metal and the earthy substances mixed with it are rapidly melted, and, falling down into the hearth, make room for a fresh quantity of the materials in the shaft of the furnace to sink down and undergo the same change, while the gaseous products ascend and communicate their heat to the materials in the higher part of the shaft.

When the iron ore smelted contains carbonic acid or water, and has not been previously calcined, those substances will be separated during the descent of the charge in the shaft, and will mix with the products of combustion. This will also be the case with the carbonic acid of the limestone used as a flux, and if coal be used as fuel, its volatilisable portion will likewise be expelled, and mix with the ascending gas.

In proportion as the extent of this admixture is greater, the gas will have a lower heating power when burnt, and therefore it is desirable to reduce the amount of carbonic acid and water-vapour in the blast furnace gas, by previous calcination of the ore and limestone, whenever the gas is to be used as fuel.

As a consequence of the different physical conditions of the products resulting from the changes that take place in smelting iron ores, those products are continuously discharged from the blast furnace in a manner exactly the reverse of that in which the raw materials are supplied to it; the melted iron and slag flowing out at the bottom, while gas escapes from the top or throat of the furnace.

In considering more minutely the conditions under which these products are formed, and the chemical nature of the changes from which they result, it will be convenient to follow the course of the air supplied to the furnace as it passes from the bottom to the top.

The direct and perfect combustion of the fuel is, in all cases, confined within a comparatively small portion of the furnace, and in furnaces worked with charcoal, it extends only to a short distance above the level of the tuyeres. Beyond that portion of the furnace, heat is communicated to the materials in the upper part of the furnace by the ascending heated gaseous products of combustion, consisting of a mixture of nitrogen and carbonic acid, the temperature of the gas being proportionally reduced thereby as it passes up to the mouth of the furnace. But since the materials in that part of the furnace immediately above the region of combustion are at a high red heat, the carbonic acid enters into combination with a further quantity of carbon, and is converted perhaps entirely into carbonic oxide, its volume being thereby doubled. This reaction being attended with a considerable absorption of heat (see FUEL, ii. 727), the temperature of that part of the furnace where it takes place, though still very high, must be, on that account, much lower than it is within the region of direct combustion near the tuyeres.

The following analyses of gas, taken from different heights in the shafts of blast furnaces, will serve in some degree to illustrate the nature of the changes resulting from the reaction taking place between the solid and gaseous materials contained in the furnace, and *figs.* 587 and 588 represent the shape of two of the furnaces from which the gases were taken.

The formation of carbonic oxide is probably one of the most important features of this process: for there is every reason to consider that the reduction of the iron ore, as it descends towards the boshes of the furnace, is effected mainly, if not entirely, by this gas, aided perhaps in some cases, by hydrocarbon vapour or gas produced from the fuel by the action of heat. Previously to this, no alteration of the relative proportion existing by weight or volume, between nitrogen and oxygen in atmospheric air, would be effected either by the combustion of the fuel or by the subsequent

production of carbonic oxide. But by the reduction of the ore resulting from the reaction of carbonic oxide with ferrous or ferric oxides at a high temperature, carbonic acid is

again produced, equal in volume to the carbonic oxide undergoing the change, and the effect of this transfer of oxygen from the solid to the gaseous contents of the furnace would be to produce a proportionate alteration of the ratios existing between both the relative weights and volumes of the nitrogen and oxygen. However, the influence exercised by this change on the composition of the gas passing upwards through the furnace will be slight; for, since the consumption of fuel in smelting iron ores so far exceeds the amount that would be chemically sufficient for the mere reduction of the ferric oxide, and since it is probable that the whole of the carbon consumed passes into the state of carbonic oxide at some part of the furnace not far above the level of the tuyeres, it follows that the extent to which carbonic acid is produced by the reaction between ferric oxide and carbonic oxide, must be small compared with the total amount of carbonic oxide produced in the operation; and, in fact, taking the consumption of fuel to be at the rate of 2 pounds carbon to 1 pound of pig iron made, only one-sixth part of the carbonic oxide formed at the lower part of the furnace, would be converted into carbonic acid by the reduction of the iron in the ore from the state of ferric oxide, taking place at the upper part of the furnace.

Most probably the reduction of ferric oxide by carbonic oxide takes place progressively, and since the temperature increases, it may extend over a considerable range in the descending column of materials, in proportion to the temperature prevailing in the upper part of the furnace.

From the relation existing between the calorific power of iron and that of carbonic oxide (see HARR, p. 105), it is probable that the reduction of ferric oxide by carbonic oxide, generates a certain amount of heat, since the quantity of heat generated by the combustion of iron is less than that generated by the combustion of the carbonic oxide requisite for its reduction from the state of ferric oxide. Thus:

Quantity of heat generated
by combustion of 0.75 lb.
carbonic oxide,
heat units.
1802.25

Quantity of heat generated by com-
bustion of 1 lb. iron to ferric oxide,
heat units.
1582

Difference.
220

Unless, therefore, the thermal effect of the combustion of carbonic oxide by the condensed oxygen in ferric oxide, be different from that of its combustion by gaseous oxygen, this change would be attended with an increase of temperature. But in any case it does not appear that there is any other cause operative in reducing the temperature at the upper part of the blast furnace, save the transfer of heat from the ascending gas to the colder materials supplied from time to time at the top, as the charge descends, and—if hydrated or carbonated ores, or limestone, or fuel containing volatilisable substance, be used—the absorption of heat accompanying the change of water into vapour and of carbonic acid into gas.

Consequently, the maintenance of a high temperature in the upper parts of the blast furnace must have the effect of preparing the materials constituting the charge, for passing rapidly through that stage of the process taking place near the level of the tuyeres, which, as regards the present system of working, consists probably in the mere fusion of the metal and slag, and the combustion of the remaining fuel. Accordingly, a reduction in the quantity of material in the charge would admit of a given temperature being maintained at the upper part of the furnace with a less consumption

of fuel; and since the time occupied in heating the materials in the furnace to such a temperature as will determine their fusion, is directly proportionate to the quantity of materials to be heated, and inversely proportionate to the temperature of the ascending gas, other conditions being equal, such a reduction would also admit of an increase in the rate of working or production of the blast furnace, and thus effect a saving of both time and fuel.

Then, since the consumption of fuel over and above that requisite for the reduction of the ore, and equivalent, as already shown, to about one-third the weight of iron produced, is incurred chiefly in order to effect the fusion of the charge, it follows that any mode of supplying the heat requisite for this purpose, otherwise than by the combustion of fuel in the furnace, would admit of a reduction in the amount of fuel supplied in the charge, and, what is still more important, a proportionate reduction in the supply of air. As a consequence of that twofold reduction, a smaller quantity of heat would suffice to bring the charge to a given temperature in a shorter time. The greater the substitution of the extraneous source of heat for the combustion of fuel in the furnace, the nearer would be the approximation of the amount of fuel requisite in the charge to that minimum limit which is necessary for the reduction of the ore, and the greater would be the utilisation, in the blast furnace, of the full calorific and reducing power of the fuel.

These considerations will serve to illustrate the principle of the economy, both in time and fuel, resulting from the use of hot blast in iron smelting. The apparently paradoxical result of a greater thermal effect being produced by a less consumption of fuel, has given rise to a vast deal of misconception in regard to this subject, and has even led to the entire denial of any advantage attending the use of hot blast.

In smelting iron ores with mineral fuel, which almost always contains sulphur, a portion of this substance is retained by the slag, probably in the state of calcium-sulphide; but the pig iron generally contains some sulphur, and it is desirable to reduce the amount to the smallest practicable limit. The means that are considered to be capable of effecting this object are, increasing the proportion of lime in the slag, and the addition of materials containing manganese, both of which appear to determine the separation of a larger portion of sulphur in the slag.

The amount of silicon in pig iron appears also to be influenced by the proportion of lime in the charge. At the high temperature obtained in smelting with hot blast, silica is reduced, in all probability, to a greater extent than is generally the case with cold blast, and the presence of an additional amount of lime may render that reduction more difficult; but the observations that have been made on this subject are not sufficiently decisive to show that this is really the case.

The pig iron obtained by smelting phosphatic ores almost invariably contains the greater part of the phosphorus in the ore. Experiments made on this subject by Messrs. Price and Nicholson (Phil. Mag. Dec. 1855) show that this is not due to the influence of hot blast, as had been supposed; but that it is the natural result of the easy reducibility of phosphoric acid. Their investigations also lead to the conclusion that the separation of phosphorus in the slag is closely connected with the partial reduction of the ore, and the presence of a large amount of ferrous oxide in the slag; and that the production of iron free from phosphorus from phosphatic ores, such as bog iron ore, involves a large waste of iron in this way, whereas by the perfect reduction of the ore, the whole or greater part of the phosphorus passes into the iron. As yet no means of preventing this result are known, and at the present time the elimination of phosphorus is probably one of the most important problems connected with the chemistry of iron smelting.

The investigation of this and similar subjects is, however, attended with very great difficulty. The nature of the operations by which iron is produced do not readily admit of being conducted experimentally; while on the other hand it is to a great extent essential that any investigation of the processes involved in those operations should be conducted on a large scale. Consequently, though numerous attempts have been made, both by iron smelters and chemists, to investigate the chemistry of this art, and though in many instances their labours have been well directed and to some extent fruitful, still the advance that has been made in knowledge of the subject is far less than what is needed; and without in the least detracting from the merit of some who have directed their attention to the subject, it may be said that, considering the national importance of this manufacture, as well as the magnitude of the interests concerned, the chemical contributions made during the last thirty years to its elucidation and improvement have been in the highest degree meagre, desultory, and unsatisfactory.

B. H. P.

IRON, ALLOYS OF. The alloys of iron are not for the most part of much importance. The softer metals, silver, zinc, tin, antimony, &c. acquire greater hardness, and sometimes greater tenacity, by taking-up a few parts in a thousand of iron. True

alloys of iron may be prepared by fusing different metals with iron wire, in a blast furnace, a small quantity of ferric oxide being added to decarbonise the iron.

1. An alloy of iron and aluminium, nearly in the proportion Al^1Fe , is obtained by melting 10 pts. aluminium and 5 pts. ferrous chloride with 20 pts. of a mixture of the chlorides of potassium and sodium in equivalent proportions, and treating the resulting crystalline regulus with dilute hydrochloric acid. The alloy then remains in iron-coloured six-sided prisms; it is attacked by hydrochloric acid, and soda-ley extracts from it a small quantity of aluminium (Michel, Ann. Ch. Pharm. cxv. 104). See also ALUMINIUM (i. 155). The peculiar excellence of the Indian steel, known under the name of "wootz," has been ascribed to the presence of aluminium in it; but there is room for doubting whether this is the case (Faraday and Stodart, Quart. Journ. of Science, 1819-20, ix. 320; Karsten, *Eisenhüttenkunde*, i. 484). (See STAEL.)

2. With Antimony (i. 316).

3. With Arsenic. *Arsenical Iron, Arsenosiderite*.—Two compounds of arsenic and iron, Fe^4As^2 and $FeAs^3$, known by these names, occur as natural minerals. They appear to be isomorphous, forming trimetric crystals, in which $\alpha P : \alpha P = 111^\circ 30'$ (Grog), 122° (G. Rose); cleavage rather distinct in one direction; also massive. Hardness = 6—6.6. Specific gravity, from 6.80 to 8.71. Lustre metallic. Colour between silver-white and steel-grey. Streak greyish black. Fracture uneven. Brittle. Heated in a glass tube, they yield a sublimate of metallic arsenic; on charcoal before the blowpipe, they give off arsenical fumes and leave magnetic globules. Nitric acid dissolves them with separation of arsenious acid.

Arsenical iron always contains sulphur, generally between 1 and 2 per cent.; a specimen from Geier, in the Erzgebirge, contains 6 per cent. If this be reckoned as arsenical pyrites (mispickel), $Fe^4As^2S^2$, the remainder is found to contain, in the lighter varieties (specific gravity 6.24—7.00), from 67.4 to 68.4 per cent. arsenic, and 32.6 to 31.6 iron, agreeing nearly with the formula Fe^4As^2 , which requires 66.8 As and 33.2 Fe; and in the heavier varieties (specific gravity 6.80 to 8.71), from 71.35 to 73.49 arsenic, and 27.88 to 26.51 iron, agreeing nearly with the formula $FeAs^3$, which requires 73.84 As and 27.16 Fe. (*Rammelsberg's Mineralchemie*, p. 19.)

Arsenical iron occurs, associated with copper-nickel, at Schladming in Styria; with serpentine at Reichenstein in Silesia, and at Löling, near Hüttenberg, in Carinthia, in a bed of spathic iron ore, associated with bismuth and scorodite; at Geier in the Erzgebirge; in Bedford County, Pennsylvania, and in Randolph County, North Carolina, where a mass was found, weighing nearly two pounds. (Dana, ii. 61.)

4. With Lead. By melting 54 pts. iron with 108 pts. arsenic in a closed vessel, obtained an arsenide of iron, having nearly the composition Fe^4As^2 ; it was white, brittle, and very easily pulverised. Arsenical cast iron (see *ante*, p. 335).

5. With Bismuth.—An alloy prepared by melting together 3 pts. bismuth and 1 iron is still magnetic.

With Copper. (See ii. 42.)

6. With Gold.—1 pt. iron forms with $\frac{1}{2}$ pt. gold a silver-white alloy; with 1 pt. gold a gray alloy.

7. With Lead.—The two metals unite with difficulty when fused together, forming two alloys, arranged one above the other, the lower containing but very little iron, and the upper but a very small quantity of lead (Morveau). By reducing a slag containing lead and iron in a crucible lined with charcoal, Biewend (J. pr. Chem. xxiii. 252) obtained a well-fused alloy, which was hard, almost perfectly brittle, lustrous, and magnetic; it had a light steel-grey colour, a fine-grained laminar fracture, and contained 96.76 per cent. of iron and 3.24 of lead.

8. With Manganese.—Cast iron, alloyed with manganese, becomes white and more brittle; when the proportion of manganese amounts to 2 per cent. the iron ceases to exhibit magnetic properties. (Mushet.)

9. With Mercury.—An amalgam of iron with mercury is described by Joule. (Brit. Ass. Reports, 1850, p. 55.) See MERCURY.

10. With Molybdenum.—Molybdiide of iron is bluish-grey, hard, brittle, fine-grained, and magnetic; fusible before the blowpipe when formed of equal parts of the two metals, but not so when formed of 2 pts. molybdenum and 1 pt. iron.

Many samples of the so-called "bears" (*Eisen-sauen*), which are metallic masses found in the hearths of blast furnaces in which copper is smelted, as at Mansfield (ii. 21), likewise consist of iron alloyed chiefly with molybdenum; a. Bear from the upper works at Eisleben, obtained in the fusion of bituminous marl-slate in smelting furnaces. b. Fine-grained. c. Coarse-grained (Heine, J. pr. Chem. ix. 176). d. The so-called "Mansfeld meteoric iron," containing slag mixed with bronze-yellow copper-sunder. Probably the bear from a copper furnace. e is the analysis of a fine-grained sample, a. A coarse-grained sample, by Stromeyer (Pogg. Ann. xlv. 335). f. The analysis of a sample, by Wehrle (Zeitschr. Phys. v. W. iii. 168). g. Bear from the Mansfeld blast furnace.

rothe Hütte in the Harz, examined by Wiggens (Pogg. xxviii. 565). d. Bear found underground at Lauchstadt. (Steinberg, J. pr. Chem. xviii. 379.)

11. With Nickel.—Iron and nickel melt together with facility, forming alloys, some of which do not rust so easily as iron itself. An alloy of 1 pt. iron with 0.03 nickel is white, of specific gravity 7.80, as extensible as iron, and less liable to rust. 1 pt. iron with 0.1 nickel has a greyish-white to yellowish colour, specific gravity 7.85, is less extensible than iron, but rusts less easily. 1 pt. iron and $1\frac{1}{2}$ pt. nickel form a grey, rather hard, perfectly extensible, and magnetic alloy.

Meteoric iron consists chiefly of an alloy of iron and nickel. (See p. 336; also METEORITES.)

12. With Palladium, iron forms a brittle alloy. (Faraday and Stodart, Phil. Trans. 1822, p. 264.)

13. With Platinum.—Equal weights of platinum and iron heated before the oxygen-hydrogen blowpipe unite, with vivid emission of sparks, and form a shining, very hard and malleable alloy, which is scarcely touched by the file. In equal volumes, the two metals yield a brittle button (Clarke). Combination does not take place in the heat of an ordinary fire (Lewis, Gehlen). An alloy of 99 pts. iron and 1 pt. platinum is not attacked by ordinary nitric acid. (Schönbein, Pogg. Ann. xlii. 17.)

When equal weights of iron and platinum are dissolved in nitromuriatic acid, the excess of acid expelled by evaporation, the solution precipitated by ammonia, and the washed precipitate reduced in a stream of hydrogen at a low red heat, an alloy of iron and platinum is obtained, which immediately takes fire on exposure to the air. If this alloy, without being allowed to come in contact with the air, so that no combustion may take place, be thrown into hydrochloric acid—which dissolves part of the iron with evolution of hydrogen—and the residue washed with water, there remains a black heavy powder, containing 80.1 per cent. platinum to 19.9 iron (which may be dissolved out by boiling nitric acid) together with a trace of moisture, but no hydrogen. This residue takes fire in the air considerably below a red heat, and burns with emission of sparks. Sometimes the combustion begins at the hottest part and spreads through the mass with a red light, as in the burning of tinder; after the combustion, the powder is found to have gained 1 per cent. in weight. (Boussingault, Ann. Ch. Phys. [2] liii. 441.)

Carbide of Platinum and Iron.—a. 9 pts. platinum and 2 pts. steel form a perfect alloy, which does not tarnish on exposure to the air; specific gravity 15.88. β. The alloy of 1 pt. platinum to 1 pt. steel takes a high polish, does not tarnish, exhibits a highly crystalline structure on the surface, and has a density of 9.862. γ. 1 pt. platinum and 8 pts. steel form a finely damasked alloy. δ. 1 platinum to 10 steel: specific gravity 8.1. ε. 1 pt. platinum to 67 pts. steel: the best adapted for cutting instruments. ζ. 1 pt. platinum to 100 pts. steel: of uniform surface, and beautiful fracture; not so hard as silver-steel, but much tougher, and therefore specially adapted to razors. η. 1 pt. platinum to 200 steel: damasked alloy, very well adapted for razors (Bréant). Steel alloyed with a small quantity of platinum dissolves in dilute sulphuric acid much more quickly than pure steel. This increase of solubility is produced even by $\frac{1}{100}$ pt. of platinum, and is strongest with a quantity between $\frac{1}{100}$ and $\frac{1}{50}$ pt. With $\frac{1}{10}$ of platinum, the solubility is perceptibly less; steel alloyed with one-half platinum does not dissolve more quickly than pure steel; and a compound of 2 pts. steel with 9 platinum is not at all affected by dilute sulphuric acid. These alloys exhibit the same relations towards other dilute acids.

When a compound of 2 pts. of steel with 1 pt. of platinum (or of any other metal insoluble in dilute acids) is treated with dilute sulphuric acid, and the undissolved portion,

containing platinum, iron, carbon, and hydrogen, is boiled with nitric acid, a black residue is left. This latter substance, when heated to 200°, detonates slightly, producing a faint light, but if gradually heated, decomposes with detonation; it dissolves in nitromuriatic acid, yielding a solution containing a larger portion of platinum, with but little iron. (Faraday and Stodart. *Phil. Trans.* 1822, p. 257, and *Quart. Journ. of Science*, p. 329.)

Cast iron and platinum form a dark, malleable, very hard alloy.

14. With Potassium.—An alloy having nearly the composition Fe^2K^2 , is obtained by igniting 12 pts. iron filings with 8 pts. pulverised tartar; it has the aspect of bar-iron, is very hard; can be forged and welded, but oxidises very rapidly in air and water. (Gay-Lussac and Thenard, *Recherches Physico-chimiques*, i. 238; Calvert, *Phil. Mag.* Oct. 1855.)

15. With Rhodium.—1 pt. rhodium and 1 pt. steel form an alloy having a specific gravity of 9.176, and a very fine colour and surface for metallic mirrors; it does not tarnish in the air. An alloy of 1 pt. rhodium and 50 to 100 steel is very hard, tolerably tough, requires for tempering a temperature higher by 39° than common steel, and by 17° than Indian steel. (Faraday and Stodart, *loc. cit.* p. 329.)

16. With Silver.—Iron is said to take up a small quantity of silver when melted with it.

17. With Tin.—When iron and tin are heated to redness together, there is formed: *a.* An alloy of 22 pts. tin and 1 iron, somewhat harder than tin, and magnetic; and below it *b.* A compound of 2 pts. iron, and 1 pt. tin (nearly FeSn), which is white, very hard, slightly malleable, and difficult of fusion: this constitutes *tinned iron-plate*.—In cast-iron retorts in which the tin-amalgam used for silvering mirrors is continually distilled, for the purpose of regaining the mercury, an alloy of tin and iron is formed, amounting to between 1 and 2 per cent. of the tin obtained: when the tin is poured out of the retorts, this alloy partly floats upon it in scales, and is partly deposited at the bottom in the form of a doughy mass. It may be freed from the pure tin which adheres to it, either by boiling with hydrochloric acid, which dissolves the latter, or by treating it with nitric acid, by which the free tin is oxidised while the alloy is not attacked. When thus purified, it has the form of shining square needles, of specific gravity 8.733, brittle, and fusing at an incipient white heat. The powder of this compound, when thrown into the flame of a candle, burns with emission of sparks and a white smoke. It does not rust in the air, when moistened with water. It is not attacked by nitric acid at any temperature or any degree of concentration; it dissolves slowly in boiling hydrochloric acid; but rapidly and completely, and with violent action, in nitromuriatic acid. (Lassaigne, *J. Chim. méd.* vi. 609.)

Deville and Caron (*Compt. rend.* xli. 920) obtained the alloy FeSn , in broad shining laminae, which were but slightly attacked by hydrochloric acid.

An alloy containing FeSn remains in the preparation of stannous chloride from Banca tin (see *Tin*), in slender (probably quadratic) needles of specific gravity 7.44, fusible only at a white heat; it solidifies in the crystalline form on cooling, and is then magnetic. The crystals are nearly insoluble in hydrochloric and nitric acid, but dissolve easily in nitromuriatic acid; they burn in the flame of a candle. (Nöllner, *Ann. Ch. Pharm.* cxv. 233.)

It has been proposed to harden malleable iron rails by introducing a portion of tin into the metal, but it has been found to render the iron extremely brittle and “cold short,” and also incapable of being welded. (Karsten, *Eisenhüttenkunde*, i. 508, and Percy, *Metallurgy*, ii. 161.)

18. With Titanium.—Pig-iron often contains titanium (p. 335), which appears to be derived chiefly from the clay of the ore, or from other siliceous compounds added as fluxes. In three samples of grey pig from the iron ore of Westbury in Wiltshire, Riley found 1.15, 0.71 and 0.47 per cent. titanium. The titanium is either minutely disseminated through the iron or else alloyed with it. The presence of titanium in the ore or in the flux appears to improve the quality of the iron, and render it of excellent quality both for castings and for conversion by the Bessemer process; but according to Riley's observations, the titanium does not appear to remain with the iron, at least only in very minute quantity, when it is converted into bar iron or steel. Mushet has patented the use of titanium in the manufacture of iron and steel, and the alloying of titanium with iron and steel; but samples of his steel, in the manufacture of which titaniferous ores were used, did not yield any appreciable evidence of titanium. (Riley, *Chem. Soc. J.* xvi. 387; see *ante*, p. 335.)

19. With Tungsten.—Iron and tungsten may be united by fusion. It is stated that steel of very superior quality may be made by simply melting cast steel, or even iron, either with metallic tungsten or with the so-called native alloy, prepared by

strongly heating a mixture of powdered wolfram and fine carbonaceous matter in a crucible lined with charcoal. (Bernouilli, Pogg. Ann. 1860, xxi. 573.)

20. With Zinc.—Iron takes up zinc when heated with it. A brittle friable alloy is readily formed by melting zinc in vessels of wrought or cast iron, or by dropping iron into melted zinc; sometimes crystalline compounds of ferruginous zinc are deposited. (Percy, *Metallurgy*, ii. 153.)

By immersing malleable iron or cast iron, perfectly free from oxide on the surface, in melted zinc, the iron becomes covered with a coating of zinc, probably in consequence of the two metals being alloyed superficially. Iron thus coated with zinc is less liable to undergo oxidation when exposed to the atmosphere, and is largely employed under the name of *galvanised iron*.

IRON, BROMIDES OF. Iron unites with bromine in two proportions, forming the *dibromide* or *ferrous bromide*, FeBr_2 , and the *tribromide* or *ferric bromide*, Fe^3Br_4 .

Ferrous bromide is a yellowish substance obtained by passing bromine-vapour over gently ignited iron wire. It is soluble in water, and may be obtained in solution by dissolving iron in hydrobromic acid, or in a mixture of bromine and water. The solution yields by evaporation rhombic tabular crystals, containing $\text{FeBr}_2 \cdot 6\text{H}_2\text{O}$. When exposed to the air it turns brown, and deposits *ferric oxybromide*.

Ferric bromide, Fe^3Br_4 , is produced by heating ferrous bromide with bromine; or by evaporating to dryness a solution of iron in excess of bromine-water. It is a brown-red mass which deliquesces in the air. It may be obtained in solution by dissolving ferric oxide in hydrobromic acid, or by mixing the aqueous solution of the ferrous bromide with bromine.

IRON, CARBIDES OR CARBURETS OF. See CAST IRON (p. 329) and STEEL. By heating alkaline ferrocyanides to redness, a compound of carbon and iron is obtained, consisting of FeC .

Three other definite compounds of iron and carbon have been supposed to exist, viz. FeC , FeC^2 , and Fe^4C , according to Karsten and Berthier (Ann. des Mines [3] iii. 229). More recently Gurlt (Chem. Gaz. xiv. 230) has endeavoured to show that there is another carbide, represented by the formula Fe^4C . The nearest approach to a definite compound of carbon and iron is specular iron, which may perhaps consist essentially of a tetracarburet; but the evidence of the existence of these compounds is exceedingly imperfect.

IRON, CARBONATE OF. See CARBONATES, i. 784.

IRON, CARBURETTED, ANALYSIS OF. It has already been mentioned that cast iron contains, besides carbon, which is an essential constituent of it, a considerable number of other elements, both metallic and non-metallic, that many of these elements are not completely removed in the processes to which the iron is subjected to convert it into bar iron and steel, and that all of them have more or less influence on the quality of the iron. It becomes, therefore, an important problem to detect these several elements in iron, and, as far as possible, to estimate their amount.

The iron used for the analysis must be finely divided, as in the form of filings, turnings, or borings; very hard iron, such as specular iron, or hard steel, may be comminuted in a steel mortar, and sifted. The iron must of course be free from dust, rust, oil, and other foreign substances.

1. *Estimation of the entire amount of Carbon.*—To estimate the whole of the carbon in iron, both free and combined, the iron must be dissolved, without evolution of hydrogen, because that gas would carry some of the carbon with it; or the carburetted iron must be completely oxidised, and the carbon estimated as carbonic acid.

When carburetted iron is brought in contact with *chloride of silver*, *cupric chloride*, or *ferric chloride*, these compounds are reduced to metallic silver, cuprous chloride, and ferrous chloride respectively, while the metallic iron is also converted into ferrous chloride, which dissolves, and the whole of the carbon remains behind, together with silicon and various metals. The action of chloride of silver is very slow; the most convenient reagent for this purpose is *cupric chloride*. A quantity of the iron (5 to 10 grms.) is covered with a moderately concentrated aqueous solution of cupric chloride, free from excess of acid, whereupon metallic copper is precipitated, and ferrous chloride is formed. As soon as trituration with a glass rod shows that the deposit is free from hard particles of iron, the solution is decanted and the residue is drenched with a concentrated solution of cupric chloride acidulated with hydrochloric acid, in order to convert the reduced copper into cuprous chloride, and dissolve it. The solution is then filtered through a glass tube drawn out at the lower end to a narrow neck, and plugged with asbestos (or platinum-sponge), so as to retain all undissolved particles. Impure carbon

is thus obtained, the weight of which may be determined by weighing the tube dried at 124° – 130° C., both before and after the experiment.

Ferric chloride may also be used instead of cupric chloride, the free acid contained in the solution being previously neutralised with carbonate of sodium or carbonate of calcium. The basic ferric salt deposited in the reaction may be removed by dilute hydrochloric acid or solution of ferric chloride.

The iron may also be dissolved, without loss of carbon, by nitric acid, provided it be first drenched with water, and then nitric acid free from chlorine or nitrous acid added. As soon as the solution has attained a sufficient degree of concentration, it is poured off, the residue is drenched with fresh quantities of water and aqueous acid, and the turbid yellowish solution, which contains nitrate of ammonia and nitrate of iron, is left to clarify, and finally filtered as above.

Another method is to heat the finely divided iron in a stream of dry chlorine gas, previously freed from air by passing through a red-hot tube containing finely divided charcoal.

Bromine or *iodine* may also be used instead of chlorine, and in the wet way, Morfitt and Booth (Chem. Gaz. 1853, p. 358) drench the iron (not very finely divided) with a small quantity of water, add iodine (5 grms. to 1 grm. iron), and leave it for five or six hours, till the action is finished; then pour off the liquid, add more water and iodine, if any iron still remains, and filter. Care must be taken not to add too much water, and not to allow the action to go on too long, otherwise a portion of the carbon will be lost. The charcoal which remains after the solution of iodide of iron has been filtered off, is washed with hot water, then with hydrochloric acid, and again with water, and the residue is weighed.

The carbon obtained by either of these methods is not pure, but is mixed with a small quantity of iron, and a larger quantity of silicic anhydride and oxide of silicon. The amount of pure carbon may be determined, either by the loss which the residue sustains when ignited in contact with the air, or by burning the carbon as in organic analysis, with oxide of copper, or better with chromate of lead, or with a mixture of that salt and chlorate of potassium, or in a stream of oxygen, and weighing the carbon as carbonic anhydride by absorption in caustic potash.

Deville (Compt. rend. li. 938) separates the pure carbon at once by igniting the finely divided iron in a current of dry hydrochloric acid gas, quite free from atmospheric air. The iron and all the foreign constituents, except the carbon, are then converted into volatile chlorides, and pure carbon remains behind.

2. *Estimation of the Graphite or mechanically mixed carbon.*—This is the portion which remains behind mixed with silica, and sometimes also with humus-like carbon-compounds, when the iron is dissolved by dilute acids. To estimate it, the iron is dissolved out by dilute hydrochloric acid of specific gravity 1.1; the washed residue is digested in potash-ley of specific gravity 1.1, to remove silica and humus-compounds, then with water, then with hot hydrochloric acid, and lastly, with hot water, after which it is dried, weighed and ignited in contact with the air, the loss of weight which it then sustains being reckoned as graphite (Morfitt and Booth). Buchner (J. pr. Chem. lxxii. 364) washes the residue with boiling water, potash-ley, alcohol, and finally with ether; then dries, weighs, and ignites as above. Gurlt (Polyt. Centralblatt, 1856, p. 378) treats the finely divided iron with recently precipitated chloride of silver and solution of sal-ammoniac, digests the residue with cyanide of potassium to remove chloride of silver, with potash to remove silica and combined carbon, then with nitric acid to remove metallic silver: the residue consists of graphite, which is to be treated as above.

3. *Estimation of the combined Carbon.*—The carbon actually in combination with the iron is for the most part converted, during the solution of the metal, into volatile hydrocarbons, which escape with the hydrogen, and impart to it a well-known offensive odour; part of this carbon, however, always remains in the liquid form attached to the graphite. When carburetted iron is digested with chloride of silver, ferric chloride, or cupric chloride, as already described, the whole of the carbon remains behind, and on treating the residue with potash-ley, that which was originally combined with the iron dissolves, and may be separated, together with silica, by supersaturation with hydrochloric acid, evaporation to dryness, and washing. The amount of carbon in the residue thus obtained may then be determined, either by the loss of weight sustained on ignition, or by combustion with chromate of lead. The combined carbon is, however, more generally estimated by difference.

4. *Estimation of Silicon.*—The amount of this element may be determined by igniting the residue obtained in the preceding operation; the carbon then burns away, and silica remains behind; as, however, a small portion of the carbon is apt to escape combustion, and the residue likewise contains a certain portion of slag, the pure silica must be dissolved out by potash-ley of specific gravity 1.1 (which will not attack the slag), and then precipitated by supersaturation with hydrochloric acid.

Carbon ignites the pulverised iron in a mixture of hydrochloric acid and air, whereby the carbon is converted into carbonic anhydride, and the iron into volatile chloride, while silica remains, sometimes mixed with the oxides of titanium, aluminium, calcium, &c.

The silicon in iron also remains as silica in the residue left on burning the iron in a stream of oxygen, and may be separated by moistening this residue with concentrated hydrochloric acid, evaporating to dryness, then digesting in dilute hydrochloric acid and filtering.

5. Estimation of Nitrogen.—The nitrogen may be detected in cast iron, according to Marchand, by igniting the finely divided iron with potassium, perfectly cleansed from oil and well dried, in an atmosphere of hydrogen quite free from air. The resulting mass, dissolved in water, yields, on addition of a ferrous-ferric salt and supersaturation with hydrochloric acid, a precipitate of prussian blue. According to Frémy, the nitrogen of iron may be converted into ammonia by ignition in pure hydrogen.

The nitrogen may be estimated by igniting the pulverised iron with six times its weight of a mixture of caustic lime and baryta, receiving the ammonia thus evolved in hydrochloric acid, and converting it into platinum-salt. Another method is to dissolve the iron in acid, whereupon ammonia remains in solution; boil the liquid with excess of slaked lime, and receive the vapours in hydrochloric acid. A portion of the nitrogen may, however, remain in the carbonaceous residue, and may be determined by igniting that residue with soda-lime in the ordinary way.

6. Estimation of Sulphur.—The sulphur in pig iron may be converted into sulphuric acid by oxidation with nitric acid, but the quantity is generally too small to be estimated in this way. A better method is to convert it into sulphydric acid, by dissolving the iron in dilute hydrochloric acid (which, of course, must not contain sulphurous acid, or free chlorine), and pass the evolved gas through a Liebig's bulb-apparatus containing an ammoniacal solution of nitrate of silver, or through a series of small flasks containing chloride of copper, or acetate of lead (the latter mixed with acetic acid), and weigh the precipitated sulphide: 100 pts. sulphide of silver = 12.91 sulphur; 100 pts. sulphide of copper = 13.46 sulphur. As, however, the precipitated sulphide may also contain phosphide or arsenide, it is better to oxidise the sulphide with nitric acid, and precipitate the resulting solution with chloride of barium.

Another mode of estimation is to fuse the pulverised iron with nitre and carbonate of sodium, dissolve the mass in dilute hydrochloric acid (silica then remaining undissolved), and precipitate the sulphuric acid as a barium-salt. If the fusion is conducted over a gas-flame, care must be taken that the mass does not pass over the edge of the vessel, because in that case the sulphurous acid in the flame, coming in contact with the fused alkali, will be oxidised, and form an alkaline sulphate, which will greatly increase the apparent amount of sulphur in the iron. If the fusion is made over a spirit-lamp, this source of error does not arise. (D. S. Price, Chem. Soc. J. xvi. 51.)

In several of the analyses already given (pp. 332, 333), the estimation of sulphur is probably too high. The results that are questionable are marked *.

7. Estimation of Phosphorus.—The iron (5 to 10 grms.) is dissolved in nitric or nitromuriatic acid; the solution evaporated to dryness; the dry residue fused with three or four times its weight of alkaline carbonate; the fused mass disintegrated by water; the filtrate supersaturated with hydrochloric acid and evaporated to dryness to separate silica; the residue digested in water; and from the filtrate the phosphoric acid is precipitated as ammonio-magnesian phosphate. The acid filtrate may also be previously used for the estimation of sulphuric acid, the excess of baryta added being then removed, previously to precipitating the phosphoric acid in the way just mentioned. If the solution also contains alumina, tartaric acid must first be added, to hold that base in solution.

The nitric acid solution of the iron may also be precipitated in the cold with carbonate of sodium; the whole of the phosphorus is then thrown down as ferric phosphate, which, after washing, may be fused with alkaline carbonate and treated as above, or decomposed by sulphide of ammonium.

The iron filings may also be fused at once with a mixture of alkaline carbonate and nitrate; the fused mass treated as above described for the estimation of sulphuric acid; and the solution, after being freed from silica, may be used either immediately or after separation of the sulphuric acid, for the estimation of phosphoric acid.

Eggertz (J. pr. Chem. lxxix. 496), evaporates to dryness the solution of 1 grm. iron in 15 grms. nitric acid of specific gravity 1.2, moistens the mass with hydrochloric acid, and dissolves it in such a quantity of water, that the filtrate measures 15 c. c., then adds 12.5 c. c. of a solution of molybdic acid (prepared by dissolving 1 pt. molybdic acid in 4 pts. ammonia, pouring the quickly filtered liquid into 15 pts. nitric acid, and leaving it to settle). On leaving the mixture to itself for a few hours at 40°, a precipitate forms, which must be collected on a weighed filter, washed with

water containing 1 per cent. of nitric acid, and dried at 95°. 100 pts. of the dried precipitate correspond to 1 pt. phosphorus.

8. *Estimation of Arsenic.*—When arseniferous iron is dissolved in dilute hydrochloric or sulphuric acid, the arsenic is not given off as arsenetted hydrogen, but is converted into arsenic acid (H. Rose), which remains dissolved if the solution has been made in the cold, but is precipitated from warm solutions not containing too great an excess of acid, as basic ferric arsenate, and is therefore often found in the carbonaceous residue.

When the iron is dissolved in nitric or nitromuriatic acid, the arsenic is converted into arsenic acid, and may be precipitated as basic ferric arsenate (together with phosphate) by boiling the solution with acetate of sodium, after the greater part of the ferric oxide has been reduced to ferrous oxide by heating it with sulphite of sodium. The precipitate is then decomposed by sulphide of ammonium, and the filtrate, acidulated, and treated with sulphydric acid, yields a precipitate of sulphide of arsenic. Or the iron may be dissolved in hydrochloric acid, with addition of a little nitric acid, to dissolve all the arsenic; the filtrate heated with sulphite of sodium, to reduce all the ferric to ferrous chloride; and the solution, freed from excess of sulphurous acid, may be treated with sulphydric acid, with the usual precautions; the arsenic is then precipitated as trisulphide (together with the sulphides of copper and lead, if present).

As a portion of the arsenic sometimes remains in the carbonaceous residue, this residue must be examined, either by treating it with sulphide of ammonium, and precipitating the arsenic from the filtrate by sulphydric acid, or by fusing it with nitrate and carbonate of sodium, and precipitating the arsenic as ammonio-magnesian arsenate.

The pulverised iron may also be fused with nitrate and carbonate of sodium, the silicic and sulphuric acids separated as above, and the arsenic then precipitated by sulphydric acid, or if no phosphorus is present, by ammonia and sulphate of magnesium.

9. *Estimation of Manganese, Cobalt, Nickel, and Zinc.*—These metals may all be separated from iron, by precipitating the latter from a neutral solution in which all the iron exists as ferric salt, with benzoate or succinate of ammonium, or from acid solution, with carbonate of barium.

10. *Estimation of Copper and Lead.*—The precipitate, thrown down as above described by sulphydric acid from the reduced iron solution, sometimes contains traces of these two metals. The arsenic may be extracted from it by monosulphide of potassium; and the residue, oxidised with nitric acid and treated with sulphuric acid, yields insoluble sulphate of lead and a soluble copper salt.

11. *Estimation of Aluminium.*—For the method of separating this metal from iron, see i. 155.

12. *Estimation of Magnesium, Calcium, and the Alkali-metals.*—These metals remain in solution after the iron has been precipitated as ferric oxide by benzoate or succinate of ammonium, or by carbonate of barium, and may be separated and estimated by the usual methods.

13. *Estimation of Chromium, Vanadium, Titanium, Molybdenum, and Tungsten.*—These metals occur especially in the black residue which remains when pig iron is dissolved in dilute acids, and may be sought for either in this or directly in the iron.

To detect and separate chromium and vanadium, a large quantity of the pulverised iron is fused with 12 pts. nitrate and 1 pt. carbonate of sodium; the fused mass (which likewise contains silicic, phosphoric, and arsenic acids) is mixed with such a quantity of nitric acid that it still retains a slight alkaline reaction, but does not give off any nitrous acid (which would reduce the chromic and vanadic acids); the solution is mixed with chloride of barium; the washed precipitate is treated with sulphuric acid; the solution is saturated with ammonia and evaporated; and a lump of sal-ammoniac is thrown in, whereby vanadate of ammonium is thrown down as a yellow or white crystalline powder, while the chromate remains in solution. The vanadate of ammonium, heated in contact with the air, yields dark red vanadic acid, the quantity of which can then be determined.

According to Sefström, the vanadic (and chromic) acid may be separated from the fused mass, after neutralisation with nitric acid, by the addition of a lead-salt; the washed precipitate is then boiled with strong alcohol and hydrochloric acid, the resulting blue solution of vanadic (and chromic) oxide, after being evaporated, is oxidised by nitric acid or chlorine-gas, then mixed with potash-ley, evaporated down, and fused; the fused mass is dissolved in water; and the vanadic acid is precipitated, as above, by sal-ammoniac. The liquid filtered therefrom (after separation of phosphoric and arsenic acids as ammonio-magnesian salts) yields with sulphydric acid a precipitate of chromic hydrate, while sulphide of molybdenum remains in solution, whence it may be precipitated by acids, and, when fused in a narrow tube, yields pure sulphide of molybdenum.

According to Müller, the mass obtained by fusing the iron with nitre and soda, may be dissolved in water, the filtrate treated with chlorine-gas, which separates phosphate of aluminium, and then saturated with nitric acid, afterwards with ammonia, and the vanadium precipitated by sal-ammoniac—or the fused mass is boiled with excess of sulphide of ammonium, or saturated with sulphydric acid gas (whereby chromic oxide and alumina are separated), and sulphide of vanadium precipitated from the solution of the alkaline sulphovanadate by an acid.

The chromic acid may be separated from the liquid filtered from the vanadate of ammonium by the ordinary methods, and most readily detected, after addition of pure nitric acid, by its reaction with peroxide of hydrogen (i. 953). The chromic acid may also be precipitated from the alkaline liquid, after neutralisation with nitric acid, by means of mercurous nitrate, the phosphoric and arsenic acids having first been precipitated by ammonia and nitrate of magnesium (the addition of sal-ammoniac and sulphuric acid must be avoided, as they would precipitate the mercurous salt).

Riley (Chem. Soc. J. xvii. 23) separates vanadium from pig-iron by dissolving the borings in dilute hydrochloric acid, and after the iron is nearly all dissolved, adding a strong acid, and boiling well; the chloride of iron is then filtered off from the graphite and silica; the filter well washed from chloride of iron, and treated with a dilute solution of potash to dissolve the silica; the potash thoroughly washed out; and the filter treated with hydrochloric acid, washed until all the acid is removed, then dried, ignited, and burnt over a Bunsen's burner, or better in a muffle. The residue is a semi-fused mass, apparently consisting of a mixture of a fusible and infusible oxide, staining a porcelain crucible yellow, and adhering strongly to it, some portions of the mass being of a purply blue colour, similar to the bloom of a plum.

The semi-fused residue, treated with concentrated hydrochloric acid, gives off chlorine, and forms a yellowish-brown solution, which on boiling soon becomes of a beautiful green colour, leaving a black, finely pulverulent, insoluble residue. The solution, freed from excess of acid by evaporation, leaves a syrupy dark green mass, which when heated with water, yields a small quantity of white insoluble flocculent matter, and a solution which has a green colour when acid, but blue when nearly neutral or largely diluted, and gives the characteristic reactions of vanadium-salts, especially the yellow precipitate, becoming greenish on standing, with ferrocyanide of potassium.

The black insoluble residue, fused with acid sulphate of potassium, forms a mass which dissolves perfectly in cold water, and yields on boiling a dense yellowish-white pulverulent precipitate, exhibiting the reactions of vanadium-salts. The black powder appears to be vanadous oxide, and the soluble portion of the original residue consists chiefly of vanadic acid. In a sample of grey pig iron from Westbury in Wiltshire, also containing a considerable quantity of phosphorus, part of which passed, as phosphoric acid, into the residue insoluble in dilute acids, Riley found—by separating the phosphoric acid from this residue as magnesium-salt, and considering the remaining portion soluble in concentrated hydrochloric acid, as vanadic acid—that the total quantity of vanadic acid in the pig was 0.686 per cent.

Molybdenum sometimes occurs in the carbonaceous residue left on dissolving pig iron in acids, and may be dissolved out together with arsenic, by sulphide of ammonium, and precipitated therefrom by acids: on heating the precipitate in a glass tube, sulphide of molybdenum remains behind.

Iron rich in molybdenum, such as the "bears" from copper furnaces (p. 367), may be dissolved in nitromuriatic acid; the solution evaporated to dryness after addition of hydrochloric acid; then redissolved and precipitated by sulphydric acid, with addition of metallic zinc. The whole of the molybdenum is thus precipitated, and may be separated from other metals by solution in sulphide of ammonium, precipitation therefrom by acids, and heating.

Titanium is obtained as titanitic acid [anhydride] when pulverised iron is heated in a current of hydrochloric acid gas and oxygen; it then remains, together with silica, alumina, lime, &c., and may be rendered soluble by fusion with carbonate of sodium.

When iron is dissolved in nitric acid, at last with aid of heat, and the solution is evaporated to dryness and redissolved in nitric acid, titanitic anhydride remains, together with carbon, silica, &c., and may be rendered soluble as above.

The iron may also be dissolved in cold hydrochloric acid, the solution mixed with tartaric acid to prevent the precipitation of the iron by ammonia, and the whole of the iron (together with cobalt, nickel, copper, &c.) precipitated by sulphide of ammonium; titanitic acid then remains in solution, and may be precipitated and estimated by methods which will be described under TITANIUM.

Riley (Chem. Soc. J. xv. 391), after dissolving the iron in hydrochloric acid, collects the residue on a weighed filter, treats the residue with dilute potash to dissolve out the silica, and after washing the filter with hydrochloric acid, dries it at 250°, and

weighs it. The weight of the residue, consisting of graphite mixed with titanio anhydride, being thus determined, the graphite is burnt off, and the dirty light brown residue is fused with acid sulphate of potassium; the fused mass dissolved in cold water; and the solution boiled, whereupon titanio anhydride is precipitated nearly pure. Part of the titanium is, however, dissolved by the acid together with the iron: hence, to obtain the entire amount, the solution obtained by fusing the residue from the silica with acid sulphate of potassium must be added to the iron solution, after the sulphur contained in it has been precipitated as a barium-salt, and the excess of baryta removed. The solution in which the titanium and phosphorus are to be determined, is first reduced with sulphite of sodium, and the excess of sulphurous acid driven off. It is then nearly neutralised with ammonia, and acetate of sodium or ammonium added. If there is only a small quantity of phosphoric acid present, there will always be sufficient ferric oxide to precipitate it; but if not, a few drops of nitric acid must be added, and the solution boiled and filtered as quickly as possible. This precipitate may be at once treated; or if it contains much ferric oxide, in excess of that sufficient to form phosphate of iron, it is better to redissolve it in hydrochloric acid, reduce it again with sulphite of sodium, and repeat the operation above described. The precipitate is then dissolved in hydrochloric acid, and chloride of magnesium, ammonia, chloride of ammonium, and tartaric acid added, the precipitate produced being allowed to stand two nights; then the ammonio-magnesium-phosphate is filtered off, dried, ignited, and weighed, and the phosphoric acid calculated from the pyro-phosphate of magnesium. The filtrate from the phosphoric acid is treated with sulphide of ammonium, and the sulphide of iron separated, the filtrate evaporated to dryness, ignited, and burnt in a muffle; or evaporated nearly to dryness, transferred to a flask, and treated with fuming nitric acid until all the tartaric acid is destroyed; in either case, the residue is fused with acid sulphate of potassium. The fused mass is dissolved in cold water, boiled for some hours, and allowed to stand a night in a warm place, when the titanio acid is filtered off and washed with dilute sulphuric acid—dried, ignited, and weighed. If the determination of phosphoric acid is not required, then the precipitate produced (either by one treatment or two) by the alkaline acetate, may be dried (without washing), burnt, and fused with acid sulphate of potassium, and dissolved in cold water, whereby a little phosphate of iron, which remains insoluble, is separated; and the solution being boiled, the titanio acid is precipitated, and may be separated as before. (For further details, see the paper above referred to.)

Tungsten, which sometimes occurs in the residue of the solution of iron in hydrochloric acid, may be rendered soluble by fusion with alkaline carbonate, and separated by precipitation with acids or with mercurous nitrate. It may be separated from the other constituents of the iron by the solubility of tungstic acid in ammonia, or of the sulphide in sulphide of ammonium.

14. *Estimation of the Iron.*—The amount of pure iron in carburetted iron is generally determined merely by difference, after all the other constituents have been estimated. It may, however, be estimated directly by Fuchs' method with metallic copper (p. 383), or by any of the volumetric methods hereafter to be described. Mohr recommends especially the use of two titrated solutions of chromate of potassium, one ten times more dilute than the other (p. 384).

IRON, CHLORIDES OF. Iron forms with chlorine two compounds, analogous to the bromides.

Ferrous Chloride, FeCl_2 , is obtained in the anhydrous state:—1. By passing chlorine or hydrochloric acid gas over iron filings or turnings heated to redness in a gun-barrel connected with a receiver into which the product may sublime.—2. By heating iron-filings with sal-ammoniac, ferrous chloride then remaining behind.—3. By boiling down a solution of iron in hydrochloric acid out of contact with the air, and heating the residue till the water is expelled.

Ferrous chloride crystallises in white or yellowish-white shining scales, which, according to Senarmont, are six-sided, and optically uniaxial; it has a specific gravity of 2.528, melts at a red heat, and sublimes when more strongly heated in a close vessel. Heated in an atmosphere of hydrogen, it is reduced, yielding hydrochloric acid and pure iron crystallised in tubes. Heated in dry air or oxygen gas, it is resolved into ferric oxide and chloride, the latter volatilising:

In contact with aqueous vapour at a red heat, it gives off hydrogen and hydrochloric acid, and is converted into ferroso-ferric oxide:

It absorbs ammonia-gas at ordinary temperatures, swelling up and crumbling to a

white powder, which, when exposed to the air, quickly takes up water and oxygen, and is converted into ferric oxychloride and ferrico-ammoniac chloride. Ferrous chloride, heated to redness in dry ammonia gas, is converted into a nitride of iron, Fe_3N_2 , containing 9.3 per cent. nitrogen (Frémy, Compt. rend. iii. 323). When mixed with a little charcoal powder, it is reduced by zinc-vapour at a red heat, yielding crystalline metallic iron, sometimes in dendrites, sometimes in tetrahedrons, and of specific gravity 7.84. (Ponmarède, Compt. rend. xxix. 520.)

Ferrous chloride exposed to moist air, absorbs water, and deliquesces. It dissolves easily in water and alcohol, but is insoluble in ether. It dissolves in 2 pts. water at 81.75° (Abt, Oesterreich. Zeitschr. f. Pharm. viii. 20); in 1 pt. of strong alcohol at 82.5° . (Wenzel.)

Hydrated Ferrous chloride, $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$, is most easily obtained by dissolving iron in aqueous hydrochloric acid, finally heating the solution with excess of metal, and filtering it at the boiling heat into a vessel moistened with strong hydrochloric acid. The bluish-green liquid, left to cool in well-closed vessels, deposits the hydrated chloride in crystals, which must be quickly pressed between paper and dried in air at about 30° . The bluish crystals are monoclinic, and cleave parallel to ∞P_{∞} and ∞P . Specific gravity, 1.937. The salt may be obtained as a crystalline powder by concentrating the solution in a flask or a retort, and evaporating the concentrated liquid over the water-bath to a paste, stirring till it is cold. The crystals heated in a close vessel first give off half their water, and the remainder at a higher temperature; when quickly heated, they melt in their water of crystallisation; they effloresce at ordinary temperatures when kept over oil of vitriol. They dissolve in 0.68 pts. water, easily in alcohol and, according to most authorities, in ether; according to Jahn, however, they are insoluble in ether. The solutions, especially the alcoholic, absorb nitric oxide gas, and assume a black-brown colour. The aqueous solution yields by electrolysis, iron and hydrogen at the negative, chlorine and oxygen at the positive pole.

Ferrous chloride forms double salts with the chlorides of the alkali-metals. A mixture of the concentrated solutions of ferrous chloride and *chloride of potassium* yields, by cooling or slow evaporation, the salt, $\text{K}_2\text{Fe}^{\text{II}}\text{Cl}_4 \cdot 2\text{H}_2\text{O}$ or $2\text{KCl} \cdot \text{FeCl}_2 \cdot 2\text{H}_2\text{O}$, in pale blue-green monoclinic crystals. A similar *ammonium-salt* is obtained by mixing the corresponding solutions, or by boiling iron filings with sal-ammoniac, hydrogen and ammonia being then set free.

Ferric Chloride. *Trichloride of Iron*, $\text{Fe}^{\text{III}}\text{Cl}_3$, also called *Perchloride of Iron*, *Iron sublimate*.—This compound is sometimes found in the craters of volcanos; it may be obtained artificially by the following processes:—1. A piece of iron wire or a watch-spring introduced red-hot, or with a piece of burning tinder at the end, into chlorine gas, burns with a red glow and forms ferric chloride, which then sublimes. The same result may be obtained by passing chlorine gas over gently heated iron.—2. Ferrous chloride heated in chlorine gas is converted into ferric chloride.—3. When ferrous chloride is heated in a vessel containing air, ferric chloride sublimes, and ferric oxide remains behind.—4. When an aqueous solution of ferric chloride is evaporated, the dry compound remains behind, mixed with more or less ferric oxychloride; the dry residue, gently ignited in a loosely closed flask, yields the ferric chloride sublimed in laminae.—5. A mixture of 1 pt. calcined ferrous sulphate, and 1 pt. chloride of calcium, is ignited in a flask till the ferric chloride sublimes. (Baur, Repert. Pharm. xxv. 432.)

Ferric chloride forms iron-black, iridescent plates, having a metallic lustre, and volatilising and subliming somewhat above 100° . When heated in contact with oxygen gas, it yields ferric oxide and chlorine; heated with aqueous vapour, it forms ferric oxide and hydrochloric acid gas. With sulphuric acid and with sulphur, it behaves like ferrous chloride. (A. Vogel.)

Hydrated Ferric chloride.—Ferric chloride dissolves in water with considerable evolution of heat, and likewise deliquesces in the air. The liquid formed by deliquescence is called *Oleum Martis*. The same solution may be obtained by the following methods:—1. By dissolving ferric oxide or its hydrate in boiling hydrochloric acid.—2. By dissolving iron to saturation in a definite quantity of hydrochloric acid; filtering the solution, and mixing it with half as much hydrochloric acid as it already contains; then heating the liquid to ebullition in a capacious vessel, and adding nitric acid in small portions, till the dark-brown colour first produced by the absorption of nitrous gas has given place to a yellowish-brown, and the further addition of nitric acid produces no evolution of nitrous gas. The mixture is very apt to froth over, especially towards the end of the operation, when all the nitric oxide which has been absorbed has been evolved. The same result may also be obtained by dissolving iron in nitromuriatic acid; but it is not easy to hit the right proportion of the acids.—3. By passing washed chlorine gas through aqueous hydrochloric acid saturated with iron, as long as the gas is absorbed. The dark brown liquid, which has a rough taste and

colours the skin yellow, yields, on evaporating and cooling, crystals containing two, or perhaps three different proportions of water.

a. *Dodeca-hydrated*, $\text{Fe}^2\text{Cl}^6 \cdot 12\text{H}^2\text{O}$ (with 40 per cent. water).—Ferric chloride deliquesces rapidly in the air, then crystallises in the form of this hydrate, and afterwards deliquesces much less quickly (Kinast, *Kastn. Arch.* xx. 281). The same hydrate likewise separates slowly from an aqueous solution of the chloride not too much concentrated—fine radii stretching out in all directions from particular points, and forming pale orange-yellow, opaque, hemispheric nodules, into which the whole liquid is ultimately converted. If the evaporation has been carried too far, the syrup will not crystallise unless it be exposed for some time to the damp air of a cellar, from which it can absorb water. (Mohr, *Ann. Ch. Pharm.* xxix. 173.)

β . A penta-hydrate, $\text{Fe}^2\text{Cl}^6 \cdot 5\text{H}^2\text{O}$ (with 21.7 per cent. water) is obtained by evaporating the liquid to a syrup, mixing it with a small quantity of strong hydrochloric acid to re-dissolve the precipitated ferric oxychloride, and leaving it to itself in the cold (Stein, *Repert. Pharm.* xiii. 264).—2. By fusing the crystals α , evaporating till the liquid becomes perfectly solid on cooling, replacing the lost hydrochloric acid, and leaving the solution to cool (Fritzsche).—3. The crystals α , placed beside oil of vitriol, under a receiver containing air, soon deliquesce and form a thick liquid, in which large crystals then form, till the whole is converted into a mass of crystals (Fritzsche, *J. pr. Chem.* xviii. 479). The 5-hydrate forms flat roseate or deep reddish-yellow crystals, which fuse readily, and solidify again at 42° ; they absorb water from the air very rapidly, and with evolution of heat (Fritzsche). When the crystals α and β are shaken together, a slight fall of temperature takes place, and a liquid is obtained—the same as that produced by imperfect evaporation of the crystals α —which produces great heat when mixed with water (Fritzsche). 1 at. ferric chloride dissolved in 9 at. water yields a liquid, which is identical with the *Oleum Martis* of the older chemists (as obtained by deliquescence of the solid chloride in the air), has a density of 1.545, and refuses to crystallise. Hence there are two solutions of ferric chloride in water to be distinguished; one containing more than 5 and less than 12 at., the other containing more than 12 at. water.

Hex-hydrate, $\text{Fe}^2\text{Cl}^6 \cdot 6\text{H}^2\text{O}$ (with 25 per cent. water)?—The hydrate is obtained, according to Wittstein, by leaving a solution of ferric chloride concentrated to a density of 1.50 in a covered plate, standing in a cool place, till it solidifies to a mass of rhombic plates; also by evaporating to a syrup and leaving it in a covered vessel in a warm place. According to Goble, Mohr, and Fritzsche, however, highly concentrated solutions of ferric chloride always yield the $\frac{5}{2}$ -hydrate.

Hydrated ferric chloride dissolves easily in *alcohol* and *ether*, forming yellow solutions, in which, however, if exposed to light or heat, especially in the ethereal solution, it is easily reduced to ferrous chloride. Ether abstracts it from the aqueous solution.

Ferric chloride is also easily reduced to ferrous chloride by *zinc*, *stannous chloride*, *sulphurous acid*, *sulphydric acid*, &c. *Hydriodic acid* reduces the concentrated, but not very dilute solutions of ferric chloride. *Silver* and *platinum*, immersed in the solution, are converted into chlorides, reducing the ferric to ferrous chloride. The reduction is likewise effected by many *organic bodies*. The reducing action of *tartaric acid* on ferric chloride has been applied to photographic purposes by Poitevin. (*Compt. rend.* lii. 94.)

A concentrated acid solution of ferric chloride yields by *electrolysis*, ferrous chloride at the negative pole, while chlorine, and a small quantity of oxygen are evolved at the positive pole. Liebig has suggested the use of this solution, instead of nitric acid, in the zinc-carbon battery; the zinc, according to Buff, should then be immersed in solution of common salt. Such a circuit is, however, less powerful than that of Bunsen.

Ferric chloride is much used in medicine; it is a powerful styptic, and is employed in the treatment of aneurisms and varicose veins. A few drops of the aqueous solution quickly coagulate albumin. (Handw. d. Chem. ii. [3] 607.)

Basic Ferric Chloride, or *Ferric Oxychloride*.—When a solution of ferric chloride is evaporated, hydrochloric acid, resulting from mutual decomposition of the ferric chloride and water, is always given off at a certain degree of concentration; at the same time a certain quantity of undecomposed ferric chloride volatilises, and a basic salt is left, consisting of ferric chloride with more or less ferric hydrate. The stronger the concentration, the greater is the quantity of basic salt in the residue. The evaporated mass no longer dissolves clearly in water, unless hydrochloric acid is added to reconvert the ferric hydrate into chloride. If the temperature be raised very high during the evaporation, a considerable quantity of ferric chloride is evolved, and a highly basic insoluble salt remains behind. A solution of ferric chloride heated to 300° in a sealed tube, deposits ferric oxide. (Senarmont.)

Insoluble ferric oxychlorides of variable constitution are likewise obtained by exposing a solution of ferrous chloride to the air; by precipitating a solution of ferric chloride with a quantity of alkali not sufficient to take up the whole of the chlorine; and by roasting iron in contact with metallic chlorides, chloride of sodium for example, all these compounds when heated, give off water, and afterwards ferric chloride, leaving ferric oxide.

Soluble ferric oxychlorides, or basic chlorides, are obtained by adding recently precipitated ferric hydrate to aqueous ferric chloride. The hydrate dissolves in considerable quantity, and a deep red solution is formed, containing from 5 to 6 or 7 molecules of ferric oxide to 1 molecule of the chloride. The solutions may be heated or diluted with water without decomposing; those which contain the larger quantities of oxide deposit a portion of it, however, on the addition of certain salts, and when evaporated, leave residues which do not redissolve in water. Compounds containing not more than 10 at. Fe^{O}_3 to 1 at. Fe^{Cl}_3 are, on the contrary, perfectly soluble in water after evaporation. (Phillips, Phil. Mag. [3] viii. 406; Ordway, Sill. Am. J. [2] xxvi. 197; Béchamp, Ann. Ch. Phys. [3] lvi. 306; lvi. 296.)

Ferric chloride forms with *chloride of cyanogen*, the compound $\text{Fe}^{\text{Cl}}_3 \cdot 2\text{CyCl}$, already described (ii. 279). It unites directly with *pentachloride of phosphorus*, forming the compound $\text{Fe}^{\text{Cl}}_3 \cdot 2\text{PCl}_5$, also produced by the action of pentachloride of phosphorus on ferric oxide. It is a brown substance, which melts easily, but is difficult to volatilise. (Weber, Pogg. Ann. cvii. 375.)

Ferric chloride unites with the chlorides of the alkali-metals, forming double chlorides: among which the ammonium salts are the most stable.

Ferrico-ammoniac chloride, $4\text{NH}^{\text{Cl}}_4 \cdot \text{Fe}^{\text{Cl}}_3 \cdot 2\text{H}^{\text{O}}_2$.—A solution of sal-ammoniac in a large excess of ferric chloride, when evaporated over oil of vitriol within a receiver containing air, yields garnet-coloured monoclinic crystals, which may easily be mistaken for regular octahedrons; they are not decomposed by water, like the corresponding compound of chloride of potassium (Fritzsche, J. pr. Chem. xviii. 484). By slowly evaporating a mixture of this nature, L. Gmelin obtained very deliquescent rectangular octahedrons, having two of the basal edges and four of the basal summits truncated.

A solution of from 3 to 24 pts. of sal-ammoniac and 1 pt. of ferric chloride in water, yields, on evaporation, roseate transparent crystals, which, according to Geiger, are acute rhombohedrons when they contain a medium quantity of iron, but obtuse when the proportion of iron is either very small or very large; according to Marx also (Schw. J. liv. 304) they appear to be made up of a very great number of small cubes not quite regularly grouped together, whereby the cubical shape is somewhat altered. The quantity of iron is small and variable. If 24 pts. of sal-ammoniac are used to 1 pt. of the ferric chloride, the crystals contain 0.86 per cent. of ferric chloride; if 14 pts. of sal-ammoniac are used, they contain 1.93; and with 3 sal-ammoniac, they contain 5.12 per cent. of ferric chloride. The mother-liquor of the last-mentioned crystals yields, on further evaporation, brown-red crystalline granules, containing 5.76 per cent. of ferric chloride (Geiger). When 10 pts. sal-ammoniac have been used with 1 pt. ferric chloride, the crystals contain 0.86 per cent. of the latter (Winckler, Repert. Pharm. lxvii. 155). The crystals, when heated, become yellow and opaque, and evolve, first sal-ammoniac, and afterwards ferric chloride. They dissolve in 3 pts. of cold water; those in which the proportion of ferric chloride does not exceed 5.12 per cent., become moist only in damp air; those which contain 5.75 per cent. Fe^{Cl}_3 , become moist even in dry air (Geiger, Repert. xiii. 422). When their aqueous solution is evaporated, sal-ammoniac crystallises out, nearly pure at first, but afterwards continually richer in iron, being first yellow and then red, and there remains a mother-liquid richer in iron.

To these mixtures of ferric chloride and sal-ammoniac belong the *Ferruginous Flowers of Sal-ammoniac*, *Flores Salis-ammoniaci martialis*. These are obtained:—1. By subliming 16 pts. sal-ammoniac with 1 pt. ferric oxide, whereupon ammonia is evolved: or with 1 pt. iron filings, in which case hydrogen is set free and protochloride of iron and ammonium is produced; the latter, however, if the air has moderately free access to it, is converted into ferrico-ammoniac chloride, while ferric oxide is left behind.—2. By subliming a mixture (obtained by evaporation) of 12 pts. sal-ammoniac, and ferric chloride prepared from 1 pt. of iron filings.—3. By dissolving 16 pts. sal-ammoniac and 1 pt. ferric chloride in water, and evaporating to dryness. Some pharmacopœias, however, direct the preparation of the crystals above described. The product is a yellow saline mass, which is yellower and more deliquescent in proportion as it is richer in iron.

Ammonio-trichloride of Iron, $2\text{NH}^{\text{Cl}}_4 \cdot \text{Fe}^{\text{Cl}}_3$, or *Chloride of Ferricum and Ferrico-ammonium*, $\text{NH}^{\text{Cl}}_4 \cdot \text{Fe}^{\text{Cl}}_3 \cdot 2\text{H}^{\text{O}}_2$.—Ferric chloride slowly absorbs ammonia gas at common temperatures, with slight evolution of heat, but without alteration of external appear-

ance. Part of the compound volatilises undecomposed when heated; the rest leaves ferrous chloride. It deliquesces in the air, but not so quickly as pure ferric chloride. When thrown into water in considerable quantities, it dissolves with a hissing noise, and forms a dark red transparent solution. (H. Rose, Pogg. Ann. xxiv. 302.)

Ferrico-potassic Chloride, $4\text{KCl} \cdot \text{Fe}^3\text{Cl}^3 \cdot 2\text{H}^2\text{O}$.—A solution of chloride of potassium in excess of ferric hydrochlorate evaporated under a bell-jar over oil of vitriol, yields small yellowish-red monoclinic crystals. A small quantity of water extracts chloride of iron from them, and leaves crystals of chloride of potassium undissolved, as may be seen by examination with the microscope. A larger quantity of water dissolves the whole; but, on evaporation, colourless crystals of chloride of potassium separate out first, and afterwards coloured crystals of the ferrico-potassic chloride; and at this degree of concentration, the crystals of chloride of potassium redissolve without any warming or stirring, and are reconverted into crystals of ferrico-potassic chloride. (Fritzsche, J. pr. Chem. xviii. 483.)

Ferrico-sodic Chloride melts at 200° , forming a very mobile liquid. (Deville.)

Ferrico-ammonio-potassio-sodic Chloride— $4(\text{NH}^1; \text{K}; \text{Na})\text{Cl} \cdot \text{Fe}^3\text{Cl}^3 \cdot 2\text{H}^2\text{O}$ (containing 12.1 per cent. potassium to 6.2 ammonium and 0.16 sodium)—is found, together with sublimed ferric chloride, in the craters of volcanos, and remains, after the removal of the ferric chloride by deliquescence, in ruby-red regular octahedrons, which may be dried over oil of vitriol. It is very deliquescent, and difficult to recrystallise without decomposition. (Kremer, Pogg. Ann. lxxxiv. 79.)

IRON, CYANIDES OF. (See CYANIDES, ii. 221.)

IRON, DETECTION AND ESTIMATION OF.—1. *Blow-pipe reactions.*—Iron-salts fused in small quantity, with borax on platinum wire in the outer flame, colour the bead yellow while hot, the colour disappearing on cooling. With a larger proportion of iron, the bead is red while hot, and yellow after cooling. In the inner flame a bottle-green glass is produced. With phosphorus-salt, when a moderate quantity of iron-salt is added, the bead is reddish-yellow in the outer flame while hot, becoming yellow as it cools, then green, and finally colourless. With a large proportion of iron, the bead is deep red while hot, becoming red-brown and dirty green as it cools, and reddish-brown when quite cold. The colours change by cooling much more quickly than those of the borax bead. These reactions are common to ferrous and ferric compounds (H. Rose). Ferrous oxide in minerals may be specially distinguished by heating the substance for a very short time in the inner flame with a bead of borax coloured pale blue by a small quantity of oxide of copper; the ferrous oxide then reduces the cupric oxide to cuprous oxide or metallic copper, which forms red spots on the bead. The heat must not be too long continued, as in that case ferric oxide, if present, would be reduced to ferrous oxide, which would then produce the reaction just mentioned. To check this result, a portion of the substance may be heated for a moment in the oxidising flame with a new borax bead containing copper; the bead will then assume a pale green colour if ferric oxide is present, whereas ferrous oxide would produce the red spots in this case also. (Chapman.)

2. Reactions in Solution.

Some compounds of iron are soluble in water, and the greater number are soluble in acids; many, however, especially native ferric oxide, and the artificially prepared oxide, after strong ignition, require prolonged boiling with strong hydrochloric acid to dissolve them. The solution of many iron ores, and of ferric oxide in a state of very dense aggregation, may be facilitated by addition of zinc or stannous chloride, which reduces the ferric to ferrous oxide. Many iron ores can be rendered soluble only by fusing them with alkaline carbonates; some only by fusion with acid sulphate of potassium or sodium.

Iron usually exists in solution as a ferric or ferrous salt, or partly in one state, partly in the other; rarely as ferric acid, on account of the great instability of the salts of that acid.

Ferric salts in solution are mostly yellow or reddish-yellow, more rarely (as in the case of the iron-alums) colourless or pale violet. *Sulphydric acid gas* passed into the neutral or acid solution of a ferric salt reduces it to a ferrous salt, with precipitation of sulphur, thus:

In a solution of neutral or basic ferric acetate, however, sulphydric acid forms a black precipitate of sulphide of iron; if, on the other hand, the liquid contains free acetic acid, nothing but a milky precipitate of sulphur is produced.

Sulphhydrate of ammonium produces, in neutral solutions of ferric salts, a black precipitate of sulphide of iron insoluble in excess of the precipitant, and becoming red-brown by oxidation in contact with the air. If the quantity of iron present is very

minute, no precipitate is formed at first, but the liquid acquires a green colour, and if kept for some time in a closed vessel, deposits sulphide of iron in black flocks.

Alkalis and alkaline carbonates produce a red-brown precipitate of ferric hydrate insoluble in excess of either of these reagents.

The carbonates of barium, strontium, and calcium, shaken up with a ferric solution, likewise form a precipitate of ferric hydrate.

Phosphate of sodium forms a white precipitate of ferric phosphate, which is turned red-brown by alkalis, dissolves easily in nitric or hydrochloric acid, but is insoluble in acetic acid.

Ferrocyanide of potassium forms a deep blue precipitate of Prussian blue, insoluble in acids, but dissolving in alkalis, with separation of ferric oxide. If the quantity of iron present is very small, the precipitate appears green, or the liquid merely acquires a green colour, and deposits blue flocks on standing.

Ferricyanide of potassium forms no precipitate, but changes the colour of the liquid to greenish-brown. If the least trace of a ferrous salt is present, a blue precipitate is produced.

Sulphocyanate of potassium changes the colour of ferric salts to deep blood-red, the coloration being very decided even in extremely dilute solutions: this is, in fact, the most delicate of all tests for the presence of iron in the ferric state. The red colour is not modified by addition of a small quantity of hydrochloric acid; but a large quantity nearly destroys it. A certain quantity of nitric acid destroys it completely after a while, and it is not restored by subsequent addition of the ferric salt. The red colour is also destroyed by oxalic, iodic, phosphoric, and arsenic acids, but reappears on again adding a solution of a ferric salt. Ammonia instantly decolorises the red solution and precipitates ferric hydrate. Sulphide of ammonium forms a black precipitate of ferric sulphide.

Infusion of galls colours ferric solutions deep blue-black, and renders them turbid. The precipitate is dissolved and the colour destroyed by free acids.

Ferric salts are easily reduced to ferrous salts by various *de-oxidising agents*; as by sulphydric acid, as already mentioned; by sulphurous, hyposulphurous, and phosphorous acids; by stannous chloride; by metallic iron, and even by silver at the boiling heat.

The reactions with sulphide of ammonium, alkalis, ferro- or ferri-cyanide of potassium, and sulphocyanate of potassium, serve to distinguish ferric salts from all other metallic salts.

Solutions of ferrous salts have a bluish-green or bluish colour, and, when exposed to the air, take up oxygen and are converted wholly or partially into ferric salts; and unless a sufficient excess of acid is present to form a neutral ferric salt with the quantity of iron present, part of the iron is precipitated in the form of a yellow-brown basic salt. They are likewise converted into ferric salts by *aërated water*, by *hypochlorous acid*, *nitric acid*, and by easily reducible metallic oxides and salts, such as those of silver, gold, and mercury. When nitric acid is the oxidising agent, the nitric oxide separated from it does not escape from the liquid at ordinary temperatures, so long as any portion of ferrous salt remains unoxidised, but remains dissolved, forming a dark greenish-brown solution.

A concentrated solution of ferrous sulphate or chloride placed in the circuit of a powerful voltaic battery, deposits metallic iron in small granules on the negative platinum wire. If the positive wire is dipped into a solution of common salt separated from the iron solution by moist clay, the iron is obtained in glittering crystals which exhibit magnetic polarity (Bequerel). Zinc immersed in a perfectly neutral solution of ferrous sulphate or chloride contained in a stoppered bottle, throws down metallic iron (together with oxide) which is deposited partly on the zinc, partly on the contiguous side of the glass. (Fischer, Pogg. Ann. ix. 266.)

Sulphydric acid forms no precipitate in a solution of ferrous salt containing an excess of one of the stronger mineral acids, but from a solution containing only a weaker acid, such as carbonic, oxalic, tartaric, or acetic acid, it precipitates part of the iron, in the form of a black hydrated ferrous sulphide, the precipitation in the three last-mentioned salts going on only till a moderate portion of acid is set free; the same reagent precipitates ferrous benzoate, and even, to a slight extent, the sulphate and chloride, if the acids are completely saturated with base. From the sulphate or chloride mixed with acetate of potassium, it throws down a considerable portion of the iron, but not the whole, even when the acetate is in excess. The black precipitate acquires a rusty brown colour by exposure to the air. It dissolves readily in hydrochloric or sulphuric acid, and likewise in a large quantity of acetic acid, provided it does not contain excess of sulphur.—The same precipitate, but containing the whole of the iron, is produced in all ferrous salts, on the addition of an alkaline *sulphydrate*, and it is not soluble in an excess of the reagent. A very dilute iron-solution to which sulphydrate of ammonium

is added, assumes a green colour, from the presence of iron-sulphide in a state of suspension.

Fixed caustic alkalis completely precipitate the iron in the form of a white hydrate, which, by exposure to the air, acquires a dingy-green and afterwards a red-brown colour.—*Ammonia* throws down part of the iron in the form of hydrate, the rest remaining dissolved in the liquid, which, when exposed to the air, becomes covered, first with a green and afterwards with a brown film. If the ferrous salt is previously mixed with sal-ammoniac, ammonia yields no precipitate, but forms a pale-green mixture which exhibits similar appearances on exposure to the air.

Monocarbonate of potassium or sodium, and *sesquicarbonate of ammonium*, throw down white ferrous carbonate, which soon acquires a green and afterwards a brown colour by exposure to the air, and, if sal-ammoniac be added, dissolves in the liquid, which then exhibits a green, and subsequently a brown turbidity on exposure to the air. *Acid carbonate of potassium or sodium* forms the same precipitate, with evolution of carbonic anhydride; but, if the solutions are dilute, a clear mixture is formed, which deposits ferrous carbonate on boiling, and on exposure to the air yields a precipitate of ferroso-ferric hydrate.—The carbonates of alkaline earth-metals do not precipitate ferrous salts. (Fuchs.)

Phosphate of sodium precipitates white ferrous phosphate, which acquires a bluish-green colour by exposure to the air.—*Arsenate of sodium* precipitates white ferrous arsenate, which becomes dingy-green on exposure to the air.

Oxalic acid and *acid oxalate of potassium* communicate a yellow colour to ferrous salts, and, after a while, throw down yellow ferrous oxalate, the precipitation being immediate when an alkaline oxalate is used.

Ferrocyanide of potassium forms a precipitate which is white, if the solution has been perfectly freed from air by boiling and the iron-salt is absolutely free from ferric oxide, but otherwise bluish-white: by exposure to the air, this precipitate is converted into Prussian-blue. *Ferricyanide of potassium* gives a deep blue precipitate (ii. 244), even in very dilute solutions.

Sulphocyanate of potassium neither alters the colour of ferrous solutions, nor forms any precipitate in them.

Tincture of galls neither colours nor precipitates ferrous salts when they are quite free from ferric oxide; but the mixture acquires a violet-black colour on exposure to the air.

The preceding reactions, especially those with the alkalis, and with ferrocyanide, ferricyanide, and sulphocyanate of potassium, afford marked distinctions between ferrous and ferric salts; it is but rarely, however, that ferrous solutions can be obtained so pure as to give the reactions exactly as they are above described, exposure to the air for a very short time being sufficient to convert a portion of the ferrous into ferric salt: hence the precipitate formed by ferrocyanide of potassium is generally somewhat bluish, and those formed by the alkalis have more or less of a dark-green tinge. The best way of obtaining a solution of iron quite free from ferric salt, is to immerse a few pieces of bright iron wire in aqueous sulphurous acid: a mixture of ferrous sulphite and hyposulphite is then formed, which gives a perfectly white precipitate with ferrocyanide of potassium.

Solutions containing both ferrous and ferric salts, such as are obtained by dissolving magnetic oxide of iron in hydrochloric acid, of course give reactions intermediate between those of pure ferrous and pure ferric salts; in particular, they give blue precipitates both with ferrocyanide and with ferricyanide of potassium; the formation of both these precipitates in a solution obtained by dissolving a mineral in hydrochloric or sulphuric acid, without the addition of any oxidising agent, such as nitric acid, may be taken as an indication that the mineral contains a mixture or compound of ferrous and ferric oxides. From such mixed solutions, the ferric oxide may be precipitated by means of carbonate of barium, while the ferrous oxide will remain in solution.

For the reactions of iron in the state of ferric acid, see ii. 637.

3. Quantitative Estimation of Iron.

Iron is always estimated by weight in the form of ferric oxide. If the solution contains ferrous oxide, either alone or mixed with ferric oxide, it is first boiled with a sufficient quantity of nitric acid to convert the whole of the ferrous oxide into ferric oxide, and then treated with ammonia in excess to precipitate the latter. The precipitate is collected on a filter, washed, dried, and ignited at a moderate red heat; too high a temperature expels a portion of the oxygen. Every 10 pts. of pure ferric oxide correspond to 7 pts. of metallic iron. In some cases, however, it is necessary to use potash as the precipitant. In that case, the precipitated ferric oxide is very apt

to carry down with it a portion of the potash, which is exceedingly difficult to remove by washing. It is best therefore, after having washed it two or three times with hot water, to redissolve it in acid and precipitate by ammonia. In other cases, as when the solution contains organic matter, the iron must be precipitated by *sulphide of ammonium*, because such substances prevent the precipitation of the oxide. To ensure complete precipitation, the liquid, after being mixed with excess of sulphide of ammonium, should be left for some time in a covered vessel standing in a warm place till it becomes quite colourless or yellow, then filtered as quickly as possible, protecting it from the air, and the precipitate washed with water containing sulphide of ammonium. The precipitated sulphide is then dissolved in nitric acid, and the iron precipitated by ammonia as before.

If the iron is mixed or combined merely with volatile or with easily combustible substances, its amount may be determined by simple ignition in contact with the air; all the volatile and combustible matters will then be driven off or burnt away, and the iron will be left in the form of ferric oxide: to ensure its complete conversion into this oxide, however, the residue should be moistened with nitric acid, and heated again.

An indirect method of estimating iron, given by Fuchs (J. pr. Chem. xvii. 160), depends upon the fact that metallic *copper* does not dissolve (or dissolves but very slowly, and only when finely divided, ii. 40) in hydrochloric acid, if kept from contact with the air, but when boiled with ferric chloride, it dissolves, with formation of ferrous and cuprous chlorides:

The solution of ferric chloride mixed with excess of dilute hydrochloric acid and diluted with water, is boiled in a flask, and clean copper-foil, not too thin (from 15 to 20 pts. copper to 2 or 3 pts. ferric oxide), is completely immersed in the liquid; the flask is closed with a perforated cork, having a narrow glass tube passing through it, and the liquid is boiled till it becomes permanently bluish-green or colourless. It is then left to cool with the flask closed; decanted from the undissolved copper; this copper washed by repeated affusion with hot water, and decantation, then dried between bibulous paper, and finally by heat, taking care not to rub it, and weighed. The loss of weight multiplied by 0.883 gives the quantity of iron in the solution: for each atom of copper (= 63.4) represents 1 at. iron (= 56) in the solution, and $\frac{56}{63.4} = 0.884$. Or

the loss of weight multiplied by $\frac{80}{63.4} = 1.261$ will give the quantity of ferric oxide

in the solution. To ensure the complete reduction of the ferric to ferrous chloride, it is essential that the air be entirely excluded from the vessel, and therefore that the boiling be kept up uninterruptedly till the liquid has become colourless.

Silver in the spongy state may also be used to reduce the ferric chloride. The products of the reaction are ferrous chloride, which remains in solution, and chloride of silver, which mixes with the metallic silver, and increases its weight. As in this reaction, each atom of chlorine that enters into combination with the silver corresponds to 1 at. iron ($\text{Fe}^{\text{e}}\text{Cl}^3 + \text{Ag}^0 = 2\text{FeCl}^2 + 2\text{AgCl}$), the increase of weight multiplied by

$\frac{56}{35.5} = 1.5774$ gives the quantity of iron in the solution; or $\frac{80}{35.5} = 2.2535$ gives the quantity of ferric oxide.

The method of reduction by copper or silver may be applied to determine the quantities of ferrous and ferric oxides, when they exist together in solution. The quantity of ferric oxide, or of iron existing as ferric salt, is first determined as above, the ferrous salt present not interfering with the reaction. It is necessary, however, to guard against the conversion of the ferrous into ferric salt by atmospheric oxidation: for which purpose it is best to perform the determination in an atmosphere of nitrogen or carbonic anhydride. Another portion of the solution is then treated with chlorine to convert the ferrous salt contained in it into ferric salt, and in this solution the total quantity of iron is determined by the same method. The difference of the two determinations gives the quantity of iron existing as ferrous salt.

Ferrous and ferric oxides may likewise be separated by means of *carbonate of barium* or *carbonate of calcium*, which precipitates ferric oxide from slightly acid solutions, but not ferrous oxide. It is necessary to have the solution slightly acid, since if it is perfectly neutral, a small quantity of ferrous oxide may likewise be precipitated. The solution, which should be slightly warmed, is shaken up with recently precipitated carbonate of barium (which acts more quickly than carbonate of calcium), in a corked flask filled with carbonic anhydride; then left to stand, and shaken up again from time to time, till it has become quite colourless, afterwards filtered, and the precipitate washed, always in an atmosphere of carbonic anhydride. The precipitate, consisting

of carbonate of barium mixed with ferric hydrate, is dissolved in dilute hydrochloric acid, the baryta precipitated by sulphuric acid, and the ferric oxide from the filtrate by ammonia. This determines the quantity of iron existing in the solution as *ferricum*. To find the quantity existing as *ferrosus*, the liquid filtered from the precipitate of carbonate of barium and ferric oxide is boiled with nitric acid, to convert the ferrous into ferric salts, then freed from baryta by sulphuric acid, and the iron is precipitated as ferric oxide by treating the filtrate with ammonia. Or another portion of the original solution may be treated with nitric acid, to bring all the iron into the ferric state, and the total quantity of iron determined by precipitation with ammonia. The difference of the two determinations will then give the quantity of iron existing as *ferrosus*.

Anhydrous ferroso-ferric oxides may be analysed by dissolving them in nitric or nitromuriatic acid, and precipitating the iron as ferric oxide by ammonia. The proportions of iron and oxygen are thus determined, whence the formula may be calculated.

Volumetric estimation of iron.—When iron is contained in a solution as ferrous oxide or ferrous salt, it may be estimated by determining the quantity of an oxidising agent required to convert it into ferric oxide; if, on the other hand, it is present as ferric oxide, the estimation may be made by measuring the quantity of a reducing agent required to bring it to the state of ferrous oxide.

1. *Methods depending on oxidation.*—The reagent most generally employed for converting ferrous into ferric oxide in volumetric analysis is *permanganate of potassium*. The method of applying it is fully described in the article ANALYSIS, VOLUMETRIC (i. 263).—If the iron in the solution under examination is present wholly as ferrosus, the method is directly applicable; if, on the contrary, the iron is present wholly or partly as ferricum, it must first be brought to the ferrous state by heating it with sulphurous acid or sulphite of sodium, or better with a few grains of pure zinc. In a mixture of ferrous and ferric salts, the ferrosus may be determined by treating one portion with the permanganate directly, and another after reduction of the ferric salt in the manner just described.

Acid chromate of potassium may also be used for the volumetric estimation of iron, and has the advantage of not varying in strength when its solution is kept in well closed vessels. The reaction between ferrous oxide and chromic acid may be represented by the equation:

whence we find that 1 grm. of iron requires 0.8849 grms. of acid chromate of potassium, $\text{K}_2\text{O} \cdot 2\text{CrO}_3$, to convert it from ferrous into ferric oxide. If, then, 8.849 grms. of the pure acid chromate are made into a litre (1000 cub. cent.) of solution, 100 cub. cent. of this solution will correspond to exactly 1 grm. of iron. The solution of the acid chromate is slowly added to the acid ferrous solution till a drop of the liquid no longer forms a blue precipitate with red prussiate. (Penny, Chem. Gaz. 1850, p. 599.)

Bunsen (Ann. Ch. Pharm. lxxxvi. 288) adds to the ferrous solution mixed with hydrochloric acid, a weighed quantity of acid chromate, more than sufficient for the complete oxidation of the ferrous salt, passes the chlorine evolved on heating, into a solution of iodide of potassium, and estimates the quantity of iodine thus liberated by the method described under ANALYSIS, VOLUMETRIC (i. 265). If no ferrous oxide were present, 1 at. $\text{K}_2\text{O} \cdot 2\text{CrO}_3$ would give 3 at. chlorine, and therefore 3 at. iodine; but as a portion of the chlorine is used up in converting the ferrous into a ferric salt, there will be 1 at. less of iodine set free for every 1 at. iron present as ferrous salt. The quantity of iron x will therefore be given by the formula:

$$x = \frac{3\text{Fe}}{\text{K}_2\text{O} \cdot 2\text{CrO}_3} \cdot p - \frac{\text{Fe}}{1} a (nt - t')$$

where p denotes the weight of acid chromate used, and a, n, t, t' have the same significations as in the article just cited.

For the exact estimation of iron in cast iron, iron ores, &c., Mohr uses two titrated solutions, one containing 8.785 grms. of the acid chromate in a litre, therefore 1 cub. cent. = 0.01 grm. iron; the second diluted ten times as much, therefore 1 cub. cent. = 0.001 grm. iron. A quantity of the substance, containing about 1 grm. of pure iron (that is to say 1.05 grm. pig iron, or 2.00 grms. iron ore, supposing the latter to contain about 50 per cent. iron) is then weighed out, and dissolved in hydrochloric acid; the whole of the iron in solution is brought to the ferrous state by reduction with zinc, &c.; the solution is then mixed with 100 cub. cent. of the stronger solution of chromate

and the more dilute solution is afterwards added from a burette, till the liquid no longer gives a blue colour with ferricyanide of potassium.

Or 1 grm. of the carburetted iron is dissolved in acid, &c.; the solution is mixed with 100 cub. cent. of the stronger chromate-solution; and as an excess of the latter is then present, it is titrated backwards with a graduated acid solution of ferrous-ammoniac sulphate (1 litre of this solution containing 7000 grms. of the crystallised salt $(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, together with a small quantity of free sulphuric acid, so that 1 cub. cent. = 0.001 grm. iron), till a blue colour is produced on addition of ferricyanide of potassium. The number of cubic centimetres of this iron-solution used must of course be deducted, as so many milligrammes of iron. (Mohr, *Dingl. pol. J.* cliix. 124.)

2. *Methods depending on Reduction.*—Strong (Pogg. Ann. xciv. 493) dissolves the metal or ore to be valued in boiling hydrochloric acid; oxidises, if necessary, with chlorate of potassium; dilutes with cold water, after expelling the free chlorine, and mixes the solution with excess of iodide of potassium, whereby iodine is set free:

A dilute titrated solution of *stannous chloride* is then added—whereby the brown colour of the solution is rendered lighter—and when only a small quantity of iodine remains in the free state, some clear starch-solution; then more stannous chloride, by drops, till the blue colour disappears. If the tin-solution has been titrated with acid chromate of potassium, the percentage of metallic iron is given by the formula:

$$x = \frac{100 \cdot 6\text{Fe} \cdot c}{A \cdot (\text{K}^{\text{e}}\text{O} \cdot 2\text{CrO}^{\text{e}})} \cdot \frac{CG}{g}$$

where c denotes the quantity of acid chromate in 1 c.c. of the standard solution of that salt, G the number of cubic centimetres of tin-solution added to produce decoloration, g the number of cubic centimetres of the same tin-solution used in determining its strength, C the number of cubic centimetres of the chrome-solution used to oxidise the y cub. cent. of tin-solution, and A the quantity of iron or ore dissolved.

Mohr (Ann. Ch. Pharm. cxiii. 257) after bringing the whole of the iron to the state of ferric chloride (by treating the solution of ferrous chloride with artificially prepared peroxide of manganese, and boiling to expel free chlorine), adds a small quantity of sulphocyanate of potassium, and then a standard solution of *stannous chloride*, till the red colour disappears, the tin-solution having been previously titrated with a solution of pure ferric chloride. Or the solution of ferric chloride under examination is mixed with starch and iodide of potassium heated to 50° or 60° , and the standard tin-solution added till the colour disappears. Fresenius uses a solution of stannous chloride of such a strength, that from 50 to 100 c.c. are required to reduce 1 grm. of pure iron (1.003 grm. harpsichord-wire) from ferric to ferrous chloride. He dissolves the iron or iron-compound in hydrochloric acid, oxidises with chlorate of potassium, and adds to the slowly but continuously boiling liquid, after all the free chlorine has been expelled, a quantity of standard tin-solution rather more than sufficient to decolorise it. The cooled liquid is then mixed with starch-solution; and a solution of iodine and iodide of potassium (containing about 0.005 grm. iodine in a litre), previously titrated against the tin-solution, is added till a permanent blue colour is produced. The quantity of this iodine-solution required for the purpose gives the *excess* of tin-solution previously added.

In using a solution of stannous chloride for the estimation of iron, it is essential that the water with which the iron-solution is diluted be free from air; otherwise a portion of the stannous salt will be oxidised thereby.

When ferric chloride is brought in contact with *hyposulphite of sodium*, tetrathionate of sodium is formed, together with chloride of sodium and ferrous chloride, but no sulphuric acid:

According to this equation, 248 parts crystallised hyposulphite of sodium $\text{Na}^{\text{e}}\text{S}^{\text{e}}\text{O}_3 \cdot 5\text{H}_2\text{O}$ correspond with 162.5 pts. ferric chloride; or 100 pts. iron, present as ferric, require for reduction to ferrous, 442.9 pts. of the crystallised hyposulphite.

Mohr (*loc. cit.*) uses hyposulphite of sodium in the same way as stannous chloride, mixing the solution of ferric chloride with iodide of potassium, a little hydrochloric acid and starch-paste, heating it to 50° – 60° , and adding the standard solution of hyposulphite till the blue colour disappears.

These reduction-processes may also be used for determining the proportions of ferric and ferrous salt existing in the same solution, one portion of the solution being titrated in its original state, another after all the iron has been converted into ferric salt; the difference gives the amount of iron existing as ferrous salt.

4. Separation of iron from other elements.

From all metals of the first group (i. 217), iron is easily separated by *sulphydric acid*, which throws down all those metals, leaving the iron in solution. The filtrate, which contains the iron in the form of ferrous salt, must then be heated with nitric acid to oxidise the iron, which may afterwards be precipitated by ammonia.

The separation of iron from the metals of the second group, which are not precipitated by *sulphydric acid* from acid solutions, but are precipitated, together with iron, by *sulphide of ammonium* from neutral or alkaline solutions, is more difficult.

From manganese (present as manganous salt) and from zinc, iron is most effectually separated by *succinate* or *benzoate of ammonium*. The solution, after all the iron has been brought to the state of ferric salt, is mixed with a sufficient quantity of *sal-ammoniac* to hold the manganese or zinc in solution, and very carefully neutralised with ammonia; it is then treated with *benzoate* or *succinate of ammonium*, which throws down the iron as ferric benzoate or succinate, leaving the manganese or zinc in solution. The precipitate is washed, dried, and ignited in an open platinum crucible, so that the air may have sufficient access to it, to prevent any reduction of the iron by the carbon of the organic acid. Should such reduction take place, the iron must be reoxidised by nitric acid. The success of this mode of separation depends entirely on the care with which the acid in the solution is neutralised with ammonia before adding the benzoate or succinate. If too much ammonia has been added, manganese or zinc goes down with the iron; if too little, a portion of iron remains in solution. The addition of ammonia should be continued till a small quantity of ferric oxide is precipitated, and does not redissolve on agitation. The supernatant liquid has then a deep brown colour, the greater part of the iron being still in the solution.

The separation of iron (as *ferricum*) from manganese and zinc may also be effected by agitating the solution with *carbonate of barium* (as in the separation of ferric from ferrous oxide, p. 383), which precipitates the iron as ferric oxide, leaving the other metals in solution.

According to J. Schiel (Sill. Am. J. [2] xv. 275) manganese may be separated from iron by mixing the solution with *acetate of sodium*, and passing *chlorine* through it, which throws down the manganese as peroxide.

Zinc may be separated from iron (*ferricum*) when both are present as acetates in a solution containing a sufficient quantity of free acetic, but no inorganic acid, by passing *sulphydric acid gas* through the solution, the zinc being then precipitated while the iron remains in solution. If the two metals are combined with any other acid, they must be precipitated by *carbonate of potassium*, and redissolved in acetic acid; or if they are present as sulphates, they may be converted into acetates by decomposition with *acetate of barium*.

For the methods of separating iron from cobalt, see vol. i. p. 1046. When the two metals are precipitated together by *sulphide of ammonium*, the separation may be effected by digesting the sulphides with acetic, as well as with dilute hydrochloric acid; the iron then dissolves as acetate, while the cobalt remains behind.

Iron may be separated from nickel by the same methods as from cobalt (excepting that with nitrite of potassium). Nickel may also be separated from iron (*ferricum*) by mixing the solution with a large quantity of *sal-ammoniac* (20 pts. of that salt to 1 pt. of nickel), precipitating the iron with *carbonate of ammonium*, then heating the liquid slowly to the boiling point, keeping it at that temperature for some time, adding a small quantity of ammonia and filtering: ferric oxide then remains on the filter, while all the nickel passes through in solution (Schwarzenberg, Ann. Ch. Pharm. xevii. 216). Iron and nickel may also be separated by precipitating the iron as ferric oxide with *carbonate of barium*. For the separation of iron from cobalt, this method is not so well adapted, because a small portion of the cobalt is apt to be precipitated at the same time.

Uranium may be separated from iron, both being in the state of sesquioxides, by treating the solution with excess of *carbonate of ammonium*, which precipitates the ferric oxide, and retains the uranium in solution. The carbonate of ammonium must, however, be quite neutral, as if it contains any excess of carbonic acid, part of the iron may be redissolved. To ensure this condition, the carbonate of ammonium should be previously boiled, and the solution of the metals, if acid, must be neutralised with ammonia till a slight permanent precipitate begins to form; the solution is then to be diluted with water, the carbonate of ammonium added, and the precipitate digested with it for some time before filtering.

For the separation of iron from cerium, chromium, didymium, lanthanum, molybdenum, niobium, platinum and its congeners, tantalum, titanium, tungsten, and vanadium, see those metals; also pp. 374, 375.

From aluminium, iron in the form of ferric salt may be separated by caustic potash, which when added in excess, and boiled with the concentrated solution of the two salts, precipitates the iron as ferric oxide, and retains the alumina in solution. If the proportion of iron is small (not exceeding 1 pt. ferric oxide to 100 alumina), this method of separation is sufficiently exact; but when it is larger, a portion of the alumina always remains with the ferric oxide, and must be separated by redissolving the precipitate in a small quantity of hydrochloric acid, and repeating the treatment with potash. With very large quantities of iron, this treatment must sometimes be repeated three or four times before complete separation is effected. The process may be modified by first reducing the ferric solution with sulphurous acid or an alkaline sulphite, and then boiling with potash till the iron is precipitated as dark green ferrous-ferric oxide; but in this way also the separation is not quite complete; if too much sulphurous acid is added, a small quantity of sulphite of aluminium is sometimes precipitated on boiling.

Iron and aluminium may, however, be much more easily separated by means of *hyposulphite of sodium*, which precipitates alumina together with sulphur, leaving the iron in solution (i. 155).

Another very good method of separating iron and aluminium is to mix the solution with a quantity of *tartaric acid*, sufficient to prevent the precipitation of the oxides when the liquid is rendered alkaline, then add excess of ammonia, and precipitate the iron as sulphide by *sulphide of ammonium*. The same method serves to separate iron from various other metals, *e.g.* cerium, glucinum, magnesium, thorium, yttrium, and zirconium.

Aluminium (or glucinum) may also be separated from iron by precipitating the alumina and ferric oxide together with *ammonia*, and igniting a weighed quantity of the washed and calcined precipitate in a stream of hydrogen. The iron is then reduced to the metallic state, while the alumina remains unaltered. The loss of weight gives the quantity of oxygen which was combined with the iron, whence the quantity of ferric oxide may be calculated, and the alumina determined by difference. As a check on the result, which is especially necessary when the quantity of iron is small, the residue may be digested for 24 hours, without heating, in very dilute nitric acid (1 pt. acid of specific gravity 1.2 diluted with more than 30 pts. water), which dissolves the iron without attacking the ignited alumina. A slight loss may arise in this process, in consequence of particles of the alumina (or glucina) being carried over by the stream of hydrogen (Rivot). Deville modifies this process by exposing the mixture of metallic iron and alumina, obtained as above, to a very strong red heat, in a stream of *hydrochloric acid* gas, whereby the iron is volatilised as chloride, while the alumina remains unaltered, and may afterwards be weighed; the iron is then determined by difference. Or the iron may also be directly determined by passing the vapour of boiling hydrochloric acid into the tube and attached receiver, in which the chloride of iron is condensed, oxidising the solution of ferrous chloride thus obtained with nitric acid, and precipitating by ammonia.

From glucina, and from most other protoxides, iron in the form of sesquioxide may be separated by precipitation with carbonate of barium (p. 383).

From *magnesia*, ferric oxide may be separated by precipitation with *ammonia* after addition of sal-ammoniac—better with *succinate* or *benzoate of ammonium*, as already described for manganese (p. 386), or with *carbonate of barium*.

From the alkalis and alkaline earths, ferric oxide may be separated by *ammonia*; in the case of the alkaline earths, however, care must be taken not to add more than a slight excess of ammonia, and to protect the precipitate from the air during filtration and washing; otherwise carbonic acid will be absorbed, and earthy carbonates will be precipitated, together with the ferric oxide, and the precipitate, after washing, will appear light-coloured; it must then be redissolved in acid, and reprecipitated by ammonia. If the solution contains any organic substance, the iron must be precipitated by sulphide of ammonium (p. 383).

Precipitation by ammonia serves to separate iron in the ferric state from most of its inorganic salts, *e.g.* the nitrate, sulphate, &c. From phosphoric or boric acid it may be separated by dissolving the salt in hydrochloric acid, adding tartaric acid in sufficient quantity to prevent precipitation by alkalis, then adding excess of ammonia, and precipitating the iron by sulphide of ammonium.—For other methods of analysing phosphates of iron, see PHOSPHORIC ACID.

From *arsenic*, iron may be separated by precipitation with *sulphydric acid*, the arsenite or arsenate of iron being dissolved in hydrochloric acid. These salts may also be decomposed in the dry way, by ignition in a stream of *sulphydric acid* gas, sulphide of arsenic then volatilising, and sulphide of iron remaining. (See also p. 374.)

5. Assay of Iron ores.

1. *In the wet way.*—From most ferruginous minerals that are actually used for the extraction of iron, viz. the oxides and carbonates, the iron may be dissolved out by boiling with hydrochloric acid, the insoluble residue consisting of quartz, clay, &c which may be further analysed by fusion with an alkaline carbonate.

The acid solution generally contains—besides iron—manganese, aluminium, calcium magnesium, the alkali-metals, and small quantities of sulphur, phosphorus, arsenic, silicon, and titanium, and less frequently copper, zinc, lead, vanadium, chromium, molybdenum, and tungsten. These elements may be detected and separated by method already described, or to be described, under their respective heads (see also pp. 374–376). The last four, together with titanium, may be separated by fusing the pulverised ore with a mixture of alkaline carbonate and nitrate, and treating the fused mass with water, whereby a solution is formed, which may contain titanate, vanadate, chromate, molybdate, and tungstate of alkali-metal, together with silicate, arsenate, and phosphate.

If the whole of the iron cannot be extracted from an ore by boiling with hydrochloric acid, it must be pulverised and fused with carbonate or acid sulphate of alkali metal (bisulphate of potash), and the fused mass then dissolved in water or aqueous acid, freed from silica by evaporation, and further examined for the above-mentioned constituents.

In the complete quantitative analysis of iron ores, it is necessary to determine the water and carbonic acid. The water may be estimated by igniting the ore in a glass tube, and condensing the aqueous vapour by means of chloride of calcium; the carbonic acid by the method described under ALKALIMETRY (i. 119). When either water or carbonic acid is present alone, its amount may be determined by the loss of weight sustained on ignition.

If the percentage of iron in the ore is the only point to be determined, the iron, after being brought into the ferric state by oxidation with nitric acid, may be precipitated by ammonia, or, if phosphoric and arsenic acids are present, by sulphide of ammonium after addition of tartaric acid (p. 387). Alumina, if present, must be separated by one of the methods already described. All the trouble of these separations may, however, be avoided by adopting Fuchs' method of estimation with metallic copper, which gives correct results, provided all necessary precautions are taken to exclude the air, or by one of the volumetric methods already described.

2. *In the dry way.*—The object of this mode of assaying, which is an imitation, on the small scale, of the process which goes on in the blast furnace, is to determine, not only the quantity of iron contained in an ore, or rather the quantity that can be extracted by smelting, but likewise the quality of the pig iron obtainable, and generally also that of the slag.

10 grms. of the finely-pounded ore are mixed with 3 to 10 grms. of anhydrous borax (according to the proportion of the gangue); and the mixture is placed in a crucible lined with charcoal (*creuset brasqué*),* and exposed in a powerful air-furnace or a portable blast-furnace—Griffin's blast gas-furnace (ii. 787), for example—to a gradually increasing heat, raised at last to whiteness. After cooling, there is found in the crucible, if the operation is successful, a well-fused regulus of cast iron, and above it a slag composed of borax and the materials of the gangue. The regulus must be carefully freed from slag and weighed. It should have a grey colour without much appearance of separated graphite. A large separation of graphite shows that the heat has been too great. If the metal is white, it is very fusible and probably contains manganese; it is then imperfectly carbonised, or it contains phosphorus, arsenic, or sulphur. The slag should not contain either globules of iron mechanically mixed (these, if present, must be separated from the pulverised slag by levigation, or by the magnet), or iron chemically combined, which latter condition will be indicated by a green colour in the slag. The weight of the regulus is increased by the carbon which it contains, but, on the other hand, a small quantity of iron always remains in the slag, and the two errors thus produced may, for the most part, be regarded as compensating one another.

Sometimes powdered glass free from metal is used instead of borax, to increase the fusibility of the gangue; or the ore to be assayed is mixed with the same kind of flux that is to be used in the actual smelting process—that is to say, with chalk, if the

* To prepare these crucibles, a Hessian or Cornish crucible is lined with successive layers of a paste composed of fine charcoal-powder mixed with water, the whole being well stamped with a wooden pestle. As soon as a layer has been well pressed, its surface must be roughened with a knife, so that the next layer may adhere to it well; otherwise the layers will separate when heated. The crucible having been thus filled with stamped charcoal, the portion which projects over the edge is removed, a cavity with rounded bottom is made in the middle, and the sides and bottom of this cavity are polished with a rounded glass rod.

gangue consists of quartz or clay, or with clay if the gangue is chiefly limestone. To ascertain approximately the quantity of flux required, a preliminary analysis may be made:—1. By gently igniting 10 grms. of the ore, to determine the amount of water and carbonic acid.—2. By exhausting another sample with very dilute nitric acid, to determine, by the loss of weight after washing and heating, the amount of water, carbonic acid, and lime, taken together.—3. By boiling with hydrochloric acid till all the iron is dissolved out, and weighing the residue, which consists of quartz and clay: the loss of weight in this experiment, compared with that in the second, gives the amount of ferric oxide.

These points being determined, 10 grms. of the ore are mixed with such a quantity of clay or chalk that the assay may contain 3 pts. chalk to 2 pts. clay (Regnault). A certain quantity of fluorspar or borax may likewise be added. For rich ores, Karsten takes 1 gm. fluorspar and 1 gm. calcined borax to 10 grms. of ore; for the poorer ores 2.5 grms. fluor and an equal quantity of chalk; and for very poor ores, the same, with 1 gm. borax.

For ores not containing silica, a certain quantity of clay or quartz is added with the fluorspar. Or 10 grms. of ore are mixed with the following proportions of flux:

Magnetic iron ore . . .	1 gm. chalk and	2.5 grms. fluorspar.
Specular iron ore . . .	0.5 " "	2.5 " "
Red hæmatite . . .	2.5 " "	2.5 " "
Brown hæmatite . . .	2.0 " "	2.0 " "
Clay iron ore . . .	2.5 to 3.0 " "	2.5 to 3.0 " "
Sparry iron ore . . .	1.0 " "	2.0 to 3.0 " "

If the right proportion of flux has been added, and the proper temperature attained, a well-constituted regulus is produced (p. 388), together with a good slag, having a grey-yellowish or sometimes violet colour, an enamel-like or sometimes glassy aspect, and a conchoidal fracture. If the slag is stony or earthy, yellow, grey, or brown, with rough fracture, it is too rich in bases; too great an excess of lime causes it to crumble easily when touched. If, on the other hand, there is an excess of silica, the slag is glassy, more or less transparent, of green colour (arising from ferrous oxide), and very brittle. The results of a successful assay yield the requisite data for smelting on the large scale.

6. Atomic Weight of Iron.

The atomic weight of iron has been determined in several ways:—1. From the weight of ferric oxide obtained by dissolving a known quantity of pure iron (harpsichord wire) in nitric acid, precipitating with ammonia, &c., the small quantity of carbon contained in the iron being estimated and allowed for.—2. From the quantity of iron obtained by reducing a known weight of ferric oxide with hydrogen.—3. By measuring the volume of hydrogen evolved in the solution of iron in hydrochloric acid.—4. From the quantity of chloride of silver obtained by precipitating a known quantity of pure ferrous or ferric chloride with nitrate of silver. The following table exhibits the results obtained by various chemists; the determinations are arranged in chronological order, and the bracketed numbers indicate the method employed:

Berzelius* (1) . . .	Fe = 27.12	Berzelius§ (1) . . .	Fe = 28.03
Gay-Lussac† (1) . . .	Fe = 28.36	Erdmann & Marchand (2) Fe =	28.01
" (3) . . .	Fe = 28.27	Maumené¶ (1) . . .	Fe = { 27.98
H. Davy‡ (4) . . .	Fe = 27.98		{ 28.02
Svanberg and Norlin§ (1) . . .	Fe = 27.94	Dumas** (4) . . .	Fe = { 28.10
" (2) . . .	Fe = 27.99		{ 27.99

The number 27.12, deduced from the first experiments of Berzelius, was for many years received as the true atomic weight of iron, although Bucholz, some years before, had made a determination of the composition of ferric oxide, which now appears to have been nearer the truth. Berzelius was afterwards led to conclude that his first experiments were affected with an error, arising from the action of the nitric acid on the glass vessel used, and from subsequent experiments, in which platinum vessels were employed, he obtained the higher number 28.03. The whole number 28, which is the mean of all the most trustworthy determinations, is now universally adopted as the true atomic weight of iron, on the supposition that the metal is univalent in the ferrous, and sesqui-valent in the ferric salts, e.g. ferrous chloride = FeCl ; ferric

* Gilt. Ann. vii. 313.

† Ann. Ch. Pharm. i. 422.

‡ Ann. Ch. Pharm. cxlii. 26.

§ Ann. Chim. lxxx. 163.

|| Ibid. lii. 212.

¶ Phil. Trans. cii. 161.

** Ann. Ch. Phys. [3] xxx. 200.

chloride = Fe^2Cl^2 . If, however, iron is supposed to be bivalent in the ferrous, and trivalent in the ferric compounds—which is the view now generally adopted, e.g.

Ferrous chloride . . .	$FeCl^2$	Ferric chloride . . .	$FeCl^3$
Ferrous oxide . . .	FeO	Ferric oxide . . .	FeO^3

then the atomic weight is $Fe = 56$. (See METALS, ATOMIC WEIGHTS OF; also i. 470; ii. 30.)

The equivalent of iron, that is to say, the quantity of the metal which replaces 1 at. of hydrogen, is, in the ferrous compounds, e.g. $FeCl^2$, equal to 28, and in the ferric compounds, e.g. Fe^2Cl^4 , or $FeCl^3$, it is $\frac{2}{3}$ of 28, or $18\frac{2}{3}$, which number is denoted by fe . (See EQUIVALENTS, ii. 403.)

IRON, FLUORIDES OF. *Ferrous fluoride*, FeF^2 , is obtained by dissolving iron in aqueous hydrofluoric acid, and crystallises by evaporation, or as the solution approaches saturation, in small, colourless, rectangular plates containing water, which they give off without decomposition when moderately heated. The anhydrous fluoride is not altered by ignition, even in contact with the air, but the hydrated salt soon turns yellow on exposure to the air, and if quickly heated, oxidises partially, giving off hydrofluoric acid. The hydrated crystals dissolve slowly in pure water, more easily in acids. Ferrous fluoride forms with *fluoride of potassium* a soluble double salt, $2KF.FeF^2$, which separates in granular crystals. (Berzelius.)

Ferric fluoride, Fe^2F^3 , is obtained by dissolving ferric oxide or hydrate in aqueous hydrofluoric acid, and separates on evaporation in pale flesh-coloured crystals. When heated in a platinum crucible, over a lamp urged by a blast, it melts, sometimes exhibiting on the surface small cubic crystals of the fluoride, while the fused mass has a rose-red colour, perhaps due to the formation of a small quantity of ferric oxide. Ferric fluoride is isomorphous with fluoride of aluminium, somewhat more fusible than that compound, and equally volatile. (Deville, Compt. rend. xliii. 970.)

Ferric fluoride dissolves slowly but completely in water, forming a colourless, sweetish, astringent liquid. Its solution mixed with ammonia deposits a basic salt, or oxyfluoride, which, when dry, forms a rust-yellow powder.

Mixtures of the solutions of ferric fluoride and fluoride of potassium deposit, on slow cooling, colourless, crystalline, sparingly soluble double salts. If the solution of the ferric fluoride is added by drops to that of the potassic fluoride, the salt formed is $2KF.Fe^2F^3$, in the contrary case, $4KF.Fe^2F^3$. (Berzelius.)

IRON-GLANCE. *Specular Iron ore.* See IRON, OXIDES OF (p. 385); also IRON (p. 388).

IRON, HYDRATES OF. See IRON, OXIDES OF (pp. 393—399).

IRON, HYDRIDE OF. The flame of hydrogen evolved by dissolving iron in dilute acids sometimes yields black spots when a cold piece of porcelain is held in it, and has hence been supposed to contain a gaseous compound of iron and hydrogen; but Fresenius and Schlossberger (Ann. Ch. Pharm. xlv. 264), and other chemists, have shown that these spots are produced by phosphorus, and that the gas, when perfectly freed from mechanical impurities, does not produce them. Cameron (Chem. News, ii. 181) has shown that no ferruretted hydrogen is formed by dissolving the alloy of iron and sodium in acids.

When ferrous iodide is treated with zinc-ethyl and ether, gas is evolved (consisting of hydride of ethyl and hydrogen), and the residue, after washing with ether, yields a hydride of iron, mixed with metallic iron, in the form of a black powder, resembling metallic iron, and decomposing with evolution of hydrogen, in contact with water, or when heated. (Wanklyn and Carius, Ann. Ch. Pharm. cxx. 74.)

IRON, IODIDES OF. *Ferrous Iodide*, FeI^2 , is obtained by heating or triturating iodine with a slight excess of iron filings, is a brown compound, which melts at a red heat, forms a grey laminar mass on cooling, and volatilises at a stronger heat. It dissolves readily in water, and the pale green solution, which may also be formed directly by digesting 1 pt. iron and from 2 to 4 pts. iodine in water, yields, when evaporated in contact with iron, and protected from the air, green deliquescent crystals, containing $FeI^2.5H^2O$. Both crystals and solution, when exposed to the air, very quickly turn brown, from formation of oxyiodide, and separation of ferric hydrate and iodine. Ferrous iodide cannot, therefore, be easily kept unaltered, either in the solid state or in solution; it keeps best when mixed with a sufficient quantity of common sugar or milk-sugar. For preparing the compound for medical use, Mohr recommends that 1 pt. iodine be converted into ferrous iodide by trituration with iron and water, the filtered liquid mixed with 25 pts. of simple syrup, and the whole quickly evaporated down to 25 pts.; 20 pts. of this syrup contain 1 at. of ferrous iodide. It is best,

IRON, METEORIC—IRON, NITROSULPHIDES OF. 391

however, to prepare the compound fresh every time it is wanted, which is not difficult, as the action is very quick.

The solution of ferrous iodide treated with alkaline carbonates, yields iodides of the alkali-metals, and may be used for the preparation of those compounds.

Ferrous iodide easily dissolves an excess of iodine: on adding 1 at. iodine to 3 at. ferrous iodide, a brown solution is formed (containing Fe^2I^4), which, when mixed with carbonate of potassium, yields iodide of potassium and black ferrous-ferrie hydrate; it is doubtful whether the brown solution contains iodated ferrous iodide, or a ferrous-ferrie iodide, analogous to the magnetic oxide.

Ferric iodide, Fe^3I^4 , is not known with certainty, but appears to be formed when iron is heated in excess of iodine-vapour. The resulting compound dissolved in water, yields a brown-red solution, which reacts like that which is obtained by dissolving iodine in ferrous iodide, as above, or by dissolving ferrous hydrate in hydriodic acid. All these solutions, when exposed to the air, give off iodine and deposit ferric hydrate.

IRON, METEORIC. See p. 336.

IRON, NATIVE. See p. 335.

IRON NATROLITE. See NATROLITE.

IRON, NITRIDE OF. Iron heated to dull redness in a porcelain tube, and subjected to the action of ammonia gas, becomes white, brittle, and increases in weight by about 12 per cent. The compound thus formed is supposed by Despretz (Ann. Chim. Phys. [2] xlii. 122) to be a nitride of iron; but it has not been analysed, and is supposed by some chemists to contain hydrogen. It dissolves in weak acids, with evolution of hydrogen and nitrogen, and formation of ammoniacal salts. At a white heat it decomposed, giving off its nitrogen. Hydrogen, at a red heat, withdraws the nitrogen, forming ammonia.

Sometimes the iron, after ignition in ammonia-gas, is found to be altered in physical properties, and yet not to have increased in weight; in such a case, the combination of the nitrogen with the iron is but transient, but nevertheless appears to alter its molecular structure.

Nitride of iron is also produced when oxide of iron is ignited in ammonia gas; also in minute quantity when nitrogen gas is passed over red-hot iron. (Pelouze et Frémy. *Traité*, ii. 452.)

Respecting the controversy about the existence of nitrogen in steel, see STEEL.

IRON, NITROSULPHIDES OF. *Nitrosulfures de fer.* (Roussin, Ann. Ch. Phys. [3] li. 285.)—Compounds produced by the simultaneous action of nitrites and alkaline sulphides on iron-salts. They contain nitric oxide, together with sulphide of iron and sulphide of hydrogen or an alkali-metal, and may therefore perhaps be regarded as analogous in composition to the nitroferri-cyanides (ii. 250), that is to say, as sulphides of iron in which 1 at. sulphur is replaced by 2 at. *nitrosyl*, NO. They contain in fact a disulphide of iron, FeS_2 , in which the fourth, or sometimes the half, of the sulphur may be supposed to be replaced by an equivalent quantity of nitrosyl. The analogy of the nitrosulphides to the nitroferri-cyanides is shown by the fact, that when a solution of nitroferri-cyanide of sodium is completely decomposed by sulphydric acid, and the solution boiled and evaporated, the residue contains dinitrosulphide of iron, which may be reconverted into a nitroferri-cyanide by treating it with cyanide of potassium. A mixture of iron-salt and nitrite of potassium yields a nitroferri-cyanide when treated with cyanide of potassium, and nitrosulphide of iron when treated with sulphide of potassium. In neither of these classes of compounds can the iron be detected by ordinary reagents.

Dinitrosulphide of Iron, $\text{Fe}^2\text{S}^2(\text{NO})^4 = \text{Fe}^2\text{S}^2(\text{NO})^2.\text{FeS}(\text{NO})^2.\text{H}^2\text{S}$, or $\text{Fe}^2\text{S}^2(\text{NO})^4.\text{H}^2\text{S}$.—This compound is prepared by dropping a solution of ferric chloride or sulphate, with constant stirring, into a mixture of the solutions of nitrite of potassium and sulphide of ammonium, heating the liquid to boiling, keeping it at the boiling heat for a few minutes, and filtering to separate sulphur; the deep-coloured liquid deposits crystals of the compound on cooling.—Or 36 grms. ferrous sulphate dissolved in 0.2 litre of de-aerated water is added to a solution of 21 grms. dry nitrite of potassium, and 16 grms. crystallised sulphide of sodium also in 0.2 litre of water, and the solution is boiled and filtered. When a ferrous salt is used in the preparation, no separation of sulphur takes place. The crystals are purified by recrystallisation.

Dinitrosulphide of iron forms black, needle-shaped, oblique rhombic prisms, 2 mm. long, more soluble in hot (about 2 pts.) than in cold water, easily soluble in alcohol, wood-spirit, amylic alcohol, and glacial acetic acid; they dissolve in all proportions in ether, and deliquesce even in ether-vapour. The solutions are very deep-coloured, taste styptic at first, then persistently bitter; they remain unaltered in air containing ammonia, and may be recrystallised from alkaline solutions. When heated to 115° — 140° , they give off reddish vapours, together with sulphur, sulphite of ammonium, and

nitrite of ammonium, and leave iron in the residue; when quickly heated, they burn away. The compound is easily decomposed by mineral acids, with evolution of reddish vapours, not by organic acids. Chlorine and iodine decompose it, with evolution of nitric oxide and separation of sulphur. It is precipitated from solution by potash and ammonia, much more slowly by soda. The crystals are decomposed by permanganate of potassium, peroxide of lead, and mercuric oxide. Many metallic salts precipitate the solution, with elimination of nitric oxide. Cyanide of potassium and cyanide of mercury convert the crystals into nitroferri-cyanides.

The crystals are not decomposed by sulphide of ammonium, sulphydric acid, ferro- or ferri-cyanide of potassium, or tannic acid, neither of these reagents giving any indication of the presence of iron in them. Neither are they decomposed by caustic potash or soda in the cold, but when heated therewith, they give off ammonia gas and yield ferric hydrate, together with a filtrate which deposits the following compound.

Sulphuretted Nitrosulphide of Iron and Sodium, $\text{Fe}^2\text{Na}^2\text{N}^2\text{S}^4\text{O}^2$ or $\text{Fe}^2\text{S}^2(\text{NO})^2.2.3\text{Na}^2\text{S}$.—This compound forms large black crystals having a very bitter taste, easily soluble in water and in alcohol, but insoluble in ether. The crystals decompose at 120° ; their solution is decomposed, with evolution of nitric oxide, by chlorine, iodine, or mercuric oxide. It forms precipitates with metallic salts, the reaction being in some cases attended with evolution of nitric oxide. The solution yields crystalline compounds on addition of potash or ammonia, but is not altered by caustic soda; the crystals are not altered by sulphide of ammonium or ferrocyanide of potassium, but with ferri-cyanide of potassium they yield nitric oxide gas and prussian-blue.

Sulphuretted Nitrosulphide of Iron and Hydrogen, $\text{Fe}^2\text{H}^2\text{N}^2\text{S}^4\text{O}^2 = \text{Fe}^2\text{S}^2(\text{NO})^2.4\text{H}^2\text{S}(?)$, separates in reddish flocks, when the preceding compound is decomposed by acids, but gives off sulphydric acid and suffers further decomposition, even during washing.

Nitrosulphide of Iron, $\text{Fe}^2\text{S}^2\text{N}^2\text{O}^2$ or $\text{Fe}^2\text{S}^2(\text{NO})^2$, separates, with evolution of sulphydric acid, when sulphuretted nitrosulphide of iron and sodium is decomposed by an acid at the boiling heat. It is a black substance, which when freshly prepared and dried, burns away like tinder, when set on fire. It decomposes spontaneously, leaving sulphide of iron. It is insoluble in water, alcohol, and ether, but dissolves in caustic potash, with partial decomposition and separation of ferric hydrate.

Nitrosulphide of Iron and Sodium, $\text{Fe}^2\text{Na}^2\text{N}^2\text{S}^4\text{O}^2.\text{H}^2\text{O} = \text{Fe}^2\text{S}^2(\text{NO})^2.\text{Na}^2\text{S}.\text{H}^2\text{O}$.—Formed by evaporating a solution of nitrosulphide of iron in sulphide of sodium at 100° , and treating the residue with alcohol and ether. Crystallises in red prisms, black by reflected light; dissolves with deep red colour in water, alcohol, and ether, but is insoluble in chloroform and in sulphide of carbon. The solution is precipitated by metallic salts, forming insoluble compounds in which the sodium is replaced by the other metal. Some of these precipitates are tolerably permanent, whereas others, the silver precipitate for example, decompose quickly, with evolution of nitric oxide.

IRON ORES. The ferruginous minerals containing sufficient quantities of iron to be available for the extraction of the metal, have already been described (pp. 337—343). For the methods of assaying them, see p. 388.

The following mineralogical terms must here be noticed.

Argillaceous or Clay Iron Ore.—This term is applied to several ores consisting of oxide or carbonate of iron mixed with clay. The argillaceous carbonate is called simply "clay iron-stone;" anhydrous and hydrated ferric oxides with a similar admixture, are called "red clay iron-stone," and "brown or yellow clay iron-stone," respectively.

Azotomous Iron Ore, or Kibdelophane. A variety of ilmenite or titaniferous iron ore. (See TITANATES.)

Bog Iron Ore.—A brittle or loosely aggregated variety of brown hæmatite, occurring in low marshy grounds. It proceeds from the decomposition of other species and often takes the form of leaves, nuts, or stems, found in the marshy soil.

Brown Iron Ore.—Hydrated ferric oxide (p. 338).

Columnar Iron Ore.—Red clay iron stone, having a columnar structure.

Green Iron Ore.—Hydrated ferric phosphate. (See DUFRENITE, ii. 347.)

Jaspery Iron Ore.—A variety of red clay iron ore, having a large, flat conchoidal fracture.

Lenticular Iron Ore.—A variety of red clay iron-stone having a flat granular structure.

Magnetic Iron Ore.—Ferroso-ferric oxide (pp. 337, 397).

Micaceous Iron Ore.—Specular iron ore with a micaceous structure.

Ochreous Iron Ore.—Red hæmatite, having a soft earthy consistence.

Octahedral Iron Ore.—Syn. with magnetic iron ore.

Pitchy Iron Ore.—A variety of red hæmatite.

Red Iron Ore.—Native ferric oxide (p. 337).

Sparry or Spathic Iron Ore.—Crystallised ferrous carbonate (i. 785).

Specular Iron Ore.—Red hæmatite having a perfect metallic lustre (pp. 338, 394).

Titaniferous Iron Ore.—Ferric titanate. (See TITANATES.)

IRON, OXIDES OF. Iron forms two oxides corresponding with the chlorides, viz. the *protoxide* or *ferrous oxide*, FeO , the *sesquioxide* or *ferric oxide*, Fe^3O^3 , and several oxides of intermediate composition, called *ferroso-ferric oxides*, which may be regarded as compounds of the two just mentioned: the most important of these is the *magnetic oxide*, $\text{Fe}^2\text{O}^4 = \text{FeO} \cdot \text{Fe}^3\text{O}^3$. A *trioxide*, FeO^3 , may be supposed to exist in the ferrates (ii. 636); e.g. ferrate of potassium, $\text{K}^2\text{FeO}^3 = \text{K}^2\text{O} \cdot \text{FeO}^3$, but it has not been isolated.

Ferrous oxide, FeO , is never found in nature in the free state, but may be supposed to exist, in combination with carbonic anhydride, as ferrous carbonate ($\text{FeCO}^2 = \text{FeO} \cdot \text{CO}^2$) in spathic iron ore, and in solution in chalybeate waters; also combined with ferric oxide in magnetic iron ore. It is not easily obtained in the pure state, on account of the avidity with which it absorbs oxygen. According to Debray, it is obtained by passing a mixture of equal volumes of carbonic anhydride and carbonic oxide over red-hot ferric oxide. According to Liebig, it is obtained, mixed with a little metallic iron, by igniting ferrous oxalate in a close vessel. The impure ferrous oxide thus obtained is a black pyrophoric powder, which in contact with the air quickly takes fire, and is converted into ferric oxide.

Hydrated Ferrous Oxide, or *Ferrous hydrate*, is obtained by precipitating the solution of a pure ferrous salt, perfectly free from air, with potash-ley, also free from air, in a vessel filled with de-aerated water. The hydrate is then precipitated in white flocks, which must be washed by decantation with recently boiled water, then dried and preserved in an atmosphere perfectly free from oxygen. Schmidt (Ann. Ch. Pharm. xxxvi. 101), by a very careful preparation thus conducted, obtained the hydrate as a non-magnetic, very friable mass, having a pale greenish colour, probably arising from partial oxidation. When exposed to the air, even in the dry state, it quickly absorbs oxygen, becoming strongly heated, even to ignition, and is converted into ferric oxide. In the moist state it is converted by oxidation, first into greenish ferroso-ferric, then quickly into brown ferric hydrate. It reduces iodic acid, also platinum- and mercury-salts. It dissolves, according to Bineau, in 150,000 pts. of water, forming an alkaline liquid. It dissolves easily in acids, forming ferrous salts, and absorbs carbonic anhydride quickly, even in the dry state, so that it cannot be dried in an atmosphere of that gas.

Ferrous salts.—Ferrous oxide and hydrate dissolve in acids, forming salts in which the iron is mono- or di-atomic, according as its atomic weight is 28 or 56: e.g.

The soluble ferrous salts are likewise produced by dissolving iron in dilute acids. The insoluble salts, e.g. the carbonate and phosphate, are obtained by precipitation. The carbonate is of frequent occurrence as a natural mineral (p. 339).

Most ferrous salts are soluble and crystallisable, white in the anhydrous, pale greenish-blue in the hydrated state. The solutions are green or greenish-blue, have a sweetish taste, with inky after-taste, and quickly absorb oxygen from the air, yielding a yellow-brown deposit of basic ferric salt, because the quantity of acid in the solution is not sufficient to form a normal ferric salt, inasmuch as iron is trivalent in the ferric, and only bivalent in the ferrous salts; thus ferrous sulphate yields by oxidation a basic ferric sulphate, or oxy-sulphate containing only 2 at. SO^4 ;

or

whereas the soluble normal ferric sulphate has the composition $\text{Fe}^3\text{O}^3 \cdot 3\text{SO}^4$ or $\text{Fe}^3(\text{SO}^4)^3$.

Those ferrous salts which contain a volatile acid, give it up on ignition, leaving a residue of ferric oxide, if the acid, such as sulphuric or nitric acid, gives up its oxygen readily; of ferroso-ferric oxide, if the acid, such as carbonic acid, retains its oxygen more forcibly; and of metallic iron, either pure or mixed with ferrous oxide, if the acid is organic.

For the reactions of ferrous salts in solution, see p. 381.

Ferric oxide. Fe^3O^3 . *Sesquioxide* or *peroxide* of iron. This oxide occurs in nature very abundantly and widely distributed, viz. 1. As specular iron ore in rhombohedral forms, R. oR, also R. $\frac{1}{2}\text{P}2$. $\frac{1}{2}\text{R}$ (ratio of principal to secondary axes = 1.3668 : 1).—2. As martite, in regular octahedrons.—3. As red hæmatite, in columnar, granular, botryoidal, and stalactitic shapes, also lamellar and granular, either alone or associated with clay, forming the several varieties of red clay iron-stone

(p. 340). It is formed by heating iron or its lower oxides and hydrates in contact with the air.

Ferric oxide may be obtained in small crystals by decomposing ferric chloride with lime at a red heat (Daubré, Compt. rend. xlix. 143); in micaceous laminae by heating the amorphous oxide with borax, and treating the resulting mass with hydrochloric acid (Hauer, Wien. Akad. Ber. xiii. 456), or by melting the amorphous oxide with chloride of calcium (Kuhlmann, Compt. rend. lii. 1283). Rhombohedral or laminar crystals of ferric oxide are likewise obtained by igniting the amorphous oxide in a slow current of hydrochloric acid gas. (Deville, Compt. rend. lii. 1264.)

When equal parts of ferrous sulphate (green vitriol) and common salt are heated to redness, and the product exhausted by washing, ferric oxide remains in red-brown shining scales. When pulverulent ferric oxide is ignited with sal-ammoniac, part of it becomes crystalline, while another portion volatilises as ferric chloride.

Ferric oxide is obtained in the amorphous state by igniting ferrous sulphate with $\frac{1}{12}$ pt. of saltpetre, and lixiviating the product; by dissolving iron in nitric acid, evaporating, and heating the resulting nitrate to redness; also by deflagrating iron filings with saltpetre. In the distillation of fuming sulphuric acid from green vitriol, a residue of impure ferric oxide is obtained, formerly known as *Caput mortuum vitrioli*. Amorphous ferric oxide is usually prepared for pharmaceutical use by igniting ferric hydrate or ferrous carbonate in contact with the air; the preparation thus obtained is called *Crocus Martis adstringens* or *Ferrum oxydatum rubrum*. Very pure ferric oxide may be prepared by heating ferrous oxalate in contact with the air; the salt then takes fire and is completely converted, without further heating, into ferric oxide. (A. Vogel.)

Ferric oxide prepared by either of the latter methods, is amorphous, and has a brown-red, red, or nearly black colour, according to the particular mode of preparation adopted. It is very hygroscopic, not magnetic, very hard, and is therefore used as a grinding and polishing material. The specific gravity of the artificially prepared oxide is 5.04 to 5.17 (H. Rose, Pogg. Ann. lxxiv. 440); that of red hæmatite and specular iron ore, from 4.5 to 5.3; of some columnar varieties as low as 4.2; that of martite from Peru, 3.80; from Puy de Dome, 4.65; from Brazil, 4.80 (Breithaupt); from Monroe, New York, 5.33 (Hunt). Hardness of hæmatite and specular iron ore = 5.5 to 6.5; of martite = 6. The cubic expansion of ferric oxide = 0.00004 for 1° C. (Kopp). Ferric oxide is not volatile, but at a full white heat it gives off oxygen, and is partially converted into ferroso-ferric oxide, which is attracted by the magnet.

Ferric oxide is reduced to the metallic state by hydrogen gas, at a heat even below redness, and completely at red heat by charcoal or carbonic oxide, also by ammonia gas. When ignited with sulphur, it yields sulphurous anhydride and a sulphide of iron. It easily gives up its oxygen when ignited with combustible bodies, but takes it up again when heated in contact with the air: hence it facilitates the combustion of organic bodies, and may be used for incinerating them (Gräger, Ann. Ch. Pharm. cxi. 124). Even at ordinary temperatures, it frequently acts as an oxidising agent in contact with organic matter, and is thereby reduced to magnetic oxide, or even to ferrous oxide, and then, by taking up carbonic acid, converted into spathic iron; the reduced oxide, if in contact with moisture, is frequently also reconverted into ferric hydrate (limonite or brown hæmatite) by atmospheric oxidation. The oxide is also sometimes further reduced by the action of sulphydric acid, and converted into pyrites: hence magnetite, limonite, and pyrites often occur as pseudomorphs after red hæmatite. According to Kuhlmann (Compt. rend. lii. 1169), it easily converts sulphide of calcium into gypsum at the expense of atmospheric oxygen; the oxysulphide of calcium of the soda-residues mixed with an equal weight of ferric oxide (the residue of the burning of pyrites), forms a very useful cement, which hardens quickly in contact with the air.

Ferric oxide dissolves in acids, but less easily in proportion as it has been more strongly ignited: the best solvent for it is strong boiling hydrochloric acid. The solution is facilitated by the addition of zinc or stannous chloride, the oxide then dissolving as ferrous chloride.

Ferric oxide, on account of its hardness, is much used as a grinding and polishing material. A very hard compact kind of red hæmatite, called bloodstone, forms, when well polished, the best material for producing a high lustre on coat-buttons, and on the gilding of porcelain. Ferric oxide in the pulverulent state is used for polishing gold, silver, and other metals, for polishing and sharpening cutting instruments, and for grinding and polishing glass for mirrors and lenses. According to Vogel (Dingl. pol. J. cxxxii. 275), the oxide obtained by the combustion of ferrous oxalate (p. 393) is peculiarly adapted for these purposes. That which is prepared by igniting green vitriol in crucibles is also much used, the least calcined portions, which are of a scarlet colour, forming jeweller's rouge for polishing gold or silver, and the more calcined portions, which are bluish or purplish, forming the *crocus* which

is used for polishing brass and steel. Lord Rosse prepares ferric oxide for polishing the specula of his telescopes, by precipitating a pure dilute solution of ferrous sulphate with ammonia, pressing the washed precipitate in a screw-press till nearly dry, and exposing it to a heat which appears dull red in the dark. (See *Use's Dictionary of Arts*, iii. 369.)

Ferric oxide is also used as a colouring material for glass and porcelain, especially the latter; it yields a fine purple-red, or when more strongly heated, an orange-yellow enamel colour, the tint produced depending essentially on the mode of treatment; according to Bontemps (*Phil. Mag.* [4] xxxv. 439), ferric oxide may be made to colour glass with all the tints of the spectrum, according to the degree of heat applied.

Hydrated ferric oxide, or *Ferric hydrate*, occurs abundantly in nature, either crystallised as göthite or needle iron ore (ii. 940), or in stellate groups of needles or fibres, as xanthosiderite, or more frequently in stalactitic, botryoidal or mammillary forms, having a fibrous or subfibrous structure; also massive and occasionally earthy, as brown hæmatite or limonite; also mixed with clay, as brown or yellow clay iron-stone (pp. 338, 339). It is the colouring principle of many minerals, of ochre, of the deposit of mineral waters, of yellow sandstone, Turkish umber, &c. It is formed by the precipitation of ferric salts with alkalis or alkaline carbonates; also when ferrous salts are precipitated in like manner, and the precipitate is exposed to the air; and by the rusting of iron, which takes place when the metal is exposed to moist air, and is accelerated by contact with small quantities of acids, and of various saline solutions, especially ammoniacal salts and urine.

Ferric hydrate is most easily prepared by precipitating a moderately dilute solution of ferric chloride with excess of ammonia (with a smaller quantity, a basic salt would be thrown down); it is apt, however, to retain small quantities of ammonia, to remove which it must be washed several times with water, then dried, and washed completely after being reduced to powder. This precipitate formed in the cold (the *Ferrum oxidatum fuscum* of the pharmacopoeias) has the composition $\text{Fe}^{\text{O}} \cdot 2\text{H}^{\text{O}}$, according to Gmelin (*Handbook*, v. 198) and Lefort (*J. pr. Chem.* liv. 305); $\text{Fe}^{\text{O}} \cdot 3\text{H}^{\text{O}}$, according to Wittstein (*Pharm. Centr.* 1853, p. 367); or $2\text{Fe}^{\text{O}} \cdot 3\text{H}^{\text{O}}$, according to Péan de Saint-Gilles (*Ann. Ch. Phys.* [3] xlv. 47), the proportion of water doubtless varying according to the degree of dilution, the mode of precipitation, and the temperature to which the hydrate has been exposed in drying. The hydrate precipitated from hot solutions is $\text{Fe}^{\text{O}} \cdot 2\text{H}^{\text{O}}$. (Lefort; Schaffner, *Ann. Ch. Pharm.* li. 117.)

Native ferric hydrates are also of various composition. - Göthite is $\text{Fe}^{\text{O}} \cdot \text{H}^{\text{O}}$; limonite, $2\text{Fe}^{\text{O}} \cdot 3\text{H}^{\text{O}}$; xanthosiderite, $\text{Fe}^{\text{O}} \cdot 2\text{H}^{\text{O}}$; and a variety of bog iron ore (called *Quellern*) from Nischnei-Nowgorod in Russia, consists, according to Hermann (*J. pr. Chem.* xxvii. 53), mainly of $\text{Fe}^{\text{O}} \cdot 3\text{H}^{\text{O}}$.

Ferric hydrate has a light yellow to dark brown colour, and is sometimes a loose earthy powder, sometimes a heavy friable mass, according to the mode of preparation. When recently precipitated, it is easily soluble in acids, but its power of uniting with acids is diminished by drying, and frequently even by prolonged immersion in liquids.

A remarkable insoluble modification of ferric hydrate is produced by boiling the ordinary yellow hydrate, $2\text{Fe}^{\text{O}} \cdot 3\text{H}^{\text{O}}$ (precipitated from the chloride by ammonia), in water for seven or eight hours. The colour then changes from ochre-yellow to brick-red, and the hydrate thus altered is scarcely acted upon by strong boiling nitric acid, and but very slowly by hydrochloric acid. In acetic acid, or dilute nitric or hydrochloric acid, it dissolves, forming a red liquid, which is clear by transmission, but turbid by reflected light; is precipitated by the smallest quantity of an alkali-salt or a sulphate; and on addition of strong nitric or hydrochloric acid, yields a red granular precipitate, which redissolves on diluting the liquid with water. The modified hydrate does not form prussian blue with ferrocyanide of potassium and acetic acid. It appears to consist of $\text{Fe}^{\text{O}} \cdot \text{H}^{\text{O}}$. This insoluble hydrate is likewise precipitated when a solution of the ordinary hydrate in acetic acid is rapidly boiled. The same solution, if kept for some time at 100°C . in a close vessel, becomes light in colour, no longer forms prussian blue with ferrocyanide of potassium, or exhibits any deepening of colour on addition of a sulphocyanate; strong hydrochloric or nitric acid, or a trace of an alkali-salt, or sulphuric acid, throws down all the ferric oxide in the form of the insoluble hydrate. (Péan de Saint-Gilles, *Ann. Ch. Phys.* [3] xlv. 47.)

Ferric hydrate gives off part of its water between 80° and 100° , and the whole at a red heat; it is also completely dehydrated by heating it to 160° — 200° , with a saturated solution of chloride of calcium or chloride of sodium. (Senarmont.)

Ferric hydrate easily gives up part of its oxygen to oxidable bodies, and is easily reduced by sulphurous acid, stannous chloride, &c. In contact with putrefying organic bodies, out of contact with the air, it forms ferroso-ferric compounds; or ferrous carbonate; but if the air has access to it, it quickly recovers the oxygen which it has given up to the putrefying substance, and can then again exert an oxidising

action, thus acting as a carrier of oxygen from the air to the organic body: hence it accelerates the oxidation of woody fibre in the soil. (Kuhlmann, J. pr. Chem. lxxi. 110.)

Ferric hydrate is rarely used alone in medicine; but in the recently precipitated state, it acts as an antidote to arsenic, as, when given in sufficient quantity, it forms a highly basic ferric arsenite, very difficultly decomposable by water.

Ferric hydrate unites with colouring matters, and easily fixes itself on many organic bodies, especially on tissues: hence its use as a mordant, and the formation of iron-mould on linen, cotton, &c. Such spots may be removed by oxalic acid, or acid oxalate of potassium, the action being greatly accelerated by contact with metallic tin.

Ferric salts.—In these salts, the iron may be regarded as trivalent, or the group Fe^3 as sexvalent, e.g. the chloride, Fe^3Cl^3 ; the nitrate, $\text{Fe}^3(\text{NO}^3)^3$; the sulphate, $\text{Fe}^3(\text{SO}^4)^3$. (The oxygen-salts may, of course, be regarded as compounds of ferric oxide with anhydrous acids, e.g. the nitrate, $\text{Fe}^3\text{O}^3 \cdot 3\text{N}^2\text{O}^3$, the sulphate, $\text{Fe}^3\text{O}^3 \cdot 3\text{SO}^3$.) Accordingly, it requires three molecules of a monobasic acid, such as nitric acid, to form a normal salt with one molecule of ferric oxide.

The normal ferric salts are for the most part soluble in water, and difficult to crystallise; some of them are deliquescent. They are mostly analogous in composition to the salts of aluminium, and frequently isomorphous with them; this correspondence of form and composition is most conspicuous in the alums; thus ferrico-potassic sulphate, $\text{FeK}(\text{SO}^4)^3 \cdot 12\text{H}^2\text{O}$, is isomorphous with common alum, $\text{AlK}(\text{SO}^4)^3 \cdot 12\text{H}^2\text{O}$.

Soluble ferric salts are obtained by dissolving ferric oxide or its hydrates in aqueous acids, or by oxidising ferrous salts with nitric acid, adding the quantity of acid required to form a normal ferric salt; e.g.:

The insoluble salts are obtained by double decomposition.

Ferric salts are white in the anhydrous, yellow or yellowish-red in the hydrated state. The solutions have also, for the most part, a yellowish-red colour, especially when heated; the solutions of the nitrate and fluoride, however, are colourless; that of the chloride is brown-red, and those of the acetate, meconate, and sulphocyanate are blood-red.

The presence of free hydrochloric acid in a solution of ferric chloride changes the colour of the solution to orange yellow; this coloration, like that of other acid solutions of ferric salts (e.g. ferric sulphocyanate), is completely destroyed by addition of a sufficient quantity of phosphate of sodium; on the other hand, the colouring power of ferric chloride, in presence of an excess of strong hydrochloric acid, is very great, the bright yellow colour of commercial hydrochloric acid, for instance, being caused by a quantity of ferric chloride too small to impart a perceptible colour to the liquid when somewhat diluted with water.

Ferric oxide has a great tendency to form basic salts, which may be regarded as compounds of the normal salts with excess of ferric oxide: thus, besides the triacid or normal sulphate,

Most of these basic salts are insoluble in water, and are precipitated on heating a moderately dilute and nearly neutral solution of the corresponding normal salt (e.g. ferric acetate), or on adding to the solution of a normal ferric salt, a quantity of alkali not sufficient to precipitate the whole.

Ferric salts containing volatile acids are decomposed by ignition, leaving a residue of ferric oxide, ferrous oxide, or metallic iron, according to the nature of the acid present. For their reactions before the blowpipe and in solution, see page 380.

Ferroso-ferric Oxides and Hydrates.—The term ferroso-ferric is applied to oxides of iron which are intermediate in composition between ferrous and ferric oxide, and may be regarded as compounds of the two. The principal of these intermediate oxides are the scale-oxide and the magnetic oxide.

a. *Scale oxide*, $\text{Fe}^{\circ}\text{O} = 6\text{FeO}.\text{Fe}^{\circ}\text{O}^{\circ}$.—When iron is heated to redness in the air, two layers of scale oxide are formed, which may easily be separated. The inner layer, $6\text{FeO}.\text{Fe}^{\circ}\text{O}^{\circ}$, is blackish-grey, porous, brittle, and attracted by the magnet. The outer layer contains a larger quantity of ferric oxide, but in variable proportion; it is of a reddish iron-black colour, dense, brittle, yields a black powder, and is more strongly attracted by the magnet than the inner layer. The amount of ferric oxide in the outer layer is between 32 and 37 per cent., and on the very surface it is as much as 52.8 per cent. (Mosander, Pogg. Ann. vi. 35; also Schw. xlvii. 81). The specific gravity of the scale-oxide is 5.48 (P. Boullay). Berthier (Ann. Ch. Phys. [2] xxvii. 19; also Schw. xliiii. 319) regards the scale-oxide as $4\text{FeO}.\text{Fe}^{\circ}\text{O}^{\circ}$; Mosander attributes the greater amount of ferric oxide found by Berthier to the fact of Berthier having analysed the inner and outer layers together.

β. *Magnetic oxide*, $\text{Fe}^{\circ}\text{O}^{\circ} = \left(\frac{\text{Fe}^{\circ}}{\text{Fe}^{\circ}}\right)_v \left\{ \text{O}^{\circ} \right\} = \text{FeO}.\text{Fe}^{\circ}\text{O}^{\circ}$.—This oxide occurs abundantly as a natural mineral, and is one of the richest and most valuable ores of iron, containing, when pure, nearly 72 per cent. of the metal (p. 337). It occurs in monometric crystals, the dominant form being usually the octahedron, sometimes the rhombic dodecahedron, these forms being modified as in figures 194, 195, 196, 199, 200, &c. (CRYSTALLOGRAPHY, ii. 129, 130); twins also occur, like figure 319 (ii. 160).

It is isomorphous with spinel $\left(\frac{\text{Mg}}{\text{Al}^{\circ}}\right)_v \left\{ \text{O}^{\circ} \right\}$, gahnite, $\left(\frac{\text{Zn}}{\text{Al}^{\circ}}\right)_v \left\{ \text{O}^{\circ} \right\}$, zoilanite, $\left(\frac{\text{Fe}}{\text{Al}^{\circ}}\right)_v \left\{ \text{O}^{\circ} \right\}$, franklinite, $\left(\frac{\text{Zn}}{\text{Fe}^{\circ}}\right)_v \left\{ \text{O}^{\circ} \right\}$, chrome-iron ore, $\left(\frac{\text{Fe}^{\circ}}{\text{Cr}^{\circ}}\right)_v \left\{ \text{O}^{\circ} \right\}$, and other minerals in which the

bivalent radicles, Mg, Zn, Fe, and likewise the sexvalent radicles Al° , Fe° , Cr° , replace one another in various proportions, or into which other diatomic metals enter in various proportions, e.g. calcium, Ca, with magnesium in pleonast and chlorospinel. Cleavage octahedral, more or less distinct. The dodecahedral faces are commonly striated, parallel to the longer diagonal. Much more frequently, however, it occurs massive, with granular structure (p. 336).

Ferroso-ferric oxide, $\text{Fe}^{\circ}\text{O}^{\circ}$, is produced when iron is heated to redness in aqueous vapour (Regnault, Gay-Lussac); when ferrous chloride is heated to low redness with excess of carbonate of sodium (Liebig and Wöhler, Pogg. Ann. xxi. 582); also according to Mitscherlich (Pogg. Ann. xv. 622), when iron is burned in oxygen-gas or before the blowpipe. It is obtained crystallised in octahedrons, by igniting ferroso-ammoniac chloride in contact with the air (Hauer, Wien. Akad. Ber. xiii. 466); also, together with ferrous chloride, by heating ferrous oxide in a slow stream of hydrochloric acid gas (Deville, Compt. rend. liii. 199); by fusing ferric phosphate with 3 or 4 times its weight of sulphate of sodium (Debray, *ibid.* lii. 985); and by heating ferrous sulphate with chloride of calcium in covered crucibles (Kuhlmann, *ibid.* lii. 1283). Deville and Caron (*ibid.* xlv. 764), by heating ferric fluoride with boric anhydride out of contact with the air, obtained the magnetic oxide in long needles, made up of aggregates of regular octahedrons. Ebelmen obtained crystalline magnetic oxide by the action of heat on ferrous silicate. Artificially prepared ferroso-ferric oxide is, however, most frequently a black mass, which yields an iron-black powder, and is attracted by the magnet.

Many metallurgic products also contain ferroso-ferric oxide, either free or combined with silica—refinery-slugs for example, according to Plattner (Ann. Ch. Pharm. xx. 233). The iron plates which are laid beneath the hearths of iron-smelting furnaces, and are exposed to a red heat, are sometimes, in the course of 6 or 10 years, completely converted, by the moisture of the soil, into magnetic oxide, partly crystalline, partly compact, and attracted by the magnet (but not itself magnetic). The same compound is formed on the under side of the refining hearths, where the iron comes in contact with aqueous vapour. (Koch, *Ueber krystall. Hüttenproducte*, p. 17.)

γ. Crystallised ferrous carbonate, ignited in close vessels, yields ferroso-ferric oxide, consisting, according to Krämer, of $\text{FeO} \cdot \text{Fe}^{\text{O}}_2$; according to Döbereiner, of $3\text{FeO} \cdot \text{Fe}^{\text{O}}_2$; according to Glasson, of $4\text{FeO} \cdot \text{Fe}^{\text{O}}_2$, the composition of the product being doubtless influenced by the rapidity of the heating.

δ. The old pharmaceutical preparation called *Ethiops martialis*, is a ferroso-ferric oxide, or mixture of ferrous and ferric oxides in various proportions, obtained by oxidising iron in a current of aqueous vapour, or by partially reducing ferric oxide by ignition with iron filings, or with a quantity of oil just sufficient to make it into a moist powder; the preparation obtained by this last method always contains carbon.

Ferroso-ferric oxide is easily reduced to the metallic state by ignition with hydrogen, charcoal, carbonic oxide, or ammonia-gas. When ignited in the air, it is converted into ferric oxide.

Ferroso-ferric Hydrates.—These are compounds of various composition, obtained by the partial oxidation of ferrous, or reduction of ferric hydrate, by precipitating mixtures of ferrous and ferric salts with alkalis, and by the oxidation of iron in contact with air and water.

a. *Dingy-green Hydrate*.—By exposing white ferrous hydrate to the air for a short time—or by precipitating a mixture of a ferrous salt and a small quantity of ferric salt, with potash or ammonia—a dingy-green hydrate of ferroso-ferric oxide is obtained, which, on further exposure to the air, is quickly converted into rusty-brown ferric hydrate.

b. *Black Hydrate*.—1. This hydrate, which has nearly the composition $\text{FeO} \cdot \text{Fe}^{\text{O}}_2 + x\text{H}^{\text{O}}$, is precipitated from a solution of magnetic oxide in hydrochloric acid, or from a mixture of equivalent proportions of ferrous and ferric salts, on the addition of potash or ammonia. The yellow solution of magnetic oxide in hydrochloric acid yields, with ammonia, a brownish-black precipitate, which is magnetic even while in the liquid, so that it collects round a magnet dipped into that liquid. It may be washed on the filter without becoming more highly oxidised (Liebig and Wöhler, Pogg. Ann. xxi. 583).—2. The same precipitate is obtained by mixing ferrico-ammonic sulphate with ferrous sulphate, in such proportion that the ferric oxide present in the mixture may contain three times as much oxygen as the ferrous oxide, and precipitating with ammonia (Abich, Pogg. Ann. xxiii. 354).—3. Two equal portions of ferrous sulphate are taken; the first is dissolved in water acidulated with sulphuric acid, and oxidated at a boiling heat by the addition of nitric acid in small portions at a time. The other portion is dissolved in water freed from air by boiling. The two solutions are then mixed; the mixture, while still hot, precipitated by ammonia added at once in excess; and the liquid, together with the brown-black precipitate, heated for some minutes to the boiling point. The precipitated ferroso-ferric oxide is then collected on a filter and washed—during which process it undergoes further oxidation—and then dried at a gentle heat (Wöhler, Ann. Ch. Pharm. xxii. 56). This process should yield $2\text{FeO} \cdot \text{Fe}^{\text{O}}_2$; but even if a greater quantity of ferric oxide is not produced by the nitric acid still remaining, or by contact with the air, the proportion of that oxide is sure to be increased by decomposition of water.—4. Böttger (*Beiträge*, ii. 12) precipitates ferrous sulphate free from ferric oxide by the addition of carbonate of sodium; washes the precipitate several times by decantation; and then boils it with tolerably concentrated caustic potash. This process yields a velvet-black powder, much less liable to absorb an additional quantity of oxygen than that which has been precipitated by ammonia.—5. Noel (J. Pharm. [3] i. 62) precipitates ferrous sulphate with carbonate of sodium, washes the ferrous carbonate by decantation, leaves it to drain upon linen, and then heats it in a cast-iron vessel, with constant stirring, till it is dry. It is thereby converted into a velvet-black powder. Soubeiran obtained by this process a precipitate which was not perfectly black, and when treated with hydrochloric acid, evolved carbonic anhydride.—6. Preuss introduces 4 pts. of pulverised iron and 5 pts. of ferric oxide into a flask, together with a two or threefold quantity of water, and boils the liquid gently for some time. The mixture gives off fetid hydrogen gas, and turns dark brown at first, but afterwards black. When the evolution of gas ceases, and the resulting black powder settles down readily, it is separated by levigation from the excess of iron; thrown on a filter of grey porous paper; and the filter, after the water has drained off, is wrapped up in a large quantity of paper, and quickly dried in hot air. The black, very loose powder dissolves in acids without evolution of gas, and the solution yields a black precipitate on the addition of an alkali. The precipitate must not be dried by heat, because in that case it would turn brown from higher oxidation. (Wöhler, Ann. Pharm. xxviii. 92.)

The black hydrate of ferroso-ferric oxide exhibits, after drying, the appearance of brown black, brittle, strongly magnetic lumps, having a conchoidal fracture, and yielding a dark-brown powder. It contains about 7 per cent. of water, which it gives off when heated in a retort, leaving black anhydrous ferroso-ferric oxide. When heated

in the air, it is converted into ferric oxide. From its yellow solution in hydrochloric acid, it is precipitated unchanged by ammonia (Wöhler).

Ferroso-ferric hydrate was formerly much employed in medicine, but has now almost fallen into disuse. In preparing iodide of potassium from iodide of iron, it is advisable to take the iron and iodine in such proportion (Fe^{II}) that, on precipitating with carbonate of potassium, this black ferroso-ferric hydrate shall be formed, because it is much less bulky than ferric hydrate, and therefore easier to wash.

The ferroso-ferric oxides and hydrates dissolve in acids, forming brownish or yellow solutions, according as the one or other of the oxides predominates. These solutions, commonly said to contain ferroso-ferric salts, are mere mixtures of ferrous and ferric salts, and give reactions intermediate between the two. They give black precipitates with alkalis; blue, both with ferro- and with ferri-cyanide of potassium, also with cyanide of potassium (ii. 219, 227), a reaction not produced either by ferrous or by ferric salts when pure.

Trioxide of Iron, or Ferric anhydride, FeO^3 , is not known in the free state, but may be supposed to exist in the ferrates (salts obtained by fusing iron or its oxides with nitre, (ii. 626) e.g. *Ferrate of potassium*, $\text{FeK}^3\text{O}^4 = \text{K}^3\text{O.FeO}^3$).

IRON, OXYBROMIDE OF. Ferric oxybromide is obtained by evaporating the aqueous solution of ferric bromide, or by treating it with a quantity of potash not sufficient for complete precipitation, or by exposing a solution of ferrous bromide to the air. (Löwig.)

IRON, OXYCHLORIDE OF. See page 378.

IRON, OXYFLUORIDE OF. A ferric oxyfluoride is precipitated by ammonia from the solution of ferric fluoride. (Berzelius.)

IRON, OXYGEN-SALTS OF. The general properties of these salts have been already described (pp. 380, 393, 396). For the special descriptions, see the several ACIDS.

IRON, OXYSULPHIDE OF. See page 401.

IRON, PHOSPHIDES OF. Phosphorus unites readily with iron, forming a grey, fusible, very hard compound, which takes a high polish. This compound, which has the composition Fe^3P , may be prepared by heating a mixture of phosphate of iron and charcoal in a crucible lined with charcoal and placed in a forge fire.

A very small quantity of phosphorus produces a great alteration in the properties of iron, rendering it brittle in the cold (pp. 329, 334).

IRON, PULVERISED. *Ferrum pulveratum; Limatura ferri s. Martis alcoholisata.*—Finely pulverised iron for medical use may be prepared by mechanical trituration of filings of bar iron, and subsequent boiling and straining. Iron-powder is prepared in large quantities by this method in the Tyrol. The iron is, however, obtained in a much finer state of division, by reducing an oxide of iron with hydrogen. Wöhler (Ann. Ch. Pharm. cix. 126; cr. 192) mixes 1 pt. of ferrous sulphate perfectly free from copper, with three times its weight of chloride of sodium; heats the mixture till it becomes red-hot and fuses; washes the residue completely; heats the ferric oxide thus produced to dull redness in a glass tube or gun-barrel; and passes over it a stream of dry hydrogen, perfectly free from carbon, sulphur, phosphorus, and arsenic, as these substances, if present, would unite with the iron. It is difficult, however, when ferrous sulphate is used, to obtain iron quite free from sulphur; hence, Luca (Compt. rend. li. 333) precipitates ferrous chloride with ammonia, and reduces the washed oxide with perfectly washed hydrogen-gas, avoiding the use of vulcanised caoutchouc-tubes (because the gas might take up sulphur from them). It is doubtful, however, whether the presence of minute quantities of sulphur and carbon in the pulverised iron, would be at all injurious in its application. To preserve the iron from rust, it is kept in sealed vessels filled with hydrogen.

Reduced iron is an impalpable, slate-grey powder, which may be set on fire by a glowing body, and then burns away very quickly (mechanically pulverised iron cannot be set on fire in this way); it should be heated strongly enough in the hydrogen-atmosphere to prevent it from becoming actually pyrophoric. It is much more active than mechanically pulverised iron, on account of its finer state of division.

IRON, SELENIDES OF. Selenium in the state of vapour, passed over iron-filings, combines with the metal, producing considerable evolution of light and heat. The product is a yellowish-grey substance, with metallic lustre, hard and brittle. It melts before the blowpipe, giving off oxide of selenium, and forming a black brittle globule, apparently consisting of ferrous selenite. (Berzelius.)

G. Little (Ann. Ch. Pharm. cxii. 211), by passing selenium-vapour over red-hot iron wire, and melting the brittle product under borax, obtained a metallic-looking

greyish-yellow, easily pulverisable compound, having a specific gravity of 6.38, and the composition of ferric selenide, Fe^3Se^4 .

IRON, SULPHIDES OF. Iron and sulphur unite directly with one another, under various circumstances, and in several different proportions. Besides two sub-sulphides containing less than 1 at. sulphur to 1 at. iron, there is a *protosulphide* or *ferrous sulphide*, FeS ; a *sesquisulphide* or *ferric sulphide*, Fe_2S_3 ; a *disulphide*, FeS_2 ; and a compound called the *magnetic sulphide*, intermediate in composition between the proto- and sesqui-sulphides. Metallic iron heated with excess of sulphur, yields one or other of the four last-mentioned compounds, according to the heat applied, the degree of sulphuration being less as the temperature is higher. (Rammelsberg, Pogg. Ann. cxxi. 337.)

An *octoferrie sulphide*, Fe^8S , is formed by passing hydrogen-gas over red-hot dibasic ferric sulphate (p. 396). It is a blackish-grey magnetic powder, which, when treated with dilute acids, yields a mixture of 7 vols. hydrogen-gas and 1 vol. sulphydric acid.

A *hemisulphide*, Fe_2S , is produced by heating anhydrous ferrous sulphate in hydrogen gas, half of the sulphur being then given off as sulphurous anhydride. It is a dark grey, coherent, magnetic powder, which dissolves easily in dilute acids, giving off equal volumes of hydrogen and sulphydric acid. When ignited in sulphydric acid gas, it takes up sulphur and is converted into the protosulphide. It occurs, combined with other metallic sulphides, in many furnace-products obtained in the smelting of lead and copper ores.

Protosulphide, or Ferrous sulphide, FeS . This compound occurs in many specimens of meteoric iron, sometimes imbedded in small yellow-brown masses, sometimes as a grey powder possessing metallic lustre. (Berzelius; Rammelsberg, Pogg. Ann. cxxi. 363.)

It has not been found in the free state as a terrestrial mineral, but exists in combination with sulphide of nickel, and mixed with copper-pyrites, in a massive, bronze-coloured mineral, with octahedral cleavage and specific gravity = 4.60, from Lillohammer, in Norway. This mineral, after deducting 5.14 per cent. of copper pyrites, contains 36.7 per cent. sulphur, 41.1 iron, and 22.2 nickel, agreeing approximately with the formula $2\text{FeS.Ni}_2\text{S}$. (Rammelsberg, *loc. cit.*)

Ferrous sulphide is produced: 1. By the direct combination of sulphur and iron, either at a red heat, or at lower temperatures in presence of water.—a. Heated iron wire introduced into sulphur-vapour burns brightly, and forms ferrous sulphide.—b. When iron filings are gradually heated in a covered crucible with about two-thirds their weight of sulphur, the mass, when heated to about the temperature of low-redness, begins to glow, and combination rapidly takes place, with vivid combustion throughout the entire mass.—c. Sulphur pressed against a red-hot iron bar, perforates it, and forms ferrous sulphide, which runs off in drops, and may be quenched in water. 3. Ferrous sulphide may also be obtained in the wet way by moistening a mixture of 28 pts. iron filings and 16 pts. sulphur, and applying a gentle heat; combination then takes place, attended with considerable rise of temperature. When a considerable quantity of mixture of 2 pts. sulphur and 3 pts. iron-filings is made into a paste with water, and covered with earth, the mass after a while becomes red-hot, and gives off a large quantity of steam, which throws up the earth with violence, producing the effect of an artificial volcano.

2. By igniting ferric oxide or scale-oxide of iron with sulphur.—3. By heating iron pyrites, ferric sulphide, or magnetic pyrites, either alone to a bright red heat, or with iron filings, or in an atmosphere of hydrogen.—4. By reducing ferrous sulphate at a bright red heat in a crucible lined with charcoal. Ferrous sulphate is also reduced to sulphide in the wet way by contact with decomposing organic matter.—5. By precipitating ferrous salts with alkaline sulphides.

Ferrous sulphide prepared in the dry way is a dense yellow mass with metallic lustre, or sometimes a black porous mass. It is sometimes magnetic, but according to Berzelius, only when it contains a portion of one of the higher sulphides. It does not alter sensibly by exposure to the air at ordinary temperatures, and is not decomposed by ignition, even to whiteness, in close vessels; but when gently heated in the air, it is partly converted into ferrous sulphate; while at a stronger heat, sulphurous anhydride is evolved, and ferric oxide remains behind. With *nitric acid* it evolves nitrous gas, ferric oxide and sulphuric acid being formed, and sulphur separated. It dissolves in dilute *sulphuric* or *hydrochloric acid*, with evolution of pure sulphydric acid gas. If, however, it is mixed with metallic iron, which is generally the case with the protosulphide obtained by igniting iron filings with sulphur, it gives off a mixture of sulphydric acid and free hydrogen. *Aqueous vapour* passed over red-hot proto-sulphide of iron converts it, with evolution of much hydrogen and sulphydric acid gas, into a black and

partly magnetic mass. The water forms with the sulphide of iron, sulphydric acid and ferrous oxide, which, by further decomposition of water, yields hydrogen gas and ferroso-ferrie oxide; but a portion of the sulphur remains, even after three hours' ignition (Regnault, Ann. Ch. Phys. [2] lxii. 379). Chlorine gas does not decompose cold sulphide of iron; but that compound, when heated in the gas, yields chloride of sulphur and sublimed ferric chloride (H. Rose, Pogg. Ann. xlii. 640). Protosulphide of iron, heated to low redness with once or twice its weight of carbonate of sodium or potassium, fuses into a black, crystalline, highly magnetic mass, from which water extracts sulphide of sodium or potassium, with a trace of sulphuric acid. Baryta and lime behave in the same manner, only that the viscosity of the slag prevents the iron from fusing into a mass (Berthier, Ann. Ch. Phys. [2] xxxi. 170). When protosulphide of iron is fused with 30 times its weight of protoxide of lead, the whole of the sulphur is given off in the form of sulphurous anhydride, metallic lead is separated, and a fused mixture of protoxide of iron and protoxide of lead is produced.

Ferrous sulphide prepared in the wet way is a black amorphous substance, perhaps containing water; in the finely divided state, it has a dark green colour. In the moist state, it oxidises quickly on exposure to the air, being converted, first into ferrous sulphate, then quickly into yellow-brown basic ferric sulphate. It exhibits the same reactions as the protosulphide prepared in the dry way, but is much more easily decomposed, and dissolves much more quickly in acids, with violent evolution of sulphydric acid gas.

The black mud at the bottom of drains, cess-pools, ponds and morasses, owes its colour to sulphide of iron, probably formed by the putrefaction of organic matters in contact with ferric oxide contained in the soil.

Sesquisulphide or Ferric Sulphide. Fe^2S^3 .—This compound is probably a constituent of copper pyrites, $\text{Cu}^2\text{S}.\text{Fe}^2\text{S}^3$ (ii. 77), and of magnetic pyrites (see below). It is produced by heating iron to moderate redness, or ferric oxide to low redness with excess of sulphur: in the latter case, however, the product is mixed with ferric oxide, unless the process is several times repeated (Rammelsberg, Pogg. Ann. cxxi. 339). According to Berzelius, it may also be obtained by the action of sulphydric acid on ferric oxide at 100° , or on ferric hydrate at ordinary temperatures, or by dropping a neutral solution of ferric sulphate into excess of sulphhydrate of ammonium. According to Rammelsberg, however, the product obtained by heating ferric oxide in sulphydric acid gas to a temperature short of redness, is an oxysulphide containing 1 at. ferric oxide to 3 at. ferric sulphide; after stronger heating, the product contains less ferric oxide, but in place of it a certain quantity of ferrous sulphide; and if the heat be raised to bright redness, there remains at last a sulphide of iron free from oxygen and having the composition of magnetic pyrites.

Ferric sulphide dried out of contact with air, is a yellow-grey, non-magnetic powder. When heated to redness in close vessels, it gives off sulphur and leaves magnetic pyrites. In the moist state it oxidises very quickly in contact with the air, especially when prepared by precipitation of ferric salts. Acids decompose it, with formation of ferrous salt, evolution of sulphydric acid, and precipitation of sulphur.

Ferroso-ferric or Magnetic Sulphide.—This sulphide occurs native as magnetic pyrites, and is formed by heating iron with a slight excess of sulphur till the mass fuses; also by heating the disulphide to redness in a covered crucible. As thus prepared, it has a brownish-yellow to speiss-yellow colour; is attracted by the magnet, and sometimes itself magnetic. It does not lose weight when simply ignited in close vessels, but when heated in hydrogen gas, it yields sulphydric acid and the protosulphide. Dilute acids dissolve it, with separation of sulphur and evolution of sulphydric acid. Boiling potash-ley is said to remove a portion of the sulphur, leaving ferrous sulphide.

Magnetic pyrites or Pyrrhotin occurs in crystals belonging to the hexagonal system and generally tabular, exhibiting the combinations of P , $\text{P}\cdot\text{oP}$, ∞P , oP , $\infty\text{P}\cdot\text{P}$, like figures 239, 240 (ii. 139) and others. Ratio of principal to secondary axes = 1 : 1.741. Angle $\text{P} : \text{P}$ in the terminal edges of the pyramids = $126^\circ 49'$; in the lateral edges = $127^\circ 6'$. Cleavage tolerably distinct parallel to oP , indistinct parallel to ∞P . More commonly massive and amorphous, with granular structure. Hardness = 3.5 to 4.5. Specific gravity, 4.51 to 4.64 (Rammelsberg). Lustre metallic. Colour between bronze-yellow and copper-red. Streak dark greyish-black. Fracture small subconchoidal. Brittle. Slightly attracted by the magnet. Tarnishes quickly. Before the blowpipe it gives off sulphurous anhydride, and on charcoal in the outer flame, is converted into ferric oxide; in the inner flame it melts and continues to glow after the blowpipe is removed. The mass, after cooling, is magnetic and has a metallic crystalline structure, with a yellowish colour on the fractured surface.

The following are analyses of magnetic pyrites calculated to 100 parts, after deducting quartz, &c. (Rammelsberg, *loc. cit.*)

a. Massive from Klefva in Småland, Sweden; b. Massive from Modum in Norway; c. Laminar, intergrown with quartz and mica, from the Gap mine, Pennsylvania; d. Massive, intergrown with white iron pyrites, also containing a small quantity of copper pyrites, from Horbach in Baden; e. Laminar, from Hilsen in Norway.

These analyses may be represented by the formula, $\text{M}^3\text{S}^4 = 3\text{MS} \cdot \text{M}^2\text{S}^3$, and $\text{M}^4\text{S}^5 = 4\text{MS} \cdot \text{M}^2\text{S}^3$, where M stands for Fe (56) and Ni (58.9), each metal being present in both degrees of sulphuration. (Rammelsberg.)

Disulphide of Iron. FeS^2 .—This compound occurs abundantly in nature in two distinct forms, viz. as *Yellow iron pyrites*, *Cubic pyrites* or *Mundic*, which crystallises in monometric forms, and *White iron pyrites*, *Marcasite*, *Radiated pyrites*, *Spear pyrites*, *Hepatic pyrites*, or *Cellular pyrites*, which crystallises in trimetric forms. Cubic pyrites occurs abundantly in rocks of all ages, from the oldest crystalline to the most recent alluvial deposits, and has been found in small irregular crystals in the Vesuvian lavas. Marcasite occurs also in rocks of various ages, being found in granite, gneiss, and mica slate, and abundantly in the plastic clay of the brown coal formation near Carlsbad in Bohemia. The peculiar circumstances which determine the formation of one or other of these varieties are not known; neither has it been found possible to convert the one into the other. Iron pyrites is often formed from iron salts, in presence of putrefying organic matters, such as straw, wood, &c., the sulphide of iron thus produced retaining the form of the organic substance.

Yellow iron pyrites occurs in a great variety of monometric forms, the dominant forms being the cube, the octahedron, the trapezohedron $\frac{200}{2}$ (fig. 180, ii. 125), the pentagonal dodecahedrons $\frac{200}{2}$ (fig. 192), and $\frac{300}{2}$, the hexakis-tetrahedrons $\frac{300}{2}$

and $\frac{402}{2}$ (hemihedral forms of the hexakis-octahedron, ii. 127), these forms occurring

either alone or in combinations, such as figs. 194, 195, 196, 211, and numerous others. Twin-crystals are also found resulting from the intersection of two pentagonal dodecahedrons. Cleavage cubic and octahedral, more or less distinct; the cubic and octahedral faces are often striated. It likewise occurs radiated, subfibrous, and massive; often reniform or globular, with a crystalline surface. Hardness = 6 to 6.5. Specific gravity 4.983 to 5.031 (Dana); 5.0 to 5.2 (Rammelsberg). Lustre metallic, splendid; colour, bronze-yellow, nearly uniform. Streak, brownish black, opaque. Fracture conchoidal, uneven. Brittle, strikes fire with steel. [For analyses, see p. 343.]

White iron pyrites or marcasite forms trimetric crystals, in which $a : b : c = 0.7454 : 1 : 1.1548$. Angle $\angle \text{P} : \text{P} = 73^\circ 24'$; $\text{P} \infty : \text{P} \infty$ in the basal principal

section = $98^{\circ} 18'$. The crystals are pyramidal and prismatic combinations, the faces ρ_{100} being frequently predominant in the latter. Cleavage tolerably distinct, parallel to ∞P . It occurs also in globular, reniform, and other imitative shapes; often massive, columnar, or granular. Hardness = 6 to 6.5. Specific gravity = 4.678 to 4.847 (Dana); 4.86 to 4.88 (Rammelsberg). Lustre metallic. Colour, pale bronze-yellow, sometimes inclining to green or grey. Streak, greyish-black or brown-black. Fracture uneven. Brittle.

Disulphide of iron is produced artificially: 1. By heating iron with excess of sulphur to a temperature below redness (Rammelsberg, Pogg. Ann. cxxi. 339).—2. By exposing ferric oxide or hydrate, ferroso-ferric hydrate, or ferrous carbonate, at a heat above 100° , but not amounting to redness, to a stream of sulphydric acid gas, as long as the mass continues to increase in weight. At first the action is so strong, that aqueous vapour, sulphurous anhydride, and hydrogen are evolved, and lower sulphides of iron are formed; but these afterwards take up more sulphur, and liberate pure hydrogen gas. The sulphide of iron thus produced retains the crystalline form of the oxide used in its preparation, with the same lustre on the faces, and the same directions of cleavage (Berzelius).—3. The lower sulphides of iron may be brought to this, the highest degree of sulphuration, by heating them in like manner in sulphydric acid gas (Berzelius).—4. An intimate mixture of 2 pts. protosulphide of iron and 1 pt. sulphur, heated in a retort to a temperature short of redness, leaves disulphide of iron as a bulky, dark yellow, non-magnetic, metallic powder, not attacked by hydrochloric acid (Berzelius).—5. When an intimate mixture of ferric oxide, sulphur, and sal-ammoniac is heated to a temperature a little above that at which the sal-ammoniac sublimes, the residue is found to contain small, brass-yellow octahedrons and cubes, which may be separated from the rest of the powder by levigation (Wöhler, Pogg. Ann. xxxvii. 288).—6. When sal-ammoniac containing sulphate of ammonium is sublimed at a dull red heat in iron vessels coated with clay, the clay covering becomes impregnated with chloride of iron, and cubes and octahedrons of iron pyrites form upon its surface (Löwe, *J. pr. Chem.* vi. 98).—7. The compound may also be prepared in the wet way by mixing solutions of alkaline persulphides with ferrous chloride at 180° , or ferrous sulphate at 166° . (Senarmont, Ann. Ch. Phys. [3] xxx. 129.)

Artificially prepared disulphide of iron differs in character according to the mode of preparation adopted, being either a bulky dark yellow powder (Berzelius), or crystallising in small brass-yellow cubes and octahedrons (Wöhler), or a black powder (Senarmont). It is not magnetic, is not attacked by dilute acids, but is decomposed by heating with strong hydrochloric acid, with evolution of sulphydric acid, and separation of sulphur, and is oxidised when heated with strong nitric acid or with nitromuriatic acid.

Yellow iron pyrites in its compact forms, and the denser varieties of the artificial disulphide, do not alter by exposure to the air, and even that which is prepared in the wet way oxidises but slowly in the air, and only when moist; but white iron pyrites weathers very rapidly, and the yellow variety in the finely divided state oxidises even at ordinary temperatures, with sensible evolution of heat, as in the roasting of alum-stone, and the spontaneous heating of coal or lignite containing pyrites, which sometimes becomes intense enough to set fire to inflammable substances, and gives rise to the spontaneous combustion of coal-mines. The products of this spontaneous oxidation are, so long as the temperature remains moderate, sulphuric acid and ferrous sulphate, which separates partly in crystals, partly as an efflorescence on the surface, but is for the most part dissolved out by the water which permeates the mass (see SULPHATES); but at higher temperatures, sulphurous anhydride is evolved, and ferric oxide is left, with only a small quantity of sulphuric acid. This reaction renders iron pyrites available for the manufacture of sulphuric acid (*q. v.*). When ignited with charcoal, it yields sulphide of carbon. Mixed with 10 per cent. charcoal, and exposed to the action of a mixture of superheated steam and atmospheric air, it is completely desulphurised, giving off sulphur, sulphydric acid, and sulphurous anhydride, together with carbonic anhydride and carbonic oxide, while the iron remains, according to circumstances, either in the metallic state or as ferric oxide. (Brunfant, Journ. des Mines, 1861, No. 6.)

IRON, TANTALATE OF. See TANTALITE.

IRON, TELLURIC. A term applied to native metallic iron found on the earth's surface, to distinguish it from meteoric iron.

IRON, TELLURIDE OF. See TELLURIDES.

IRON, TUNGSTATE OF. See TUNGSTATES.

ISAMIC ACID. $C^6H^{10}N^2O^4$. *Imasatic acid*, *Rubindento acid*. (Laurent, Ann. Ch. Phys. [3] iii. 490.)—This acid is produced by the action of warm ammonia on isatin; but the best mode of preparing it is to dissolve isatin to saturation in

aqueous potash; evaporate the solution to dryness; dissolve in alcohol; mix the solution with a very concentrated solution of sulphate of ammonium (in the proportion of rather more than 1 at. of that salt to 1 at. isatin); filter to separate sulphate of potassium; evaporate the filtered liquid to dryness, whereby the isatate of ammonium is converted into isamate; then boil with alcohol; filter to separate isamide and sulphate of ammonium; and neutralise the filtrate with hydrochloric acid, taking care to avoid an excess. Isamic acid then separates in crystals on cooling. If a small quantity of isatin should likewise separate, in consequence of too much hydrochloric acid having been added, or of too great a heat having been applied, or of the solution of isatate of ammonium not having been sufficiently evaporated, the crystals must be treated with weak ammonia, which dissolves the isamic acid and leaves the isatin.

Isamic acid crystallises in splendid, shining, rhombic laminæ, of the colour of red iodide of mercury. By spontaneous evaporation of the solution, ruby-coloured hexagonal tables are formed, with angles of about 110° . It dissolves sparingly in boiling water, forming a yellow solution, easily soluble in hot alcohol, somewhat less in ether.

Isamic acid dissolves with fine violet colour in hydrochloric acid. By boiling with dilute acids, it is converted into ammonia and isatin. Bromine attacks it violently, forming *indichloride*, $C^{10}H^4Br^2N^2O^2$, a yellow substance insoluble in water.

Isamate of ammonium, $C^{10}H^{12}(NH^4)N^2O^4$, crystallises in small needles or very acute microscopic rhombs. When somewhat strongly heated, it gives off water, and is converted into isamide. Its solution does not precipitate the salts of barium, calcium, or magnesium. It forms a yellow precipitate with *acetate of lead*, red with *mercuric chloride*, yellow with *nitrate of silver*.

Isamate of potassium may be boiled without decomposing.

Dichlorisamic acid, $C^{10}H^{10}Cl^2N^2O^4$.—Produced by adding hydrochloric acid to a solution of dichlorisamide in dilute potash, and crystallising the brick-red flocculent precipitate from alcohol. It forms bright red elongated hexagonal laminæ, derived from a rhombus of about 110° . It is more soluble than isamic acid in alcohol and ether, and forms yellow solutions. It is decomposed by distillation. Strong acids dissolve it, with violet colour, at ordinary temperatures; but at the boiling heat, they convert it into ammonia and chlorisatin.

Tetrachlorisamic acid, $C^{10}H^4Cl^4N^2O^4$.—Tetrachlorisamide is converted by boiling alcohol into tetrachlorisamate of ammonium; and on adding nitrate of silver to this salt, a flocculent precipitate is formed containing $C^{10}H^4AgCl^4N^2O^4$.

ISAMIDE. $C^{10}H^{12}N^2O^2$. *Amasatin*. (Laurent, Ann. Ch. Phys. [3] iii. 488.) Produced by heating isamate of ammonium till water is given off, and washing the residue with water. It is pulverulent, of a fine yellow colour, tasteless, inodorous, insoluble in water, nearly insoluble in ether, very sparingly soluble in alcohol, moderately soluble in boiling alcohol containing ammonia. Potash dissolves it with yellow colour, with elimination of ammonia; the solution contains isatin.

ISATAN. $C^{10}H^{12}N^2O^2$? (Laurent, J. pr. Chem. xxviii. 346.)—This body is sometimes produced when disulphisatide is boiled with acid sulphite of ammonium, as a white precipitate, which dissolves when boiled with a large quantity of alcohol, and is deposited on cooling in crystals, which appear under the microscope, either as well-defined rectangles, or as pointed ovals, according to the side on which they are viewed. The compound, heated till it melts, turns brownish red, and yields a mixture of isatin and indin:

It is decomposed by boiling nitric acid, with formation of a violet powder, similar to nitrindin. With alcoholic potash it forms a yellow solution from which water precipitates hydroindin, and hydrochloric acid throws down isatin mixed with a resinous substance.

The composition of isatan is equal to that of 2 at. indigo-blue + 1 at. water ($2C^{10}H^8NO + H^2O$), and to that of isatide *minus* 1 at. oxygen ($C^{10}H^{12}N^2O^4 - O$).

ISATIC ACID. $C^8H^4NO^4$. (Laurent, Ann. Ch. Phys. [3] iii. 371.)—The potassium-salt of this acid is produced by the action of caustic potash upon isatin. The acid itself is not easily obtained in the free state.

The solution of the potassium-salt mixed with hydrochloric acid, deposits, after a while, crystals of isatin, which in fact differs from isatic acid, only by the elements of water:

The composition of the isatates is represented by the formula $C^8H^4MNO^3$. The ammonium-salt appears to be capable of existing only in solution; for on evaporation to

dryness, it gives off water, and is converted into isamate of ammonium (p. 404). The *barium-salt*, $C^6H^4Ba^1N^2O^4$, produced by the action of baryta-water on isatin, crystallises in scales. The *potassium-salt* contains $C^6H^4KNO^3$. Isatin dissolves in a cold strong solution of potash, forming a deep violet-red liquid, which changes to pale-yellow when diluted with water and boiled. On evaporating the solution, the salt is obtained in crystals of a faint yellow colour. It precipitates chloride of barium if the solutions are concentrated, and forms with acetate of lead, a yellow flocculent precipitate, which gradually turns red. The *silver-salt*, $C^6H^4AgNO^3$, is soluble in water, and crystallises in beautiful yellow prisms. It is obtained as a precipitate on mixing the boiling and rather concentrated solutions of isatate of potassium and nitrate of silver.

Bromisatic acid, $C^6H^4BrNO^3$, is obtained as a potassium-salt by the action of cold aqueous potash on bromisatin.

Dibromisatic acid, $C^6H^4Br^2NO^3$. (Erdmann, J. pr. Chem. xix. 360.)—This acid is obtained, by adding hydrochloric acid to a concentrated solution of its potassium-salt, as a light yellow pulverulent substance, soluble in a larger quantity of water. By desiccation, even in vacuo, at mean temperatures, it is converted into dibromisatin.

Dibromisate of potassium, $C^6H^4KBr^2NO^3.H^2O$, is prepared by dissolving dibromisatin in cold aqueous potash, and leaving the solution to itself for a while. It crystallises in pale yellow, shining needles, less soluble in water and in alcohol than the dichlorisate. It gives with metallic salts the same reactions as the dichlorisate. *Sulphurous acid* converts it into *dibromisatosulphite of potassium*, $C^6H^4KBr^2NO^3.2SO^3$.

Chlorisatic acid, $C^6H^4ClNO^3$. (Erdmann, Ann. Ch. Pharm. xxxiii. 129.—Laurent, Ann. Ch. Phys. [3] iii. 378.)—This acid is not known in the free state, but several of its salts have been prepared.

Chlorisate of potassium, $C^6H^4KClNO^3$, is obtained by mixing warm, moderately concentrated solutions of caustic potash and chlorisatin. The salt separates on cooling and may be purified by repeated crystallisation from alcohol. It crystallises in shining flattened quadrilateral needles of a light yellow colour, soluble in water and alcohol, and decomposed by heat. Hydrochloric acid added to its solution throws down chlorisatin.

The other salts of chlorisatic acid are obtained by double decomposition. The *barium-salt* separates on cooling from a mixture of the hot solutions of chlorisate of potassium and chloride of barium, sometimes in pale yellow needles containing $C^6H^4Ba^1Cl^2N^2O^4.H^2O$, sometimes in deep yellow, very brilliant laminae containing $C^6H^4Ba^1Cl^2N^2O^4.3H^2O$. Both these hydrates give off their water between 150° and 160° . The *bismuth-salt* has a deep orange-yellow colour. The *calcium-salt* resembles the barium-salt. The *cadmium-salt* is yellow. The *cupric salt*, when first precipitated, is bulky, and of the colour of ferric hydrate, but changes after a while to a heavy granular powder of a blood-red colour. The *ferric salt* is a brown-red precipitate obtained by adding chlorisate of potassium to iron-alum. The *lead-salt*, $C^6H^4Pb^1Cl^2N^2O^4.2H^2O$, is produced as a brilliant yellow gelatinous precipitate, which, in a few minutes, especially if agitated, becomes flocculent, and of a splendid scarlet colour, almost as bright as that of mercuric iodide. Under the microscope, the yellow precipitate appears pulverulent, without any trace of crystallisation, but the red flocks present the appearance of dendritic vegetation. These red flocks contain 1 at. water, which they give off at 160° . The *magnesium-* and *aluminium-salts* appear to be soluble. The *mercury-salts* are yellow precipitates. The *nickel-salt* is a yellowish crystalline powder. The *silver-salt*, $C^6H^4AgClNO^3$, is a light yellow precipitate, which dissolves in boiling water and crystallises on cooling in needles grouped in tufts, or in dendritic vegetations of yellowish colour. The *zinc-salt* is a yellow precipitate.

Dichlorisatic acid, $C^6H^4Cl^2NO^3$. (Erdmann, Laurent, *loc. cit.*)—This acid separates from a concentrated solution of its potassium-salt, on addition of a mineral acid, in the form of a yellow precipitate, which, however, cannot be obtained pure; for by desiccation, even in vacuo at mean temperature, it separates into dichlorisatin and water. It dissolves in water, forming a light yellow solution, which becomes turbid at 60° , and deposits dichlorisatin.

Dichlorisate of potassium, $C^6H^4KCl^2NO^3.H^2O$.—Dichlorisatin dissolves in cold aqueous potash, forming a deep red solution which becomes colourless when heated, and on cooling deposits the potassium-salt in shining yellow laminae, which may be purified by crystallisation from alcohol. They contain 1 at. water (= 5 per cent.), which is not completely expelled below 130° . When crystallised from absolute alcohol, the salt appears to contain only half of that quantity of water. It is decomposed by heat, with a kind of explosion.

The *barium-salt*, $C^6H^4Ba^1Cl^2N^2O^4.2H^2O$, forms shining golden-yellow needles. The *cupric salt* is a red-brown precipitate, which soon becomes greenish yellow on alter-

nately crimson, these changes of colour arising from the crystallisation within the liquid. The *lead-salt* is a yellow precipitate. The *silver-salt* is a yellow precipitate, which dissolves in a large quantity of boiling water, and crystallises on cooling in transparent yellowish needles, grouped in tufts. When heated in contact with the air, it melts to a brown mass, and yields a sublimate of dichlorisatin.

ISATILIM. $C^8H^{10}N^2O^4 = 3 \text{ at. isatin} + NH^3 - H^2O$.—A substance stated by Laurent (J. pr. Chem. xxxv. 121) to be sometimes obtained when dry ammonia-gas is passed over isatin moistened with alcohol. Yellow non-crystalline flocks easily decomposed by potash. Its composition is rather doubtful.

ISATIMIDE. $C^8H^{11}N^2O^4$. (Laurent, *loc. cit.*)—Obtained by passing dry ammonia-gas over isatin moistened with alcohol, either ordinary or absolute. When absolute alcohol is used, *imesatin* (p. 246) first crystallises out in prisms with square or rectangular base; and the solution decanted therefrom deposits isatimide in the form of a yellow, shining, crystalline powder. It is insoluble in water, scarcely soluble in boiling alcohol or in ether, but dissolves easily in boiling alcohol, containing ammonia. Potash dissolves it with yellow colour and evolution of ammonia; the liquid contains isatin.

ISATIN. $C^8H^6NO^4$. (Laurent, Ann. Ch. Phys. [3] iii. 371.—Erdmann, J. pr. Chem. xxiv. 11.—A. W. Hofmann, Ann. Ch. Pharm. liii. 11.—Gm. xii. 51.—Gerh. iii. 534.)—This body, which was discovered simultaneously by Laurent and by Erdmann, in 1841, is produced by the action of nitric or chromic acid upon indigo:

Preparation.—1 kilogramme of finely powdered, good commercial indigo is stirred up in a large dish to a thin paste with water; it is then placed over a moderate fire, and commercial nitric acid is gradually added (which causes a violent effervescence, without evolution of nitrous acid), until the blue colour has disappeared, for which, from 600 to 700 grms. of nitric acid are necessary. The solution is boiled with several quarts of water, and filtered at the boiling heat, as rapidly as possible; after 12 hours, the isatin separates in reddish crystalline nodules. The mother-liquor is boiled with the undissolved residue and filtered, the operation being two or three times repeated: the last mother-liquor still yields isatin on evaporation. The crystals are moistened with water containing a little ammonia, in order to remove a resinous matter; they are then washed with cold water, and finally recrystallised several times from boiling alcohol (100 pts. of indigo yield 18 pts. of isatin) (Laurent). When an excess of nitric acid is employed, nitrosalicilic acid is formed. After each addition of nitric acid, it is necessary to wait until the effervescence is over. If no effervescence takes place, in consequence of the indigo being mixed with too much water, and if the boiling is continued, whilst more and more nitric acid is added, a violent reaction suddenly ensues when the solution has reached a certain concentration, the mass overflowing the vessel even when it is very capacious: the residue generally contains nitrosalicilic acid (Hofmann).—2. Indigo is heated with chromic acid, properly diluted, until the whole nearly boils, when it is filtered hot; isatin then crystallises out on cooling, and is purified by repeated recrystallisation from water, and lastly from alcohol. If the chromic acid is so concentrated that it causes an evolution of carbonic anhydride, the solution deposits little or no isatin on cooling, but a small quantity by spontaneous evaporation or in vacuo; on evaporating the solution by heat, only sesquioxide of chromium and a brown powder separate (Erdmann). Laurent drops a dilute aqueous solution of chromic acid upon powdered indigo, and warms the mixture, the addition of chromic acid being discontinued as soon as the blue colour has disappeared, and the process continued as in (1). In order to purify crude isatin, which still contains resin, Hofmann dissolves it in potash, and carefully adds hydrochloric acid to the solution, as long as it forms a black or brown precipitate; when a portion on filtering is of a pure yellow colour, and gives a highly red precipitate with hydrochloric acid, the whole solution is filtered off, decomposed with hydrochloric acid, and the precipitate washed with a little water.

Properties.—Isatin crystallises in large, transparent, brownish-red prisms, or in smaller yellowish-red prisms, belonging to the trimetric system; the crystals are very brilliant, especially when obtained from an alcoholic solution. They exhibit the combination $\infty P : \infty \bar{P} : \infty P$; the faces ∞P greatly predominating. Inclination of the faces $\infty P : \infty \bar{P} = 133^\circ 50' : 133^\circ 55'$; $\bar{P} : \infty P = 127^\circ 15' : 127^\circ 30'$ (G. Rose, J. pr. Chem. xxiv. 11). Isatin is inodorous, and has a bitter taste. It melts when heated, and solidifies on cooling in a crystalline mass of needles; when heated above its melting point in contact with the air, the greater part volatilises, without decomposition, in yellow and very irritating vapours. It dissolves sparingly in cold, more freely in boiling water, forming a solution of a dark-reddish yellow colour. Nitric

It is with the aid of a gentle heat, and deposits it unchanged on cooling. It is easily in alcohol, less easily in ether.

Decompositions.—Isatin distilled in a retort leaves a large residue of charcoal (Erdmann, Laurent). When thrown upon glowing charcoal, it diffuses the same odour as indigo. Heated in the air upon platinum-foil, it burns with a brilliant flame, and leaves a fused residue of difficultly combustible charcoal.—2. When isatin is suspended in hot water, and a current of chlorine is passed through the solution, it is converted into chlorisatin; no dichlorisatin is formed, even if the solution is exposed to sunshine.—3. Isatin heated to 180° with chloride of benzoyl, yields a brown substance having the composition of benzoyl-isatin, $C^9H^7(C^7H^5O)NO^2$.—4. Moderately warm nitric acid dissolves isatin without decomposition, but on boiling, a violent action takes place, attended with evolution of nitrous fumes, oxalic acid being formed together with a reddish-brown nitro-resin, soluble in ammonia; no picric acid is formed.—5. Isatin heated with fuming sulphuric acid, dissolves with brownish-red colour; a strong effervescence then takes place, and on treating the solution with water and alcohol, a yellow substance is obtained, which has not been further investigated.—6. Isatin dissolves in cold potash without undergoing decomposition, and imparts to it a brownish red colour: after a time, or immediately on boiling, the solution becomes yellow and is found to contain isatate of potassium:

If this solution be concentrated by distillation, decomposition suddenly takes place, colourless drops of phenylamine passing over with the steam, and hydrogen being simultaneously evolved (Hofmann):

7. Ammonia forms with solutions of isatin, various products of decomposition, which vary according to the concentration of the ammonia and the solvent of the isatin; mixtures of several compounds are always formed, each containing 1, 2, or 3 at. isatin, plus 1 or 2 at. ammonia minus water.—8. Phenylamine behaves with isatin in a similar manner.—9. With sulphurous acid in presence of alkalis, isatin forms salts of isatosulphurous acid.—It dissolves in sulphite of ammonium, with formation of isatylde.—10. When sulphydric acid gas is passed through an alcoholic solution of isatin, disulphisatylde (p. 412) is formed.

Isatites.—Isatin does not unite with acids, but rather itself plays the part of an acid, exchanging 1 at. of its hydrogen for an equivalent quantity of metal. Isatin dissolves in cold strong aqueous potash, forming a very dark violet-red liquid, probably containing isatite of potassium, $C^9H^3KNO^2$. On diluting with water and boiling, the colour changes to pale yellow, and the solution is then found to contain isatate of potassium. Isatite of cuprammonium, $C^9H^3(N^2H^4Cu)^2NO^4$, is obtained as a light blue precipitate on pouring an ammoniacal solution of isatin into an ammoniacal solution of acetate of copper. Isatite of silver, $C^9H^3AgNO^2$, is a wine-red crystalline precipitate, obtained by mixing nitrate of silver with an alcoholic solution of isatin. It gave by analysis 42.5 and 42.2 per cent. silver (calculated quantity 42.52). On adding nitrate of silver to an alcoholic solution of iodine containing a considerable quantity of ammonia, a red crystalline precipitate is formed, consisting of isatite of argentammonium, $C^9H^3(NH^4Ag)NO^2$. It gave by analysis 35.23 per cent. carbon, 2.66 hydrogen, and 39.76 silver (by calculation, 35.42 carbon, 2.58 hydrogen, and 39.86 silver).

Brominated and Chlorinated Derivatives of Isatin.

These compounds, which were discovered by Erdmann, have the composition of isatin, in which 1 or 2 at. hydrogen are replaced by an equivalent quantity of bromine or chlorine. They closely resemble isatin in form and properties, and when treated with caustic potash, ammonia, sulphydric acid, or alkaline sulphites, yield the chlorinated and brominated derivatives of the bodies which are produced by the action of the same reagents upon isatin.

Bromisatin. $C^9H^3BrNO^2$. (Erdmann, J. pr. Chem. xix. 368.—Hofmann, Ann. Ch. Pharm. liii. 40.)—This compound is produced, together with dibromisatin, by the action of bromine upon indigo. The product is exhausted with boiling water, and the crystals which separate on cooling, are purified by recrystallisation from alcohol, the first portions which separate consisting principally of bromisatin (Erdmann). Another mode of preparation is to suspend isatin in water, and shake it up in sunshine with bromine, which is to be gradually added till the liquid no longer becomes colourless on agitation. The compound is then boiled with weak alcohol, freed from hydrobromic acid by washing with water, and recrystallised from boiling alcohol (Hofmann.)

Bromisatin crystallises by cooling in shining orange-coloured prisms. Caustic

potash converts it, at mean temperatures, into bromisatite of potassium. Distilled with hydrate of potassium, it yields bromophenylamine.

Dibromisatin. $C^6H^3Br^2NO^2$. (Erdmann, *loc. cit.*—Hofmann, *loc. cit.*—Ann. Ch. Phys. [3] iii. 380.)—This body remains in the alcoholic solution obtained in preparing bromisatin, by the first of the methods above described, and may be separated by crystallisation; but a better way of preparing it is to combine bromisatin with bromine in sunshine, as long as hydrobromic acid continues to evolve. It is purified by crystallisation from alcohol, from which it separates in orange-coloured trimetric prisms. When distilled with hydrate of potassium, it yields dibromophenylamine.

Dibromisatite of potassium, $C^6H^3KBr^2NO^2$, is obtained by gently heating a solution of dibromisatin in absolute alcohol, and pouring into it a hot solution of alcohol potash. It crystallises in black scales, blue by transmitted light.

Chlorisatin. $C^6H^3ClNO^2$. (Erdmann, Ann. Ch. Pharm. xxxiii. 129.—Laurent, Ann. Ch. Phys. [3] iii. 478.—Hofmann, Ann. Ch. Pharm. liii. 12.)—Produced: 1. By passing chlorine into tepid water, in which isatin is suspended.—2. By the action of chlorine on pulverised indigo suspended in water. A large quantity of a reddish yellow substance is thereby produced, consisting of a mixture of chlorisatin and dichlorisatin, which may be separated by solution in boiling alcohol, the chlorisatin separating out first. It is purified by repeated crystallisation from alcohol.

Chlorisatin crystallises in orange-coloured prisms, isomorphous with isatin. Observed combination, $\infty P : \infty P \infty : P \infty$. Inclination of the faces, $\infty P : \infty P = 131^\circ$; $P \infty : P \infty = 134^\circ 12'$ (G. Rose). It is inodorous, but has a bitter taste. Its dust irritates the organs of respiration and provokes sneezing. It is insoluble in cold water, but dissolves readily in boiling water and in alcohol. The solutions impart a disagreeable odour to the skin. Heated in contact with the air, it melts to a brown liquid, and gives off yellow vapours having the odour of burning indigo. At a high temperature, it partly sublimes and is partly carbonised.

Chlorisatin behaves with reagents like isatin. It dissolves in strong sulphuric acid, and separates on addition of water. With nitric acid it yields a resinous substance, oxalic acid, and a small quantity of an azotised body, which crystallises in yellow grains. Sulphydric acid gas passed into an alcoholic solution of chlorisatin, forms a white precipitate which increases on addition of water. Erdmann calls this precipitate sulphochlorisatin; according to Gerhardt, it is perhaps chlorinated tetrasulphisatide, $C^6H^3Cl^2P^2S^4$ (analysis, 41.7 C, 2.37 H, and 31.09 S; calculation, 44.7 C, 2.33 H, 29.83 S).

Caustic potash communicates a deeper colour to chlorisatin, converting it into chlorisatite of potassium; on heating the liquid, the colour disappears, and the liquid contains chlorisatite of potassium.

Chlorisatite of argentammonium, $C^6H^3(NH^4Ag)ClNO^2$, is a crystalline precipitate, of the colour of wine-lees, obtained by pouring an ammoniacal solution of nitrate of silver into an alcoholic solution of chlorisatin mixed with ammonia.

Dichlorisatin, $C^6H^3Cl^2NO^2$, is obtained from the alcoholic mother-liquors, which have yielded chlorisatin, and is purified by recrystallisation from alcohol. It crystallises in small shining reddish-yellow needles, or shortened laminae, fusible, partly volatile when heated in a close vessel, soluble in water and in alcohol.

Aqueous potash acts upon it in the same manner as upon chlorisatin. When dichlorisatin is thrown upon solid potash moistened with absolute alcohol, a red solution is formed, which after a short time, solidifies in a violet-black magma composed of dichlorisatite of potassium, the solution of which forms with nitrate of silver a precipitate having the colour of wine-lees.

Chlorine does not act upon chlorisatin or dichlorisatin in presence of water, when either of these bodies is dissolved in hot alcohol of 80 per cent., and chlorine is passed through the liquid until nothing is formed but products of the decomposition of alcohol, a brownish yellow viscid mass is deposited at the bottom of the vessel containing shining laminae of perchloroquinone (chloranil). Water extracts ammoniac from this mass, and alcohol dissolves chloride of ethyl, pentachloroquinone, and a resinous mass which forms the largest portion of the product. The supernatant yellow solution contains products of the action of chlorine upon alcohol. It is purified by distillation, a residue corresponding to the resinous substance, but not to perchloroquinone. (Erdmann, Hofmann.)

SULPHURIC ACIDS. (G. and A. Schlieper, Ann. Ch. Pharm. cxviii. 129.)—Sulphuric acid, treated with oxidising agents, such as nitric acid or chromic acid, yields a monobasic acid containing the elements of isatin and sulphuric anhydride, $C^6H^3SO^4$; and the salts of this acid, treated with alkalis, yield a dibasic acid containing the elements of isatin and sulphuric acid, viz. $C^6H^3NO^2SO^4H^2$.

To prepare the monobasic acid, a superior sort of commercial indigo-carmin (p. 261) is mixed with a thin paste with an equal quantity of water; 1 or 2 pts. of sulphuric acid are added, the mass is heated to boiling; and 1 pt. of pulverised acid chromate of potassium is added by small portions as long as decoloration ensues. The solution is filtered while hot; and mixed with nitrate of potassium (to facilitate the crystallisation of the isatosulphate); the crystalline paste which separates is collected on a filter, washed with thick, dark-coloured mother-liquor is separated by displacement with a small quantity of water. This liquid, evaporated and cooled, yields a small additional quantity of the potassium-salt. The isatosulphate of potassium thus obtained, in the form of a brownish yellow, heavy, sandy powder, is contaminated with a resinous body, which adheres to it obstinately, and cannot be separated. The acid and its salts may, however, be obtained pure by converting them into dibasic isatosulphates by the action of alkalis, and reconvertng these into the monobasic isatosulphates with acids. The impure potassium-salt obtained as above is dissolved in hot baryta-water, which is added till the solution is completely decolorised, and the excess of baryta is precipitated by carbonic acid, the precipitate carrying down all the resinous impurities with it. The resulting pale straw-yellow solution contains a mixture of dibasic isatosulphate of potassium and dibasic isatosulphate of barium; and on precipitating the baryta as exactly as possible with sulphuric acid, an orange-yellow solution of the monobasic salt is obtained, whence the salt may be separated by evaporation and crystallisation. If on the other hand, the solution be saturated while hot, with a quantity of hydrochloric acid just sufficient to neutralise the potash, the liquid, which has now acquired a dark orange colour, deposits bulky, bright red, shining crystalline scales of monobasic isatosulphate of barium.

Monobasic Isatosulphuric acid, $C^6H^4NSO^4 \cdot 2H^2O = C^6H^4NO^2 \cdot SO^4 \cdot 2H^2O$, may be obtained in the free state by decomposing the solution of the barium-salt with an equivalent quantity of sulphuric acid.

The resulting orange-red, strongly acid solution, solidifies, when evaporated to a syrup, into a somewhat sticky, radio-crystalline mass, drying up in vacuo over sulphuric acid to a yellow, silky crystalline mass, which does not alter on exposure to the air at common temperatures, but easily gives up its water of crystallisation at 100° .

It dissolves in alcohol less easily than in water, and is insoluble in ether and in benzene. Isatosulphuric acid is a strong acid, separating even the stronger mineral acids from their salts. It is not decomposed by strong sulphuric or nitric acid, even with the aid of heat; but nitromuriatic acid, or a mixture of hydrochloric acid and chlorate of potassium slowly decomposes it, with formation of chloranil. The aqueous solution appears to be scarcely altered by chlorine. The alcoholic solution treated with ammonia gas yields viscid, dark brown-red bodies, probably amitated compounds. The acid is not reduced by hydriodic acid, but the reduction is effected by zinc and hydrochloric or sulphuric acid, the solution being thereby completely decolorised. Sulphydic acid, and especially sulphide of ammonium, likewise reduce the acid, yielding the ammonium-salt of hydrindin-sulphuric acid (p. 266).

Salts of Monobasic Isatosulphuric acid.—*Mono-ammoniac isatosulphate*, $C^6H^4(NH^4)NSO^4 \cdot H^2O$, is obtained by decomposing any other salt of the acid with an excess of an ammonium-salt in which the resulting salt is sparingly soluble; or by mixing a solution of the free acid with excess of sal-ammoniac. The salt crystallises in shining, deep yellow needles, easily soluble in water.

The *monobarytic salt*, $C^6H^4Ba^2NSO^4 \cdot 3H^2O$, is formed by precipitating a solution of chloride or nitrate of barium with the free acid. It is insoluble in alcohol, sparingly soluble in cold, somewhat more in hot water, forming a light yellow solution.

The *monocalcic salt*, $C^6H^4Ca^2NSO^4 \cdot 2H^2O$, is obtained by precipitation, and crystallises in small, shining, gold-yellow needles which dissolve somewhat slowly in water, but more easily than the barium-salt.

The *monopotassic salt*, $C^6H^4KNSO^4 \cdot H^2O$, crystallises in small gold-yellow needles which yield a sandy powder. It is insoluble in alcohol, dissolves in about 20 pts. of water, and somewhat less of hot water, whence it crystallises slowly. It is not altered by boiling with strong hydrochloric acid. It gives off all its water of crystallisation at a rather high temperature; indeed all the salts of monobasic isatosulphuric acid lose their water till heated above 100° .

The *mono-argentic salt*, $C^6H^4AgNSO^4 \cdot H^2O$, separates slowly on mixing a solution of the sodium-salt with nitrate of silver, in hard, needle-shaped, honey-yellow crystals, sparingly soluble in water.

The *monosodic salt*, $C^6H^4NaNSO^4 \cdot 2H^2O$, is obtained by mixing a hot solution of the potassium-salt with two or three times its volume of a concentrated solution of chloride of sodium, and crystallises, on leaving the liquid at rest, in tabular crystals.

Salts of Dibasic Isatosulphuric acid, $C^6H^4M^2NSO^4 = C^6H^4NO^2$

These salts are formed, as already observed, by the action of isatin on the monobasic isatosulphates. All alkalis produce the change provided they are in excess; if an insufficient quantity of alkali be added, a deep red, or sometimes dirty violet colouring is produced, which, though transient, is sufficient to indicate the formation of an intermediate compound. The transformation is likewise effected by alkaline carbonates.

Dibasic isatosulphuric acid has not been isolated; when separated from the solution of either of its salts, it is converted in a short time at ordinary temperatures, immediately when heated, into the monobasic acid.

The *diammonic salt* is produced by boiling isatosulphuric acid for some time with excess of ammonia, or by decomposing the dibarytic salt with sulphate of ammonium. The solution dries up, in vacuo over oil of vitriol, to a yellow gummy mass exhibiting but slight traces of crystallisation.

The *dibarytic salt*, $C^6H^2Ba^2NSO^6 \cdot 3H^2O$, is obtained by dissolving the monobarytic salt in boiling baryta-water, and removing the excess of baryta with carbonic acid. The slightly coloured solution yields, by evaporation or cooling, shining, lemon-yellow silky needles, more soluble than the monobasic salt in water, but insoluble in alcohol.

The *diphumbic salt*, $C^6H^2Pb^2NSO^6 \cdot \frac{3}{2}H^2O$, is obtained by mixing a concentrated solution of the yellow potassium-salt with an excess of a concentrated solution of acetate of lead; it crystallises in slender, shining, dark yellow needles, which dissolve readily in water.

The *dipotassic salt*, $C^6H^2K^2NSO^6 \cdot H^2O$, obtained by decomposing the barium-salt with neutral sulphate of potassium, crystallises slowly, by spontaneous evaporation, in hard, shining, transparent, wax-yellow prisms, which dissolve readily in water, and give off their water of crystallisation between 140° and 150° .

The *diargentic acid*, $C^6H^2Ag^2NSO^6 \cdot \frac{3}{2}H^2O$, separates on mixing a solution of the potassium-salt with excess of nitrate of silver, in concentric groups of bulky needles, which, after drying, form a light spongy pale yellow mass. It is sparingly soluble in water, and does not give off its water of crystallisation till heated above 100° .

ISATOSULPHITES. (Laurent, Rev. scient. x. 289.—Gm. xiii. 56.—Gerh. iii. 544.)—Sulphurous anhydride does not act upon isatin alone; but in presence of potash or ammonia, peculiar salts are produced, containing the elements of isate of ammonium or potassium, together with sulphurous anhydride. The acid corresponding to these salts has not been isolated, being decomposed when the salts are treated with a stronger acid. The chlorinated and brominated isatins yield corresponding compounds under the influence of alkalis and sulphurous acid.

Isatosulphite of Ammonium, $C^6H^2(NH^4)NO^3 \cdot 2SO^2$, is obtained by boiling isatin with acid sulphite of ammonium, and concentrating the liquid by evaporation. It then separates in small rhomboidal tables of a pale yellow colour, sparingly soluble in cold, but very soluble in boiling water.

Isatosulphite of Potassium, $C^6H^2KNO^3 \cdot 2SO^2$, is produced by passing sulphurous anhydride to saturation into a solution of isatin in potash, or into a solution of isate of potassium, or by boiling powdered isatin with acid sulphite of potassium, till it is completely dissolved.

The salt is neutral, has a faint yellow colour, is moderately soluble in water, and crystallises therefrom in elongated laminae possessing considerable lustre. It is moderately soluble in boiling alcohol, very little in cold alcohol. Its solutions are yellow. When heated it acquires an orange-red colour, swells up and gives off water, and at a higher temperature blackens, and gives off a red thick matter, which solidifies without crystallising.—Iodine decomposes it at the boiling heat, isatin being precipitated and sulphuric acid remaining in the liquid. Chlorine also forms sulphuric acid, but at the same time throws down chlorisatin or dichlorisatin, according to the duration of the action. Hydrochloric acid poured into a boiling solution of the salt eliminates sulphurous anhydride, with effervescence, and precipitates isatin.

The solution of the potassium-salt does not form any precipitate with chloride of barium, strontium, or calcium, or with acetate of copper; but with nitrate of silver and acetate of lead, it forms precipitates consisting of a metallic sulphite, together with isatin.

Dibromisatosulphite of Potassium, $C^6H^2Br^2KNO^3 \cdot 2SO^2$, is a yellow precipitate, sparingly soluble in water.

Chlorisatosulphite of Potassium, $C^6H^2ClKNO^3 \cdot 2SO^2$, is obtained by passing sulphurous anhydride into a solution of chlorisate of potassium. The liquid yields by evaporation a straw-yellow, fibro-lamellar salt, sparingly soluble in cold water. Acids decompose it, with precipitation of chlorisatin and evolution of sulphurous anhydride.

Dichlorisatosulphite of Potassium, $C^6H^2Cl^2KNO^3 \cdot 2SO^2$. Yellow needles obtained by boiling dichlorisatin with acid sulphite of potassium.

ISATYDE, $\text{C}^6\text{H}^4\text{N}^2\text{O}^4$ = $(\text{C}^6\text{H}^4\text{N}^2\text{O}^4)\cdot\text{H}^+$. (Laurent, Ann. Ch. Phys. [3] iii. 282.—Gm. anal. Berz. iii. 551.)—A substance produced by the action of reducing agents, such as nascent hydrogen, sulphydric acid, sulphide of ammonium, &c. on isatin; *e.g.*

It bears to isatin the same relation that indigo-white bears to indigo-blue.

The best mode of preparing it is to mix powdered isatin in a flask with a large quantity of water and a little sulphuric acid, then add a piece of pure zinc-foil, and heat the liquid. As the isatin dissolves, it takes up the nascent hydrogen, and is converted into pulverulent isatyde, which may be washed with water, and then boiled with alcohol to remove undecomposed isatin. Isatyde may likewise be obtained by dissolving isatin in hot alcohol, and adding a small quantity of sulphide of ammonium. The mixture left to itself for a week deposits laminated and prismatic crystals of isatyde, mixed with octahedral crystals of sulphur, which must be removed by digestion with disulphide of carbon.

Isatyde is white, with a slight greyish tint, tasteless, and inodorous, and appears to be insoluble in water. It dissolves in very small quantity, in alcohol and ether, at the boiling heat, and separates on cooling in microscopic scales, having the form of oblique prisms with rectangular base.

Isatyde softens when heated, and then turns violet-brown (being perhaps converted into a mixture of indin and isatin); if the heat be increased till the body is half melted, it suffers further decomposition, yielding a substance which dissolves in alcohol and crystallises in brown-red needles by evaporation.

Boiling nitric acid decomposes isatyde, producing a violet powder which ultimately dissolves. Potash likewise decomposes it, forming isatate of potassium and indin-potassium, which ultimately changes to hydrindin-potassium and other products of unknown constitution (see p. 264).

Erdmann (J. pr. Chem. xxiv. 15) gives the name of *isatyde* to a substance which he obtained by dissolving isatin in hot sulphide of ammonium. This substance gave by analysis numbers agreeing approximately with the formula $\text{C}^6\text{H}^4\text{N}^2\text{O}^4$. It was white, very slightly crystalline, scarcely soluble in water, but soluble in ammonia, with red colour gradually changing to yellow. Potash dissolved it with deep-red colour, disappearing when the liquid was heated; the solution, on cooling, deposited a crystalline salt, and yielded yellow flocks with hydrochloric acid.

Chlorisatydes and Bromisatydes. (Erdmann, Ann. Ch. Pharm. xxxiii. 129.—Laurent, Ann. Ch. Phys. [3] iii. 382.)—*Dichlorisatyde*, $\text{C}^6\text{H}^4\text{Cl}^2\text{N}^2\text{O}^4$, is produced by the action of sulphide of ammonium on chlorisatin. It is white, crystallisable, insoluble in cold water, sparingly soluble in hot water; moderately soluble in boiling alcohol, soluble also, apparently without alteration, in a hot solution of sulphide of potassium. Heated to 180° , it is resolved into chlorisatin and chlorindin:

Chlorisatyde is coloured red by ammonia, and partially dissolved. It dissolves in boiling aqueous potash, being converted into chlorisatate of potassium, which crystallises on cooling. The mother-liquor, treated with hydrochloric acid, yields a copious light-yellow precipitate, which is partially dissolved by boiling water, the insoluble part consisting of chlorindin, and the dissolved portion of chlorisatydic acid, probably a product of the decomposition of chlorindin. This acid is deposited from the aqueous solution in the form of a lemon-yellow substance, which forms, with potash, a soluble salt having little tendency to crystallise. The solution gives, with salts of lead, copper and barium, yellow precipitates which redissolve in the liquid when heated.

Tetrachlorisatyde, $\text{C}^6\text{H}^4\text{Cl}^4\text{N}^2\text{O}^2$.—Produced by the action of sulphide of ammonium on tetrachlorisatin. It resembles the preceding compound, and is decomposed in like manner by heat into tetrachlorisatin and tetrachlorindin. It likewise behaves in a similar manner when boiled with potash, yielding, among other products, probably by a secondary decomposition of dichlorindin, the potassium-salt of a peculiar acid (*dichlorisatydic acid*) which, as the liquid cools, is deposited in yellow, shining laminae.

Tetrabromisatyde, $\text{C}^6\text{H}^4\text{Br}^4\text{N}^2\text{O}^2$, resembles tetrachlorisatyde, and is prepared in a similar manner. It turns brown when heated, and is resolved into dibromisatin and dibromindin.

Sulphisatyde, $\text{C}^6\text{H}^4\text{N}^2\text{O}^3\text{S}$. *Sulphasatyde*. (Laurent, Ann. Ch. Phys. [3]

iii. 463).—Obtained by adding alcoholic potash drop by drop to an alcoholic solution of disulphisatyde:

The liquid turns red, and after a few seconds deposits a white crystalline precipitate of sulphisatyde, which must be washed with boiling alcohol and dried. It generally has a faint rose tint, due to the presence of a small quantity of iodine.

Sulphisatyde when pure is a white, crystalline, inodorous, and tasteless powder; it crystallises from hot alcohol in microscopic rectangular scales. It is insoluble in water. Boiling alcohol dissolves only traces, which separate out on cooling in small crystalline scales. It is not more soluble in ether than in alcohol.

Sulphisatyde, when heated, melts, turns red, swells up, and decomposes, while sulphuretted hydrogen is evolved, and a rose-coloured oil distils over, together with the vapour of a substance which crystallises in needles; finally, there remains a bulky residue of charcoal. It is converted by nitric acid into a violet powder, which, in all probability, is nitrindin; the solution contains sulphuric acid. It is decomposed by cold potash with formation of various products, among which is indin; the solution evolves sulphuretted hydrogen on the addition of hydrochloric acid, and gives a precipitate consisting of sulphur and a little reddish matter. On treating sulphisatyde with warm potash, hydrindin is formed.

Disulphisatyde. $\text{C}^6\text{H}^{12}\text{N}^2\text{O}^2\text{S}^2$. *Sulphésathyde*. (Erdmann, J. p. Chem. xxiv. 16.—Laurent, Ann. Chim. Phys. [3] iii. 463.)—Produced by the action of sulphydric acid upon isatin.

The decomposition takes place in two stages, sulphur being first deposited, and isatyde produced, and this compound being afterwards converted into disulphatyde, with formation of water:

and

Preparation.—When sulphydric acid gas is passed through a boiling concentrated alcoholic solution of isatin, the liquid becomes pale yellow, and forms a crystalline deposit, which increases on cooling, and consists of microscopic sulphur-crystals and scales (isatyde). The solution is left to itself for a week, that the greater part of the sulphur may crystallise out; it is then poured off and mixed with a little water, and the resulting precipitate is removed, as it contains sulphur; it is then shaken up with more water, which precipitates the disulphisatyde as a brownish grey resinous substance. (Laurent.)

Disulphisatyde, when dried, is a yellowish grey, inodorous, and tasteless powder. It does not crystallise from its alcoholic or ethereal solution, either on cooling or by spontaneous evaporation (Laurent). On drying at 110° it always becomes bluish or brick-red; if the solution is exposed to the air for some time before the addition of water, the precipitate is brownish-red. (Erdmann.)

Disulphisatyde swells up strongly when heated in a glass tube, and melts, with evolution of sulphydric acid; at the same time a brown oil and a needle-shaped sublimate are formed, and there remains a bulky residue of charcoal. When boiled with strong nitric acid, it puffs up, evolves pernitrilic oxide, and dissolves; water precipitates yellow flakes from the solution. In boiling nitric acid diluted with its own bulk of water, it puffs up and gives off nitrous fumes. If the reddish-brown swollen mass is treated, after a few minutes, with alcohol, the latter takes up a reddish substance, which is insoluble in water, but soluble in potash, from which it is precipitated by acids. The portion insoluble in alcohol dissolves in potash, and on neutralising the solution with nitric acid, a white precipitate, insoluble in water, is formed, consisting of microscopic needles. The liquid obtained by the action of nitric acid contains sulphuric acid, but no nitric acid. Bromine acts violently upon disulphisatyde, with evolution of bromide of sulphur and hydrobromic acid, and forms a yellow mass containing bromindin, an orange-yellow crystalline mass, and a little resin. Disulphisatyde dissolves in strong sulphuric acid, with the aid of a gentle heat; the red solution is not precipitated by water; potash colours it green, but does not precipitate it. On treating disulphisatyde with potash, sulphisatyde and various other products (amongst others, indin) are formed, which, however, cannot be produced at will. (According to Erdmann, the solution deposits a crystalline salt.) Ammonia behaves in a similar manner. With acid sulphite of ammonium, at mean temperature, disulphisatyde produces various compounds, among which is found the ammonium-salt of a peculiar acid, called sulphisutanous acid. This salt is crystallisable, soluble in water and alcohol, and

its alcoholic solution forms, with dichloride of platinum, a yellow precipitate, which, when decomposed by sulphydric acid, yields the free acid.

When, on the other hand, disulphisatide is treated with acid sulphite of ammonium at the boiling heat, there is generally deposited a mixture of indin with a white substance which has not been examined; sometimes, however, a different reaction takes place, resulting in the production of *isatan* (p. 404).

ISERIN. Titaniferous iron. See TITANATES.

ISETHIONIC ACID. $C^2H^4SO^4 = C^2H^4SO^2H^2$ (Gm. viii. 428.—Gerh. ii. 234.)

—This acid, which is isomeric with ethyl-sulphuric (sulphovinic) acid, and may be regarded as ethylene-sulphurous acid, $\left. \begin{matrix} (C^2H^4) \\ (SO)^2 \\ H^2 \end{matrix} \right\} O^2$, was discovered by Magnus in 1833

(Pogg. Ann. xxvii. 378), and has been further examined by Liebig, Regnault, Wokresensky, Berzelius, Kolbe (Ann. Ch. Pharm. cxii. 241), and Carius (*ibid.* cxxiv. 257). It is produced:—1. By the ebullition of ethionic acid (ii. 523).—2. By the prolonged action of strong sulphuric acid, or of sulphuric anhydride, on alcohol or ether, and is found among the residues of the preparation of ether.—3. By the action of nitrous acid upon taurine, $C^2H^4NSO^2$, which may be regarded as the amic acid of isethionic acid. A solution of taurine in dilute nitric acid, treated with nitrite of potassium, is converted into isethionate of potassium. (W. Gibbs, Sill. Am. J. [2] xxv. 30.)

Preparation.—1. Vapour of sulphuric anhydride is passed into absolute alcohol cooled by a mixture of ice and salt; and the resulting yellowish oily liquid is mixed with water, boiled for some time, and then saturated with carbonate of barium. The product thus obtained is isethionate of barium; if the water were added gradually, and the liquid were not boiled, ethionate of barium would be produced, but no isethionate.—2. Vapour of sulphuric anhydride is passed for some time into anhydrous ether; water is then added, which separates the excess of ether containing heavy oil of wine; and the solution is heated to ebullition; it then gives off, first ether, then alcohol, and ultimately contains nothing but sulphuric and isethionic acids, which may be separated by saturation with carbonate of barium.

To obtain the free acid, the barium-salt is cautiously decomposed with the exact quantity of sulphuric acid required, and the filtrate is evaporated, first by gentle heating, then in a vacuum over oil of vitriol.

Isethionic acid is a viscid, strongly acid liquid, which decomposes acetates and common salt. It bears without decomposition a heat of 160° , but blackens at higher temperatures.

The *isethionates*, $C^2H^4MSO^4$, are obtained by decomposing the barium-salt with solutions of the corresponding sulphates. They are soluble and crystallisable, and are distinguished from the ethyl-sulphates, with which they are isomeric, by their much greater stability, most of them sustaining, without alteration, a temperature of 200° . When an isethionate is heated with caustic potash, hydrogen is evolved, and there remains a mixture of carbonate, oxalate, sulphate, and sulphite, the proportion of these products varying with the degree of heat which has been applied. Isethionate of potassium, distilled with pentachloride of phosphorus, yields $C^2H^4SO^2Cl^2$, or $\left. \begin{matrix} (C^2H^4) \\ (SO)^2 \end{matrix} \right\} Cl^2$, which, when heated in sealed tubes with ammonia, yields taurine (Kolbe):

Isethionate of ammonium, $C^2H^4(NH^4)SO^4$, forms well-defined octahedrons, which preserve their transparency in a vacuum, and do not lose weight at 120° .

The *barium-salt*, $C^2H^4Ba^2SO^4$, crystallises in transparent six-sided plates, which may be heated to 300° without loss of weight. They melt at 320° , and decompose at a stronger heat, the salt blackening, swelling up to more than 100 times its original volume, and giving off a liquid of very pungent odour.

The *copper-salt*, $C^2H^4Cu^2SO^4 \cdot 2H^2O$, forms pale-green right prisms with rhombic base, and bevelled with two faces resting upon the acute edges. At 140° it turns white, and gives off 19.7 per cent. water of crystallisation.

The *potassium-salt*, $C^2H^4KSO^4$, forms rhomboidal prisms which are unalterable in the air, and bear without decomposition a heat of 300° . It melts between 300° and 350° , forming a liquid which, on cooling, solidifies into a fibrous mass having the appearance of porcelain, and undiminished in weight. The salt crystallises readily from boiling alcohol.

ISOBUIRET. $C^2H^4N^2O^2$.—A compound isomeric with biuret (i. 600), produced by the action of ammonia on tribrom-acetyl-carbamide:

414 ISOBROMOMALEIC—ISODIGLYCOL-ETHYLENIC ACID.

It dissolves sparingly in cold, easily in hot water, and crystallises from the solution in long needles containing $C^8H^8O^2 \cdot 2H^2O$, and melting at 186° , whereas biuret forms indistinct crystalline aggregations, and melts at 177° . In all other respects, the two substances resemble each other exactly. (A. Baeyer, Ann. Ch. Pharm. cxxx. 164.)

ISOBROMOMALEIC ACID. See MALEIC ACID.

ISOCAPPUTENE. See CAPPUTENE (i. 311).

ISOCETAMIDE. See the next article.

ISOCETIC ACID. $C^4H^8O^2$.—An acid discovered in 1854 by Bouis (Compt. rend. xxxix. 923). It is produced by saponifying the oil of *Jatropha Curcas* (huile de médicinier), the quantity obtained being 18 or 20 per cent. of the weight of the oil. After separation by pressure from oleic acid, and crystallisation from alcohol, it forms shining scales which melt at 55° , and solidify again at 53.5° . Its silver-salt is soluble in water, very soluble in alcohol, melts when heated, and burns easily without odour, leaving a residue of metallic silver.

Acetate of Ethyl, $C^4H^8(C^2H^5)O^2$, prepared by the usual methods, is odourless, melts at the heat of the hand, and solidifies at 21° , remaining perfectly transparent, and assuming a crystalline structure.

Isocetamide, C^4H^8NO , is obtained by heating the oil above mentioned with ammonia in a sealed tube. It is white, nacreous, melts at 67° , and is not attacked by strong potash.

ISOCYANURIC ACID. Syn. with FULMINURIC ACID.

ISOBROMOSUCCINIC ACID. See SUCCINIC ACID.

ISODIGLYCOL-ETHYLENIC ACID. $C^8H^{10}O^4$. (Barth and Hlasiwetz, Ann. Ch. Pharm. cxvii. 96).—An acid isomeric with diglycol-ethylenic acid (ii. 914), produced by treating milk-sugar with bromine and the product with oxide of silver. A bromine-compound of milk-sugar, $C^8H^{10}O^4Br^2$, (not isolated) appears to be first formed; and this when treated with moist oxide of silver yields bromide of silver, and the acid, $C^8H^{10}O^4$.

The acid is prepared by heating 30 grms. milk-sugar (1 at. = $C^8H^{10}O^4$) with 60 grms. bromine and half a litre of water, to 100° in strong well-closed bottles. The somewhat dilute yellowish solution is neutralised with moist oxide of silver (or oxide of lead); and the filtered solution is decomposed by sulphydric acid, evaporated at a gentle heat, mixed with alcohol to remove a little lime, freed from alcohol by distillation, and saturated, while still hot, with carbonate of cadmium. The slightly acid solution, decolorised with animal charcoal, yields the cadmium-salt in groups of granular crystals. To obtain the free acid, the cadmium-salt is rubbed up to a thin paste with water, and decomposed while hot by sulphydric acid, and the filtrate is evaporated to a syrup, which gradually dries up to a soft, hygroscopic, crystalline mass.—This acid may also be obtained, without the formation of the intermediate bromine-compound, by treating milk-sugar with half the preceding quantity of bromine, neutralising the solution with carbonate of sodium, and boiling.

An acid, agreeing with the preceding in every respect excepting the amount of its rotatory power, is obtained in like manner from gum-arabic. With starch only, a small quantity of an uncrystallisable acid mass is obtained. Maunite, cane-sugar and glucose, treated with bromine and water, form hydrobromic acid, which then gives rise to the formation of humus-like products.

Isodiglycol-ethylenic acid dried over oil of vitriol contains 13.9 per cent. water, agreeing nearly with the formula, $2C^8H^{10}O^4 \cdot 3H^2O$. It has a strong acid reaction, melts below 100° , and burns on platinum-foil, giving off the odour of burnt sugar. It dissolves in alcohol and is precipitated from the solution in flocks by ether. The aqueous solution is not precipitated by neutral or basic acetate of lead, mercuric nitrate, caustic baryta, or lime-water, but forms a white precipitate with ammoniacal sugar of milk. The ammonium-salt reduces an alkaline cupric solution, and forms a speculum when heated with nitrate of silver. The acid possesses optical rotatory power.

Isodiglycol-ethylenate of ammonium, $C^8H^{10}(NH^4)O^4 \cdot H^2O$, crystallises in large, transparent, glassy crystals of the monoclinic system. It dissolves in water, is nearly insoluble in alcohol, and gives off all its water at 120° .

The cadmium-salt crystallises from a hot-saturated solution in granular aggregates of monoclinic needles containing $C^8H^{10}CdO^{12} \cdot 3H^2O$; from dilute solutions, or from the mother-liquor by slow evaporation, in well-developed monoclinic crystals, mostly united in tufts. Both these hydrates, especially the former, are sparingly soluble in water, and both retain all their water of crystallisation till heated to 150° .

The calcium-salt, $C^8H^{10}CaO^{12} \cdot 7H^2O$, crystallises in crusts, or from more dilute solutions in large shining plates; it gives off 4 at. water at 100° , and the rest at 140° . There is also a calcium-salt containing only half as much water as the preceding.

The barium- and strontium-salts are gummy.

The *copper-salt* is soluble and amorphous.

A *lead-salt* having approximately the composition, $C^4H^{10}Pb^1O^{12} \cdot 4Pb^1O \cdot H^2O$, is obtained as a white precipitate on treating the solution of the acid with neutral acetate of lead and ammonia.

The *potassium-salt* forms a viscid uncrystallisable mass, easily soluble in water, and precipitated by alcohol.

The *silver-salt* is a gelatinous, easily decomposable precipitate, formed only in concentrated solutions.

The *sodium-salt* forms tufts of prisms, which in the air-dried state contain $C^4H^8NaO^6 \cdot 2H^2O$, and give off half their water at 100° .

ISOMERISM. This term is derived from *isos* equal, and *meros* part, and its employment by chemists is an expression of the fact that very different chemical compounds have sometimes identically the same ultimate composition.

Two or more different bodies which are composed of the same elements, and of the same proportions of those elements (i.e. which have the same percentage composition) are said to be isomeric.

Isomerism is sometimes used in a narrower sense, being made to signify equality of molecular weight, as well as identity in percentage composition. When the compounds have the same percentage composition but different molecular weights, the term *polymeric* is employed. Thus there are the terms *Isomeric* (in its wide sense), signifying that the different bodies have the same percentage composition; *Polymeric*, signifying that these different bodies have the same percentage composition, but different molecular weights; *Isomeric* (in its restricted sense), sometimes called *Metameric*, that the bodies have the same percentage composition and likewise the same molecular weight.

As might naturally be expected, cases of isomerism abound in organic chemistry, where an enormous number of compounds result from the combination of very few elements. The following organic substances may be cited by way of illustrating the employment of the term isomeric and its congeners.

Butyric acid	$\left. \begin{array}{c} C^4H^8O \\ H \end{array} \right\} O = C^4H^8O^2$
Acetic ether	$\left. \begin{array}{c} C^2H^4O \\ C^2H^2 \end{array} \right\} O = C^4H^8O^2$
Aldehyde	$\left. \begin{array}{c} C^2H^2 \\ H \end{array} \right\} O = C^2H^4O$
Oxide of ethylene	$(C^2H^4)^2O = C^4H^8O$

These four bodies are quite different, and have the same percentage composition, viz.:

Carbon	54.55
Hydrogen	9.09
Oxygen	36.36
	100.00

They are *Isomeric*, or *Isomers*, using the term in its widest sense.

Again, butyric acid and aldehyde have different molecular weights:—

Butyric acid	$C^4H^8O^2 = 88$
Aldehyde	$C^2H^4O = 44$

Butyric acid and aldehyde are therefore *Polymeric*.

Similarly acetic ether and aldehyde are *Polymeric*, or acetic ether and oxide of ethylene are *Polymeric*, or butyric acid and oxide of ethylene are *Polymeric*.

Again, butyric acid and acetic ether have the same molecular weights, viz.:

Butyric acid	$C^4H^8O^2 = 88$
Acetic ether	$C^4H^8O^2 = 88$

They are therefore *Isomeric* (in the restricted sense) or *Metameric*. Aldehyde and oxide of ethylene are also metameric bodies.

Closely related to the term isomerism is the term *allotropy*. Both of them have reference to the same substantial fact, viz. that different substances have sometimes the same ultimate composition; but they differ in their manner of stating it. *Isomeric* and *allotropic* are in fact complementary terms, "isomeric" being employed to predicate identity of composition between different bodies, whilst "allotropic" expresses difference between bodies of identical composition.

Such being the force of these words, there is a certain propriety in their usage; thus whilst it is correct to say, "Butyric acid and acetic ether are *isomeric*," it should be "There are *allotropic* bodies of the formula, C^4H^8N ." The same reason which enjoins the use of "allotropic" in this case, prescribes it in the instance of single elements; thus, for example, we read of "allotropic kinds of sulphur," but never of isomeric kinds.

It is worthy of remark that cases of isomerism occurring in inorganic chemistry, are,

usually described by employing the word *allotropy* or *allotropic*, whilst the reverse obtains in *organic chemistry*. This may be partly ascribed to there being always a very wide difference—or else no difference at all—in the composition of any definite inorganic substances; and hence the fact of identity or non-identity of composition being so easily ascertainable, it is implied in the form of expression, whilst the fact of difference of properties alone needs to be made the subject of formal predication. Among organic bodies, on the other hand, it continually happens that the differences of composition are quite decided, and yet so very minute as to tax the utmost powers of chemical analysis for their recognition; and hence the superior dignity which the mere affirmation of identity of ultimate composition acquires in the organic department of the science.

The principal examples of allotropy or isomerism, *i.e.* of the coexistence of identical ultimate composition with difference of properties, will now be considered.

Hydrocarbons.—1. The olefines, a numerous class having the general formula, C^xH^{2x} , form a very remarkable case of polymerism. Methylene, the lowest term, where $x=1$, is wanting, and appears to be an impossible body; for many reactions in which it should be produced yield the higher terms instead. The olefines at present known are:

	Vapour-density.	Boiling-point.
Ethylene	C^2H^4 0.97	. .
Propylene	C^3H^6 1.45	. .
Butylene	C^4H^8 1.94	. .
Amylene	C^5H^{10} 2.42	35°
Hexylene	C^6H^{12} 2.91	69°
Heptylene	C^7H^{14} 3.39	95°
Octylene	C^8H^{16} 3.87	125°
Decatylene (paramylene)	$C^{10}H^{20}$ 4.84	165°
Cetylene	$C^{16}H^{32}$ 7.76	275°.

By the destructive distillation of wax, Brodie obtained cerotene, for which the formula $C^{22}H^{44}$ has been given; but there is in reality no reason whatever why $C^{22}H^{44}$, rather than any other out of a considerable number of formulae, should be assigned to it.

The percentage composition of the olefines is

$$\begin{array}{rcl} \text{Carbon} & = & 85.72 \\ \text{Hydrogen} & = & 14.28 \\ \hline & & 100.00 \end{array}$$

They present a certain general chemical character. All of them combine with chlorine and bromine with great readiness. They differ in vapour-density, those near the beginning of the list increasing regularly in vapour-density by 0.4844. The first two are gaseous at ordinary temperature and pressure; the third is a very volatile liquid boiling at about 0° C.; the others on the list are liquids of which the boiling-point rises as the formula increases; and the very complex olefines which, being uncertain, are not on the list are usually believed to be solids. It will be observed that the increment in boiling point for the addition of CH^2 to the formula is large; between amylene and hexylene, for instance, it is 34°. As the series is ascended, the increment becomes, no doubt, successively smaller and smaller.

The specific gravity of the different olefines in the liquid state seems to increase as the formula increases.

There are certain well ascertained chemical differences between the olefines. Thus the amount of olefine which will saturate a given quantity of chlorine, or of bromine, differs according to the olefine taken, being proportional to the vapour-density. The molecular weights of the different olefines express their saturating capacity: because the vapour-densities are proportional to the molecular weights.

Each olefine may be prepared from a peculiar alcohol, and in general may be made to yield that peculiar alcohol by certain simple processes, *e.g.*:

and again:

If the alcohol and the olefine standing in these relations to it be compared, it will be seen that they resemble one another in the number of carbon-atoms contained in their molecules.

The explanation that chemists give of the difference between the olefines is that their molecules are of different degrees of complexity, and that, in fact, different carbon-radicles are contained in them. Thus in ethylene we have the carbon radicle, C^2 , and accordingly, ethylene is easily obtained from certain compounds containing the radicle C^2 , and easily yields derivatives containing the radicle C^2 . Again in amylene there is the radicle C^5 , and amylene is obtained from compounds of C^5 , which it in turn may be made to regenerate.

The olefines present a very curious example of polymerism, being at one and the same time polymeric and homologous. Recent investigations render it probable that there is also isomerism in its restricted sense (or metamerism) among the olefines. It appears that there is more than one body having the formula, $C^{12}H^{22}$, the hexylene derived from mannite appearing to be allotropic with that got from other sources (p. 166).

It would seem also that there are distinct varieties of amyleno.

(2) Among compounds of the general formula, $C \equiv H^{2n+2}$, there is a wide field for metamerism, but polymerism is obviously an impossibility.

Two classes of compounds are commonly recognised as possessing this general formula. These are the alcohol-radicles and the alcohol-hydrides.

Methyl, the simplest alcohol-radicle is metameric with ethyl-hydride.

And, advancing higher in the series, the possibility of cases of metamerism becomes much greater. Thus putting $n = 6$ in the formula, C_6H_{2n+2} , we have the following metameric compounds, all included by the expressions hydride and alcohol-radicle :

There is, however, no reason for believing that alcohol-radicles and alcohol-hydrides form the only classes of compounds embraced by the formula, C^nH^{2n+2} . Nothing that we know would lead to the rejection of, for instance, the following additional allotropic compounds having the formula, C^nH^n .

Respecting the actual differences between isomers having the general formula C_nH_{n+2} , very little is positively known. A difference in the action of dry chlorine upon methyl and hydride of ethyl, has been observed by Frankland, methyl yielding C_2H_5Cl as a gaseous compound, whereas ethyl-hydride gives $C_2H_5Cl^l$ as a liquid.

Schorlemmer, on the other hand, who has experimented under different conditions, obtains from methyl alcohol which has the composition, vapour-density, and boiling point of chloride of ethyl. He has not, however, obtained common alcohol from it, and whether it be or be not identical with chloride of ethyl remains, for the present, undecided.

The hydride of tetryl, which occurs in petroleum, is a very volatile liquid, boiling at about 0° ; ethyl is a gas which does not condense at -18° , under the ordinary atmospheric pressure.

Hydride of tetryl and ethyl are metameric. $\begin{matrix} \text{C}^{\text{H}^*} \\ \text{H} \end{matrix} \} = \begin{matrix} \text{C}^{\text{H}^*} \\ \text{C}^{\text{H}^*} \end{matrix}$

The hexyl-hydride derived from mannite by the action, first of hydriodic acid, and then of zinc and alcohol, is remarkably insensible to the action of chlorine, even in the presence of iodine and water. The hydride of hexyl occurring in petroleum, on the other hand, seems to be readily attacked by that agent.

The circumstance that those β hexyl compounds from which the hexyl-hydride of mannite is more immediately derived, tend to split up on oxidation, lends some kind of support to the notion that the formula for the mannite-hydride is

but much remains to be done before any very positive opinion can be formed of the nature of the metamerism subsisting between this mannite-hydrate and the commoner hexyl-hydrate.

8. Two compounds with the empirical formula CH , viz. benzene and acetylene, present a curious case of polymerism.

These compounds have a certain likeness, both being products of the action of a very elevated temperature, but in other respects they are very unlike.

Benzene, C^6H^6 , is a liquid, and is related to benzoic acid and phenylamine. Acetylene, C^2H^2 , is a gas possessing the peculiar property of attacking certain metallic solutions, such as ammoniacal solution of cuprous chloride, and is related to common alcohol.

4. A large number of volatile oils differing much in smell, taste, boiling-point, action with reagents, and in other important particulars, have had the formula $\text{C}^{10}\text{H}^{16}$ assigned to them. To this class belong the different kinds of oil of turpentine, oil of lemons, neutral oil of cloves, oil of elemi-resin, carvene, and some others. Respecting these bodies, the remark may be made that we are, for the most part, quite ignorant of their true formula: for, in the almost entire absence of derivatives, the mere analysis of such hydrocarbons by our present methods is totally inadequate to distinguish between a variety of non-isomeric formulæ, all equally probable.

Isomers containing Carbon, Hydrogen, and Oxygen.

Both metamerism and polymerism occur very abundantly among these compounds.

(1.) The ethers of the organic acids afford room for endless metamerism, as will be apparent on a little consideration.

Acetate of methyl, $\left. \begin{smallmatrix} \text{C}^2\text{H}^3\text{O} \\ \text{CH}^3 \end{smallmatrix} \right\} \text{O}$, is metameric with formate of ethyl, $\left. \begin{smallmatrix} \text{CHO} \\ \text{C}^2\text{H}^5 \end{smallmatrix} \right\} \text{O}$, and with propionic acid, $\left. \begin{smallmatrix} \text{C}^3\text{H}^5\text{O} \\ \text{H} \end{smallmatrix} \right\} \text{O}$. It is obvious that if we subtract $n\text{CH}^2$ from the acid-forming radicle and add $n\text{CH}^2$ to the alcohol-forming radicle, or *vice versa*, we must get a metamer. Hence it follows that any ether of an organic acid must have many metamers, if its molecular weight be tolerably high. Here is an example:—

Valerate of amyl	$\left. \begin{smallmatrix} \text{C}^5\text{H}^{10}\text{O} \\ \text{C}^5\text{H}^{11} \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$
Butyrate of hexyl	$\left. \begin{smallmatrix} \text{C}^4\text{H}^8\text{O} \\ \text{C}^6\text{H}^{12} \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$
Propionate of heptyl	$\left. \begin{smallmatrix} \text{C}^3\text{H}^6\text{O} \\ \text{C}^7\text{H}^{14} \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$
Acetate of octyl	$\left. \begin{smallmatrix} \text{C}^2\text{H}^4\text{O} \\ \text{C}^8\text{H}^{16} \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$
Formate of nonyl	$\left. \begin{smallmatrix} \text{CHO} \\ \text{C}^9\text{H}^{18} \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$
Caproate of tetryl	$\left. \begin{smallmatrix} \text{C}^6\text{H}^{12}\text{O} \\ \text{C}^4\text{H}^8 \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$
Ænanthate of trityl	$\left. \begin{smallmatrix} \text{C}^7\text{H}^{14}\text{O} \\ \text{C}^3\text{H}^6 \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$
Caprylate of ethyl	$\left. \begin{smallmatrix} \text{C}^8\text{H}^{16}\text{O} \\ \text{C}^2\text{H}^4 \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$
Pelargonate of methyl	$\left. \begin{smallmatrix} \text{C}^9\text{H}^{18}\text{O} \\ \text{CH}^3 \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$
Rutic acid	$\left. \begin{smallmatrix} \text{C}^{10}\text{H}^{18}\text{O} \\ \text{H} \end{smallmatrix} \right\} \text{O}$	=	$\text{C}^{10}\text{H}^{20}\text{O}^2$

Thus there are no fewer than nine metamers of valerate of amyl. The difference between metamers of this kind is very neatly defined by reactions, saponification with potash yielding a different alcohol and a potassium-salt of a different acid in each case. For example, valerate of amyl gives amyl-alcohol and valerate of potassium, whilst butyrate of hexyl gives hexyl-alcohol and butyrate of potassium.

This kind of metamerism is, of course, not confined to the fatty-acid series: whenever there are homologues of the acids—no matter what the series to which the acid belongs—such metamerism is possible. And of course the same remark applies to the alcohol, the aromatic and the allylic series admitting of just the same kind of metamerism as the vinic series.

(2.) Every alcohol in a series, except the lowest one, is metameric with one or more ethers, thus:—

Methyl-ether	$\left. \begin{array}{c} \text{CH}_3 \\ \text{CH}_3 \end{array} \right\} \text{O}$	=	$\text{C}^2\text{H}^4\text{O}$
or higher up in the scale:—			
Amyl-alcohol	$\left. \begin{array}{c} \text{C}^2\text{H}^5 \\ \text{H} \end{array} \right\} \text{O}$	=	$\text{C}^2\text{H}^6\text{O}$
Teteryl-methyl ether	$\left. \begin{array}{c} \text{C}^2\text{H}^5 \\ \text{CH}_3 \end{array} \right\} \text{O}$	=	$\text{C}^2\text{H}^6\text{O}$
Trityl-ethyl ether	$\left. \begin{array}{c} \text{C}^2\text{H}^5 \\ \text{C}^2\text{H}_5 \end{array} \right\} \text{O}$	=	$\text{C}^2\text{H}^6\text{O}$

The action of iodide of phosphorus upon these different compounds enables us to distinguish them immediately.

(3.) The aldehydes are metameric with ketones, with alcohols of the allylic series, and with ethers of the glycol series, thus:

Propylic aldehyde	$\left. \begin{array}{c} \text{C}^2\text{H}^4\text{O} \\ \text{H} \end{array} \right\}$	=	$\text{C}^2\text{H}^4\text{O}$
Common acetone	$\left. \begin{array}{c} \text{C}^2\text{H}^4\text{O} \\ \text{CH}_3 \end{array} \right\}$	=	$\text{C}^2\text{H}^4\text{O}$
Allylic alcohol	$\left. \begin{array}{c} \text{C}^2\text{H}^4 \\ \text{H} \end{array} \right\} \text{O}$	=	$\text{C}^2\text{H}^4\text{O}$
Oxide of tritylene	$(\text{C}^2\text{H}^4)\text{O}$	=	$\text{C}^2\text{H}^4\text{O}$

These four compounds are very easily distinguished from one another: the first is easily oxidised to propionic acid; the second gives no propionic acid on oxidation, but lower fatty acids instead; the third gives acrolein and acrylic acid; the fourth lactic acid.

(4.) Ketones are metameric with other ketones and with aldehydes and compounds metameric therewith.

The metamerism with other ketones is very easy to understand. The rational formula of all ketones consisting of an acid-forming radicle conjoined with an alcohol-forming radicle, it follows that transference of $n\text{CH}_2$, from one radicle to the other will yield isomeric bodies. Thus, for instance, we have isomers in

Methyl-valeryl	$\left. \begin{array}{c} \text{C}^2\text{H}^4\text{O} \\ \text{CH}_3 \end{array} \right\}$	and Ethyl-butyryl	$\left. \begin{array}{c} \text{C}^2\text{H}^4\text{O} \\ \text{C}^2\text{H}_5 \end{array} \right\}$
--------------------------	--	-----------------------------	---

Our knowledge of the ketones is very slight, but it is to be expected that these two compounds would give different products on being oxidised.

Metameric Alcohols.—It has recently been discovered that there are at least two series of alcohols, the corresponding terms of which are metameric, well-marked differences having been recognised between compounds with the composition of hexylic alcohol, and also between compounds with the composition of amylie alcohol. It is at present uncertain what the nature of this metamerism is (see *HEXYLIC ALCOHOLS*, p. 152), but it seems to affect the total constitution of the two sets of compounds.

A more superficial kind of difference was noticed by Pasteur, some years ago, between varieties of amylie alcohol. Ordinary fusel-oil was found by Pasteur to be made up of two liquids having the composition of amylie alcohol, but slightly different in properties, the one being without action on polarised light, whilst the other turned the plane of a polarised ray to the left. The derivatives of each of these varieties of amylie alcohol possess the same action on polarised light as the alcohols themselves, and present some differences in solubility, &c., but on the whole they are marvellously similar. Chemists are not agreed how these varieties are to be regarded, it being still uncertain whether a mere difference in action upon polarised light points to any but the very slightest difference in constitution.

Metameric Acids.—There is some reason for believing that the fatty acids, when they are in the liquid state, have twice the molecular weight which their vapours have when heated up to 300° and higher. Their great tendency to form double salts, and the fact that their vapours at low temperature—whether under great or small pressure—have a double density, point to this conclusion.

Admitting the double formula for the fatty acids, some very interesting cases of metamerism arise. Thus, propionic acid is metameric with butyr-acetic acid:—

Propionic acid	$\left. \begin{array}{c} \text{C}^2\text{H}^4\text{O} \\ \text{C}^2\text{H}^4\text{O} \\ \text{H}^2 \end{array} \right\} \text{O}^2$	=	$\text{C}^2\text{H}^6\text{O}^4$
Butyr-acetic acid	$\left. \begin{array}{c} \text{C}^2\text{H}^4\text{O} \\ \text{C}^2\text{H}^4\text{O} \\ \text{H}^2 \end{array} \right\} \text{O}^2$	=	$\text{C}^2\text{H}^6\text{O}^4$

and, in like manner, each term of the series, except the end ones, is metameric with a compound acid formed of the next below united with the next above. It is worthy of remark, as a fact in the history of organic chemistry, that butyr-acetic acid was mistaken for, and described as, propionic acid.

The anhydrides of the aromatic and fatty acids offer a systematic metamerism, *e. g.*:

are metameric. In fact there is, among these anhydrides, just a repetition of the case of the ethereal-salts of the organic acids; by making $n\text{CH}^2$ move from the one radicle to the other, endless metamerism arises.

No case of metamerism between two single fatty acids has yet been made out; but in the aromatic series, there are such cases: thus there are two benzoic acids.

A very remarkable example of metamerism is afforded by the different varieties of tartaric acid and racemic acid. There is a tartaric acid which polarises to the right (the commonest), another which polarises to the left; racemic acid, from which both varieties of tartaric acid may be obtained; and, finally, a tartaric acid without any action upon polarised light. All these substances are metameric, having the formula

Polyatomic Alcohols.—Mannite and melampyrin are metameric, both of them having the formula

The most striking difference between these bodies is to be found in their degrees of solubility in water—mannite being comparatively soluble, melampyrin comparatively insoluble. In reactions they are, so far as is known, very similar.

There seem to be many metamers both of grape-sugar and of cane-sugar, but little is known with certainty respecting them.

Examples of polymerism are not by any means so numerous among the compounds of carbon, hydrogen, and oxygen, as we have found the examples of metamerism to be.

There can be no polymers either of the vinic alcohols or vinic ethers.

The fatty acids, and the ethers of the fatty acids, are polymeric with more complex acids, or with compounds of the sugar-class; but even among them, there is nothing approaching to the endless metamerism which has been referred to.

Acetic acid offers one of the best examples of a fatty acid polymeric with several substances:

By doubling the formula of any aldehyde, we get the formula of a fatty acid, thus:

By tripling the formula of an aldehyde, we get the formula of an acid of the lactic series, *e. g.*:

Grape-sugar is polymeric with ethyl-carbonic acid: Grape-sugar = $\text{C}^6\text{H}^{12}\text{O}^6$; 2 mole-

Isomers containing Carbon, Hydrogen, and Nitrogen.

(1.) Metamerism among the compound ammonias.

The following compound ammonias have the formula $\text{C}^x\text{H}^{2x}\text{N}$ —

A very neat reaction distinguishes the different compound ammonias from one another: on treating them with nitrous acid, they give up their different alcohol-radicles in the form of alcohols. For example, the first base on our list, hexylamine, when so treated, would yield hexyl-alcohol; the second, amyl-alcohol and methyl-alcohol; the third, tetryl-alcohol and ethyl-alcohol, &c.

According to the foregoing, triethylamine has six distinct metamers: but if, as is by no means unlikely, each one of the three atoms of hydrogen in ammonia has a different function, then the metamers of triethylamine will become very numerous indeed.

It will be obvious that the higher we go—the higher the molecular weight of a base—the more numerous are the possible metamers. Thus tricetylamine, $\left. \begin{array}{l} \text{C}^{16}\text{H}^{33} \\ \text{C}^{16}\text{H}^{33} \end{array} \right\} \text{N}$, has upwards of 300 metamers, each of which should give a different result with nitrous acid.

In addition to this kind of metamerism, due to the presence of different alcohol-radicles in the bases, there are other kinds of metamerism among the compound ammonias.

There is, for instance, the well-known case of the bases parallel with phenylamine, benzylamine, &c.

The probable explanation of the metamerism in this case is that phenylamine is a derivative of benzene, (C^6H^6), whilst picoline is derived from a hydrocarbon C^6H^{10} .

But, whatever may be the nature of the difference in constitution between these two bases, the difference in properties is very striking:

Phenylamine boils at 185° :

very slight smell:
almost insoluble in water:
specific gravity at $0^\circ = 1.0361$;
gives rosaniline or mauveine, &c. on
treatment with various oxidising
agents.

Picoline boils at 135° :

most pungent and bad smell:
very soluble in water:
specific gravity at $0^\circ = 0.9613$.

and the contrast might be carried much further.

A third series of bases, metameric with the foregoing has been discovered. The best investigated term of this series is β -lutidine, which is obtained by the destructive distillation of cinchonine. It is less soluble in water than common lutidine, boils rather higher, has a different smell, &c.

It is possible for two atoms of nitrogen to coalesce and form a group requiring either two or four hydrogen representatives for its saturation. Three or even four atoms of nitrogen also coalesce. Among the bases so resulting there must be almost infinite metamerism.

(2.) Polymerism among the Compounds of Carbon, Hydrogen, and Nitrogen.

Cyanide of ethyl and cyanethine are polymeric, the formula of the latter being three times that of the former.

Isomers among Inorganic Substances.

As before remarked, the instances of inorganic isomerism are usually called instances of allotropy—*isomeric substances* and *allotropic substances* being nearly equivalent expressions.

The elementary substances themselves offer many examples of isomerism. Thus oxygen appears to be capable of existing in two allotropic states; in one condition it is known as ordinary oxygen, in the other as ozone. Ozone and oxygen are isomeric bodies. Formula for oxygen = O_2 ; formula for ozone = O_3 (?) Experiment has shown that the molecular formula for ozone is higher than that for oxygen; but how much higher remains an open question.

Sulphur, phosphorus, carbon, and many other elements present *some* similar examples of allotropy or isomerism.

Inorganic compounds, such as the various forms of silicic acid, of sesquioxide of iron, of sesquioxide of chromium, of alumina, must be classed among substances affording examples of isomerism.

There seem to be two allotropic states of peroxide of nitrogen. The compound NO_2 is a deeply-coloured gas at 100° . The compound N_2O_4 is a liquid boiling a little below 30° . Its vapour-density is double that of the former body. Altogether, inorganic isomerism is a very wide, but as yet a very ill-explored field.

The explanation of the existence of isomerism will have become sufficiently clear from the course which has been followed in describing the different examples of it. "It is of consequence how the atoms of a compound are arranged as well as what kind of atoms they are," and hence there may be very many totally different substances composed of the same ultimate atoms. This is in fact the whole philosophy of isomerism.

J. A. W.

ISOMORPHISM. (*isos*, equal, and *μorpή*, form.) Crystalline form affords, as is well known, one of the most valuable physical distinctions between different substances, inasmuch as each element, and each compound, crystallises for the most part in forms which are reducible to one or two primary forms. Haüy, who first directed attention to the importance of this character, laid it down as a general law, that every substance has a primary crystalline form peculiar to itself, and therefore that a difference in the primary forms of two crystals may always be taken as evidence of difference of composition. But towards the end of the last, and the beginning of the present century, various observations were made tending to disprove the generality of this law. The similarity of form between phosphate of calcium (apatite) and phosphate of lead (pyromorphite) was noticed by Werner. Leblanc in 1787, showed that a mixed solution of ferrous and cupric sulphates deposits crystals containing both copper and iron, always of the same form, but with considerable variations in the proportions of the two metals; also that alum containing a considerable quantity of ferric oxide crystallises exactly in the same form as pure aluminopotassee sulphate. Vauquelin, in 1797, showed that the same form is exhibited by alum, when it contains a considerable quantity of ammonia in place of potash. Berthier, in 1806, pointed out the great similarity in the form of calc-spar, bitter spar, and spathic iron—a resemblance confirmed by the more exact measurements of Wollaston; and Gay-Lussac, in 1816, showed that a crystal of potash-alum immersed in a solution of ammonia-alum increases in bulk without alteration of form. These and other isolated observations of similar import may be said to have prepared the way for the establishment, by Mitscherlich, of the general law of isomorphism, which affirms that *bodies having a similar chemical constitution have also the same crystalline form, as determined by the measurement of their angles*, or, in other words, that *analogous elements and groups of elements may replace one another in composition without essential alteration of crystalline form*. Mitscherlich's first observations, presented to the Berlin Academy of Sciences in 1819, related to the isomorphism of the phosphates and arsenates, and showed that the corresponding salts of phosphoric and arsenic acids containing equal numbers of atoms of water, crystallise in the same forms. Similar observations were subsequently made upon the sulphates, selenates, manganates, and chromates; the protosalts of magnesium, zinc, cadmium, manganese, iron, nickel, cobalt, and copper, and the sesquisalts of iron, aluminium, chromium, and manganese, the corresponding salts being supposed in all cases to contain equal numbers of atoms of water.

Bodies having apparently an exactly similar constitution are not necessarily isomorphous, but are rather divisible into two or more groups, of which the respective members are isomorphous; on the other hand, the possession of an equal number of atoms is not essential to isomorphism, for two atoms of one element are not unfrequently isomorphous with one atom of another element; and sometimes a molecular group is isomorphous in its combinations with an elementary atom— NH_4^+ with K, for

example. There are also numerous examples of bodies crystallising in the same forms, but without exhibiting any similarity of chemical constitution.

The corresponding angles of isomorphous bodies are not always precisely equal, but may differ from each other by one or two degrees. This discrepancy, however, is rendered unimportant by the circumstance, that the angles of different crystals of one and the same substance can present similar variations, under the influence of certain modifying causes.

It will of course be understood that the similarity of form in isomorphous bodies relates to the primary forms to which they are reducible; two crystals may be really isomorphous, and yet very different in external form, in consequence of being differently modified: thus calc-spar, bitter spar, and spathic iron have the same primary form; but each exhibits numerous modifications, some of which prevail chiefly in one, some in another, of these compounds.

The following table exhibits the most important and best established examples of isomorphism, arranged according to the crystallographic systems. Bodies crystallising in the same forms (*i. e.* reducible to the same primary form) are arranged in groups, numbered consecutively, without regard to the system to which the several forms belong; the subdivisions *a, b, c, &c.*, include those also which correspond in atomic constitution.

TABLE I.

Monometric or Regular System.

Group 1. (Holohedral forms.)

- a.* Diamond,—Phosphorus,—Potassium,—Sodium,—Titanium,—Cadmium,—Lead, —Copper,—Silver,—Gold,—Platinum,—Palladium,—Iridium,—Tin (Frankenheim),—Zinc (Nicklès).
- b.* ZnS ,— MnS ,— PbS ,— PbSe ,— Ag_2S ,— NiS.2FeS (Scheerer),— MgO (periclase, according to Seacchi),— NiO (formed in a metallurgic process),— PbO ,— CuO (tetrahedral),— UO .
- c.* KCl ,— NaCl ,— LiCl ,— NH_4Cl ,— AgCl ,— CuCl ,— KI ,— NaI ,— KBr ,— NaBr ,— KF ,— NaF ,— KCy.NaCy ,— NH_4Cy (Gay-Lussac).
- d.* ZnI_2 ,— CaF_2 ,— KAgCy_2 ,— NiAs_2 (arsenical nickel),— $(\text{Co}; \text{Ni})\text{As}_2$ (cobalt-spoiss).
- e.* CoAs_2 (tesserall pyrites, according to Wöhler and Scheerer).
- f.* Cu_2O ,— Cu_2S (red copper and copper-glance).
- g.* As_2O_3 ,— Sb_2O_3 ,— Co_2S_3 (cobalt-pyrites).
- g.* $\left. \begin{matrix} \text{Mg} \\ \text{Al}^3 \end{matrix} \right\} \text{O}^4$ (spinel),— $\left. \begin{matrix} (\text{Mg}; \text{Fe})'' \\ \text{Al}^3 \end{matrix} \right\} \text{O}^4$ (pleonast),— $\left. \begin{matrix} \text{Mg} \\ \text{Fe}^2 \end{matrix} \right\} \text{O}^4$ (chlorospinel,—
 $\left. \begin{matrix} \text{Zn} \\ \text{Al}^3 \end{matrix} \right\} \text{O}^4$ (gahnite),— $\left. \begin{matrix} \text{Zn} \\ \text{Fe}^2 \end{matrix} \right\} \text{O}^4$ (franklinite),— $\left. \begin{matrix} \text{Fe} \\ \text{Fe}^2 \end{matrix} \right\} \text{O}^4$ (magnetic iron ore),—
 $\left. \begin{matrix} \text{Fe} \\ \text{Cr}^2 \end{matrix} \right\} \text{O}^4$ (chrome iron ore, according to Abich).
- h.* BaN_2O_6 ,— SrN_2O_6 ,— PbN_2O_6 . (Berzelius).
- i.* K_2PtCl_6 ,— K_2IrCl_6 ,— K_2OsCl_6 ,— $(\text{NH}_4)_2\text{PtCl}_6$,— $(\text{NH}_4)_2\text{IrCl}_6$. (Berzelius).
- k.* *Alums*: $(\text{NH}_4)\text{Al}(\text{SO}_4)_3.12\text{H}_2\text{O}$,— $(\text{NH}_4)\text{Cr}(\text{SO}_4)_3.12\text{H}_2\text{O}$,— $(\text{NH}_4)\text{Mn}(\text{SO}_4)_3.12\text{H}_2\text{O}$,— $(\text{NH}_4)\text{Fe}(\text{SO}_4)_3.12\text{H}_2\text{O}$,— $\text{KAl}(\text{SO}_4)_3.12\text{H}_2\text{O}$,— $\text{KCr}(\text{SO}_4)_3.12\text{H}_2\text{O}$,— $\text{KMn}(\text{SO}_4)_3.12\text{H}_2\text{O}$,— $\text{KFe}(\text{SO}_4)_3.12\text{H}_2\text{O}$,— $\text{NaAl}(\text{SO}_4)_3.12\text{H}_2\text{O}$ (Mitscherlich),— $\text{LiAl}(\text{SO}_4)_3.12\text{H}_2\text{O}$ (Kralovansky),— $\text{AgAl}(\text{SO}_4)_3.12\text{H}_2\text{O}$ (Church),— $\text{TlAl}(\text{SO}_4)_3.12\text{H}_2\text{O}$ (Crookes).
- l.* *Garnets*: $\left. \begin{matrix} \text{Si}^4 \\ \text{Ca} \end{matrix} \right\} \text{O}^{10}$,— $\left. \begin{matrix} \text{Si}^4 \\ \text{Mg} \end{matrix} \right\} \text{O}^{10}$,— $\left. \begin{matrix} \text{Si}^4 \\ \text{Fe} \end{matrix} \right\} \text{O}^{10}$,— $\left. \begin{matrix} \text{Si}^4 \\ \text{Mn} \end{matrix} \right\} \text{O}^{10}$,— $\left. \begin{matrix} \text{Si}^4 \\ \text{Ca} \end{matrix} \right\} \text{O}^{10}$,—
 $\left. \begin{matrix} \text{Si}^4 \\ \text{Al}^3 \end{matrix} \right\} \text{O}^{10}$,— $\left. \begin{matrix} \text{Si}^4 \\ \text{Al}^3 \end{matrix} \right\} \text{O}^{10}$,— $\left. \begin{matrix} \text{Si}^4 \\ \text{Al}^3 \end{matrix} \right\} \text{O}^{10}$,— $\left. \begin{matrix} \text{Si}^4 \\ \text{Al}^3 \end{matrix} \right\} \text{O}^{10}$,— $\left. \begin{matrix} \text{Si}^4 \\ \text{Fe}^2 \end{matrix} \right\} \text{O}^{10}$,—

Group 2. (Hemihedral forms.)

- a. $\text{CoAs}^{\text{v}}\text{CoS}^{\text{v}}$ (cobalt-glance), — $\text{NiAs}^{\text{v}}\text{NiS}^{\text{v}}$ (nickel-glance), — $\text{NiSb}^{\text{v}}\text{NiS}^{\text{v}}$ (nickel-antimony-glance).
 b. FeS^{v} (iron-pyrites).

$\text{CuSO}_4.2\text{H}_2\text{O}$,— $\text{CuSeO}_4.2\text{H}_2\text{O}$ (Mitscherlich),— $\text{FeSO}_4.2\text{H}_2\text{O}$. (Graham.)

Group 25.

$\text{MgSO}_4.7\text{H}_2\text{O}$,— $\text{ZnSO}_4.7\text{H}_2\text{O}$,— $\text{CoSO}_4.7\text{H}_2\text{O}$,— $\text{NiSO}_4.7\text{H}_2\text{O}$,— $\text{FeSO}_4.7\text{H}_2\text{O}$,— $\text{MgSeO}_4.7\text{H}_2\text{O}$,— $\text{CoSeO}_4.7\text{H}_2\text{O}$. (Mitscherlich.)

Group 26.

$\text{FeSO}_4.6\text{H}_2\text{O}$,— $\text{CoSO}_4.6\text{H}_2\text{O}$,— $\text{MnSO}_4.6\text{H}_2\text{O}$,— $\text{CoSeO}_4.6\text{H}_2\text{O}$. (Mitscherlich.)

Group 27.

$\text{MgK}^2\text{S}^2\text{O}^6.6\text{H}_2\text{O}$,— $\text{Mg}(\text{NH}_4)^2\text{S}^2\text{O}^6.6\text{H}_2\text{O}$,—and similar double salts containing calcium, nickel, cobalt, iron, manganese, zinc, and copper.

Group 28.

$\text{Na}_2\text{SO}_4.10\text{H}_2\text{O}$,— $\text{Na}_2\text{SeO}_4.10\text{H}_2\text{O}$,— $\text{Na}_2\text{CrO}_4.10\text{H}_2\text{O}$. (Mitscherlich.)

Group 29.

$(\text{NH}_4)^2\text{HPO}_4$,— $(\text{NH}_4)^2\text{HAsO}_4$. (Mitscherlich.)

Group 30.

$\text{Na}_2\text{HPO}_4.12\text{H}_2\text{O}$,— $\text{Na}_2\text{HAsO}_4.12\text{H}_2\text{O}$. (Mitscherlich.)

Group 31.

a. $\text{Na}_2\text{B}^4\text{O}^{10}.10\text{H}_2\text{O}$ (borax).—*b.* $(\text{Ca}; \text{Mg})\text{SiO}^4$ (augite).

Triclinic System.

Group 32.

$\text{MnSO}_4.4\text{H}_2\text{O}$,— $\text{MnSeO}_4.4\text{H}_2\text{O}$,— $\text{ZnSeO}_4.4\text{H}_2\text{O}$,— $\text{CoSeO}_4.4\text{H}_2\text{O}$. (Mitscherlich.)

Group 33.

$\text{CuCO}_3.5\text{H}_2\text{O}$,— $\text{CuSeO}_4.5\text{H}_2\text{O}$,— $\text{MnSeO}_4.5\text{H}_2\text{O}$. (Mitscherlich.)

Bodies occurring more than once in this table are dimorphous or trimorphous.

To each group of isomorphous bodies in the dimetric, trimetric, monoclinic, and triclinic systems, there corresponds a particular pyramid with its prisms and domes, and to each group in the hexagonal system, a particular rhombohedron.

A perfectly exact accordance of the crystalline forms of two chemically different bodies, occurs perhaps only in the monometric system. Bodies of the same group which crystallise in other systems generally exhibit small differences in the corresponding angles. Thus, the angles of the terminal edges of the rhombohedrons of calc spar, diallogite, and the other isomorphous carbonates of group 11, exhibit the following differences:—

		R : R in terminal edges
Calc spar	CaCO ³	105° 6'
Dolomite	$\frac{1}{2}\text{Ca} \left\{ \begin{array}{l} \text{CO}^3 \\ \text{CO}^3 \end{array} \right. \text{Mg}$	106° 15'
Diallogite	MnCO ³	106° 51'
Spathic iron	FeCO ³	107° 0'
Magnesite	MgCO ³	107° 26'
Calamine	ZnCO ³	107° 40'

In arragonite and the carbonates isomorphous therewith (group 17, α), the angles $\infty P : \infty P$ in the macrodiagonal principal section, and $\tilde{P}\infty : \tilde{P}\infty$ in the basal principal section, have the following values:

		$\infty P : \infty P$	$\tilde{P}\infty : \tilde{P}\infty$
Arragonite	CaCO ³	63° 44'	71° 33'
Witherite	BaCO ³	61° 30'	73° 6'
Strontianite	SrCO ³	62° 44'	71° 48'
Cerussite	PbCO ³	62° 46'	71° 47'

Perfect equality in the corresponding angles of crystals is not always found, even in the monometric system. The simpler forms of that system, namely, the cube, octahedron, and rhombic dodecahedron, do not, of course, admit of any variation in the angles; but the remaining forms, which are expressed by formulæ containing finite numerical coefficients, viz. mOm , mO , $mO\infty$, and mOn , have different angles, according to the numerical values of those coefficients; and, consequently, crystals of two different substances crystallising in one of these forms may exhibit slight differences in their angles, as well as isomorphous crystals belonging to other systems. With regard to the three simpler forms of the monometric system, it may be observed that all bodies which crystallise in them may be regarded as isomorphous in a certain sense, inasmuch as all these forms are derivable one from the other; nevertheless, some bodies are more disposed to crystallise in one form than in the other, and a further distinction is afforded by the cleavage; thus, zinc-blende, ZnS, cleaves parallel to the faces of a rhombic dodecahedron; galena, PbS, parallel to the faces of a cube. Such bodies, in spite of their similarity of form and atomic constitution, cannot be regarded as strictly isomorphous, at least in the same degree as NaCl and KCl, which agree in the direction of their cleavage as well as in their form.

From the similarity of form of two compounds, the isomorphism of certain of their constituents may often be inferred. If a compound, $a + b + c$, is isomorphous with another, consisting of $a + b + d$, it may be concluded that c is isomorphous with d . For example, the isomorphism of K^2PtCl^6 and K^2IrCl^6 leads to the conclusion that platinum and iridium are isomorphous. In this manner, the isomorphism of the following groups of elements may be inferred:

1. *Monometric Metals and Metalloids.* Carbon (diamond), phosphorus, potassium, sodium, titanium, cadmium, lead, iron, copper, silver, gold, platinum, palladium, iridium, tin, zinc (TABLE I, group 1, α),—manganese, calcium, lithium, ammonium, nickel, cobalt (1, b , and 1, c),—osmium (1, ϵ).

2. *Hexagonal Metals.* Arsenic, antimony, tellurium, osmium, iridium, palladium, bismuth.

3. Sulphur, selenium (1, b),—chlorine, iodine, bromine, fluorine, cyanogen, arsenic (?) (1, c),—oxygen (1, e).

In like manner, the isomorphism of certain groups of elements may be inferred from that of compounds in which they may be supposed to exist; thus, from the isomorphism of the corresponding phosphates and arsenates, regarded as compounds of metallic oxides, with P_2O_5 and As_2O_5 , e. g. $2Na_2O.H_2O.P_2O_5 + 24H_2O$ and $2Na_2O.H_2O.As_2O_5 + 24H_2O$, the isomorphism of phosphoric and arsenic anhydrides may be inferred.

The isomorphism of different elements and groups of elements is, however, most completely shown by their capability of replacing one another in composition in various

proportions, and without any alteration of crystalline form. Thus, in the alums, whose general formula is $M'R''(SO_4)_2 \cdot 12H_2O$ the monatomic radicle, M , may be composed of potassium, sodium, ammonium, &c., and the triatomic radicle, R , of aluminium, ferricum, manganicum, chromicum, &c., in the most various proportions, the form, all the while, remaining the same as that of common potash-alum, $KAl(SO_4)_2 \cdot 12H_2O$. Numberless examples of this isomorphous replacement are found among natural minerals; indeed, it is but rarely that any mineral is found in which the principal constituents are not more or less replaced by isomorphous substances. Striking examples of it are afforded by the spinels (p. 397, and group 1, *g*, Table I, p. 424), and by the garnets (1, *l*, p. 424).*

Relations between Crystalline Form and Atomic Volume.—Complete isomorphism between two compounds implies the fulfilment of three conditions, viz.:

1. Similar atomic constitution.
2. Similar crystalline form.
3. Equal atomic volumes of the several constituent elements.

By the volume of an atom, we understand, as explained in the article *ATOMIC VOLUME* (i. 440), the space occupied by the solid atom itself, together with a portion of the space which separates it from the intervening atoms: that is to say, the size, or rather the radius, of the atom (regarded as spherical) is supposed to include half the distance which separates it from the contiguous atoms. The atomic volume of a substance, according to this definition, is proportional to its atomic weight divided by its specific gravity $\frac{a}{s}$. It is clear that equal numbers of atoms similarly disposed will

not necessarily produce the same external form, unless the corresponding atoms in the two bodies are equal or at least proportional in volume.

Two or more bodies in which all three of the above conditions of equality are fulfilled, are isomorphous in the stricter sense. The fulfilment or non-fulfilment of all or some of these conditions gives rise to eight different cases of similarity or dissimilarity of constitution, which may be enumerated as follows:

Crystalline form.	Atomic constitution.	Atomic volume.		
a. equal	equal	equal	Isomorphous in the narrower sense	Isomorphous in the wider sense
b. equal	equal	unequal	Isotomous	
c. equal	unequal	equal	Homœomorphous	
d. equal	unequal	unequal		Anisomorphous in the wider sense
e. unequal	equal	equal	Heteromorphous	
f. unequal	equal	unequal		
g. unequal	unequal	equal	Anisomorphous in the narrower sense;	
h. unequal	unequal	unequal	Anisotomous	

The following table exhibits the atomic volumes of a number of bodies arranged according to similarity of crystalline form and atomic constitution. The first column of figures headed $\frac{a}{s}$, gives the quotient of the atomic weight divided by the specific gravity (the atomic weights being those of the oxygen scale, $O = 200$); the second gives the atomic volumes referred to that of carbon 44, as unity; the third, headed "theoretical," shows what the value of $\frac{a}{s}$ would be in each case if it were an exact multiple of 44.

* Compounds containing indefinite proportions of isomorphous elements are represented in this work by formulæ in which the isomorphous elements are separated by semicolons: e.g. alum, in which the potassium is partly replaced by ammonium, is expressed by the formula, $(K; NH_4) Al(SO_4)_2 \cdot 12H_2O$. In many works such compounds are represented by formulæ like $\frac{K}{NH_4} Al(SO_4)_2 \cdot 12H_2O$; but this is objectionable, since, according to ordinary usage, it would imply that the molecule contains an atom of potassium as well as an atom of ammonium, whereas the real meaning is that the potassium and ammonium are present in such quantities as together to make up a monatomic atom or molecule.

TABLE II.
Atomic Volumes of Isomorphous Bodies.

I. Elements.				Atomic volume.		
				$\frac{a}{z}$	44 = 1.	Theoretical.
a. Monometric.						
1	Carbon (Diamond)	C	44	1	44	
	Iron	Fe	90	2	88	
	Manganese	Mn	88	2	88	
2	Nickel	Ni	88	2	88

55	Marcasite FeS_2	306	7	308
56	Arsenical pyrites $Fe^4As^2S_2$	692	16	704
57	Trimetric (native) sulphur	195	4½	198
58	Monoclinic (fused) sulphur	201·8	4½	198

A comparison of the numbers in this table leads to the following general conclusions.

1. Only those bodies which are bracketed together in the table can be regarded as strictly isomorphous, or isotomous; and even among these, there are some whose isotomy is doubtful, *e.g.* nitrate of strontium and nitrate of lead (44); magnesio-ammonic sulphate and cuprico-ammonic sulphate (49).

2. Many substances commonly regarded as isomorphous are in reality only homœomorphous, inasmuch as their atomic volumes differ considerably. Such is the case with phosphorus and arsenic; magnesia and manganous oxide; soda and silver-oxide; lead-oxide, baryta, and strontia; manganese-blende and zinc-blende; nitrate of potassium and nitrate of sodium. The atomic volumes of these homœomorphous bodies are, however, related to one another by simple proportions, as in the following examples:—

{ Sodium 1	{ Arsenic 3
{ Potassium 2	{ Phosphorus 4
{ Arsenic 2	{ Soda (anhydrous) 3
{ Antimony 3	{ Silver-oxide 4

3. Bodies which are isomorphous in the free state, are not always so in combination. Copper is isomorphous with iron, manganese, nickel, &c.; but many copper-salts are not isomorphous with the corresponding salts of the other metals just mentioned. Zinc, titanium, and platinum are isomorphous in the free state, but by no means in their salts. On the other hand, many bodies are isomorphous in their compounds, but homœomorphous, or even heteromorphous, in the free state: thus phosphorus and arsenic are heteromorphous in the free state, but isomorphous in their compounds; and manganese and zinc, arsenic and antimony, magnesia and manganous oxide, potassium and sodium, soda and silver-oxide, are homœomorphous in the separate state,

but isomorphous in some of their compounds. This apparently paradoxical relation may arise either from dimorphism—the substances in question crystallising in the free state in a form different from that which they assume in combination—or from variation of atomic volume. In fact, the atomic volume of a compound is, in nearly all cases, less than the sum of the atomic volumes of its elements in the free state, the condensation being greater as the affinity is stronger. Hence it may happen that elements whose atomic volumes in the free state are unequal, may assume equal volumes in combination, and therefore yield isomorphous compounds.

4. Bodies of different atomic volume often crystallise in the same form, and are capable of crystallising together. Gold and silver, whose atomic volumes are nearly as 1 : 2, crystallise together in very variable proportions; so likewise do chloride of sodium, chloride of ammonium, and iodide of potassium, whose atomic volumes are to one another as 3 : 4 : 6. It is only, however, in the monometric system that perfect similarity of crystalline form is exhibited by substances of different atomic volume; in crystals belonging to other systems, difference of atomic volume in bodies of similar atomic constitution, is always accompanied by a slight difference in the magnitude of certain angles, as may be seen by comparing the angles and atomic volumes of the several members of the calc spar and arragonite groups (pp. 427, 430), the obtuse terminal angles in the former, and the angles $P\infty : P\infty$ in the latter diminishing as the atomic volume increases. This relation between atomic volume and crystalline form is further shown by the observation of Mitscherlich, that the angle of a rhombohedron of calc spar diminishes when the crystal is heated: for the specific gravity is thereby diminished, and consequently the atomic volume increased.

5. An interesting example of homœomorphism is afforded by nitrate of potassium, which is dimorphous, having a rhombohedral form similar to that of calc spar, and a trimetric form like that of arragonite. Its angles in these two forms are as follows:

	Atomic volume.	Terminal angle of rhomb. (nearly).
Hexagonal Nitro KNO^3	27	$106^\circ 30'$
Trimetric Nitro KNO^3	27	$\infty P \quad P\infty$ $61^\circ 0' \quad 70^\circ 4'$

In its rhombohedral form, this substance agrees very nearly with dolomite and diallogite, the terminal angles of which are $106^\circ 16'$ and $106^\circ 51'$ respectively, and whose atomic volumes are equal to 9: hence it appears that two substances whose atomic volumes are as 1 : 3 may crystallise nearly in the same form. Similar relations, though not quite so close, may be traced between the atomic volumes and crystalline forms of rhombic nitro and arragonite.

The relations between the atomic volumes and crystalline forms of different substances are, however, far from being established on a perfectly satisfactory basis; indeed the general conclusions of different observers relating to this subject are in some instances directly contradictory to each other: the discrepancies doubtless arise in many instances from the want of exact determinations of crystalline form, and more especially of specific gravity.

Schröder, to whose observations, together with those of Kopp, the results detailed in the preceding pages are mainly due, has recently made further experiments on the relations between chemical constitution and specific gravity, and has arrived at the following conclusions respecting the atomic volumes of isomorphous bodies. When two different elements or groups of elements, *A* and *B*, unite with other elements or groups of elements, *C*, *D*, *E*, &c., forming the compounds *AC* and *BC*, *AD* and *BD*, *AE* and *BE*, &c., belonging to the same type and isomorphous by pairs, the differences of the atomic volumes of *AC* and *BC*, *AD* and *BD*, *AE* and *BE*, &c., are always equal; but if the pairs of compounds thus formed are not isomorphous, or if they are isomorphous, but belong to different types, then the differences of atomic volume are unequal, and different from what they would be if the pairs were isomorphous or belonged to the same type. If bodies of equal atomic volume be denominated isosteric, and analogous pairs of compounds exhibiting equal differences of atomic volume, parallellosteric, the preceding law may be more shortly stated as follows:—*Pairs of compounds which are isomorphous and analogous are likewise parallellosteric.* This law has been confirmed by Tschermak. (Wien. Akad. Ber. xlv. [2] 603.)

Schröder further concludes that the volume of any element, which, in the isomorphous nitrates, chlorides, bromides, iodides or sulphides, is the greater of the two constituting a pair, is condensed in the isomorphous sulphates, carbonates, silicates, and aluminates, to a comparatively greater amount, so as often to become the lesser of the two. Thus the atomic volumes of chloride, bromide, and nitrate of potassium (calculated on the hydrogen-scale) of atomic weights, are greater by 2.7 to 2.5 than those of the corresponding ammonium salts, whereas that of sulphate of ammonium is greater by 2.5 than that of sulphate of potassium.

With regard to the elements, Schröder finds that isosterism is accompanied quite as frequently, if not more so, by heteromorphism as by isomorphism; but that elements whose atomic volumes are to one another as 1:2 (like silver and gold) are often isomorphous. In oxides and salts also, Schröder finds that isosterism is associated with isomorphism less frequently than with heteromorphism.

The relations between the atomic volumes and the proportions of the axes (which determine the angles) in series of homœomorphous bodies, are also, according to Schröder's recent observations, less constant than was formerly supposed. It is true that the limiting members of each series with regard to the proportions between the axes, are also the limiting members with regard to the atomic volumes; but the intermediate terms do not generally exhibit the regular relation between axial proportions and the atomic volumes which has been noticed in the calcspar and arragonite groups. According to Tschermak, on the contrary (Wien. Akad. Ber. xiv. [2], 603; Jahresber. 1862, p. 9), homœomorphous bodies of analogous composition form the same series with regard to their axial relations, as with respect to their atomic volumes. (Compare i. 449-452.)

Polymeric Isomorphism. This term is applied by Scheerer to express the fact that 1 at. of an element may in some cases be replaced by two or more atoms of another, or, generally, m atoms of one element by n atoms of another, or by a group of atoms of other elements, without essential alteration of crystalline form. Instances of this kind of isomorphism are afforded by the sulphides of lead and silver (PbS and Ag_2S), by the sulphide and chloride of silver (Ag_2S and Ag_2Cl_2), by numerous isomorphous chlorides and cyanides, in which the single atom Cl and the group CN discharge equivalent functions; and by the isomorphous salts of potassium and ammonium, in which NH_4^+ is equivalent to K. Numerous other examples may be found amongst organic compounds: thus the acetate and butyrate of copper, $\text{C}_2\text{H}_3\text{O}_2\text{Cu}$, and $\text{C}_4\text{H}_7\text{O}_2\text{Cu}$, are isomorphous, and the sulphates of many organic bases, e.g. ethylamine, methylamine, conine, unite with sulphate of aluminium, forming alums isomorphous with common potash-alum.

Natural minerals likewise afford examples of this kind of isomorphism, to which attention has been particularly directed by Scheerer. Thus, certain varieties of augite and hornblende contain alumina, while others, which are free from alumina, contain a larger proportion of silica, the substitution taking place, according to Scheerer, in the proportion 1 at. Al_2O_3 to 1 at. SiO_2 (or $3\text{Al}_2\text{O}_3$ to 2SiO_2), but, according to Rammelsberg, in the ratio of $2\text{Al}_2\text{O}_3$ to 3SiO_2 (p. 169). Another instance is afforded by the minerals cordierite (dichroïte), and aspasolite, which are isomorphous and agree in composition, excepting that, according to Scheerer, 1 at. magnesia in the former is replaced by 3 at. water in the latter. According to the formulæ given by Rammelsberg, however (*Mineralchemie*, pp. 768, 834), viz.,

Cordierite, $6\text{MgO} \cdot 6(\text{Al}) \cdot \text{Fe}^2\text{O}^3 \cdot 15\text{SiO}_2$.

Aspasolite, $4\text{MgO} \cdot 6(\text{Al}) \cdot \text{Fe}^2\text{O}^3 \cdot 15\text{SiO}_2 \cdot 8\text{H}_2\text{O}$,

it appears that 4 at. water in the latter take the place of 1 at. magnesia in the former.

For a full development of the theory of polymeric isomorphism as applied to minerals, see Scheerer (*Handw. d. Chem.* iv. 170).—On isomorphism in general, see Mitscherlich (*Ann. Ch. Phys.* [2], xiv. 172; xix. 350; xxiv. 264 and 355).—Breithaupt, *J. pr. Chem.* iv. 249).—Persoz, *Ann. Ch. Phys.* [2], lx. 119).—Brooke (Phil. Mag. [3], xii. 406).—Johnston (*ibid.* xii. 325 and 480; xiii. 405).—Schaffgotsch (Pogg. Ann. xlviii. 335).—H. Kopp (*ibid.* liii. 446).—Hankel (*ibid.* lv. 479).—Frankenheim (*J. pr. Chem.* xxvi. 257 and 263).—Wallmark (*ibid.* xxxi. 169).—Nicklès (Compt. rend. xxvii. 611).—Pasteur (*ibid.* xxviii. 477).—G. Rose (Pogg. Ann. lxxvi. 75; lxxvii. 143).

ISONITROPHENIC ACID. See PHENIC ACID.

ISOPHANE. Syn. with FRANKLINITE (ii. 707).

ISOPRENE. C_5H_8 .—A very volatile hydrocarbon, polymeric with caoutchouc (i. 757), obtained, together with the latter and other less volatile products, by the dry distillation of caoutchouc and gutta percha. After repeated rectification over sodium, it boils between 37° and 38° , has a specific gravity of 0.6823 at 20° , and vapour-density = 2.40 obs.; 2.36 calc. After keeping for a month, it became thickened, and acquired a bleaching action, in consequence of the absorption of ozone: on subsequently distilling it, the ozone acted violently on the hydrocarbon, and the residue suddenly solidified to a white amorphous mass having the composition $\text{C}_5\text{H}_8\text{O}$. (Gr. Williams, Proc. Roy. Soc., x. 516.)

ISOPURPURIC ACID. *Picrocyamic acid*. $\text{C}_5\text{H}_4\text{N}_2\text{O}_4$. (Hlasiwetz, Ann. Ch. Pharm. cx. 289; Jahresber. 1860, p. 465. Beyer, Bull. Acad. roy. Belgique, [2] vii. No. 8.)—An acid, isomeric with purpuric acid, but, like the latter, not known in the free Vol. III. F F

state. The potassium-salt is obtained by the action of cyanide of potassium on picric acid:

When a solution of 2 pts. cyanide of potassium (prepared by Liebig's process, ii, 215), in 4 pts. water, warmed to about 60° , is mixed with a solution of 1 pt. picric acid in 9 pts. water, the mixture being constantly stirred, a strong odour of ammonia and hydrocyanic acid is given off, and the liquid solidifies on cooling to a soft crystalline pulp; and on straining this mass upon linen, pressing it between bibulous paper, heating and triturating the red-brown crystalline residue with a small quantity of water, then throwing it on a filter, washing it with cold water, again pressing, dissolving it in a large quantity of boiling water, and leaving the hot-filtered solution to crystallise, *isopurpurate of potassium* separates, as a metal-green film, and in brown-red crystalline scales, exhibiting a green colour by reflected light. It dissolves sparingly in cold, more easily in boiling water, imparting a very deep purple colour, and is precipitated from a concentrated solution by carbonate of potassium,—which circumstance may be taken advantage of in the preparation of the salt, if, in consequence of the presence of impurities, it does not separate spontaneously as above described. The salt dissolves also in dilute *alcohol*. When heated to about 215° , it decomposes, with somewhat strong detonation, slight appearance of fire, and formation of a grey cloud: it may also be exploded by contact with sulphuric acid. Its solution is precipitated by salts of barium, lead, mercury, and silver; not by those of calcium, strontium, copper, or zinc. The solution does not give the ordinary reactions of cyanogen.—The salt dried at 100° contains $\text{C}^6\text{H}^3\text{KN}^3\text{O}^6$.

The *ammonium-salt*, $\text{C}^6\text{H}^3(\text{NH}^4)\text{N}^3\text{O}^6$ (at 100°), separates in metallic-shining, dark-green crystals, on adding a solution of chloride of ammonium to a very concentrated solution of the potassium-salt. It is easily recrystallised, and then forms small wedge-shaped crystals, brown-red by transmitted and green by reflected light. It is very slightly soluble in cold water, more easily in boiling water, forming a deep-purple solution. When heated on platinum-foil, it deflagrates like gunpowder.

The *barium-salt*, $\text{C}^6\text{H}^3\text{Ba}^2\text{N}^3\text{O}^{12}$ (at 100°), separates on adding chloride of barium to a solution of the potassium-salt, as a nearly cinnabar-coloured precipitate, sparingly soluble in cold water, perfectly soluble, with purple colour, in hot water. In the dry state it has a light-green metallic lustre, but when triturated becomes red again, and deflagrates with a dazzling green light.

On mixing the hot concentrated solutions of cyanide of barium and picric acid, the liquid acquires a blood-red colour, and deposits a dark-coloured precipitate which is resolved by hot water into a red-brown powder with green lustre, soluble in water, and a substance containing a large quantity of carbonate of barium, insoluble therein.

The *calcium-salt*, $\text{C}^6\text{H}^3\text{Ca}^2\text{N}^3\text{O}^{12}\cdot 3\text{H}^2\text{O}$, separates, after 24 hours, from a mixture of a hot-saturated solution of the ammonium-salt with chloride of calcium, in green metallic-shining needles, which give off their water at 140° .

Lead-salt, $\text{C}^6\text{H}^3\text{Pb}^2\text{N}^3\text{O}^{12}$.—The solution of the potassium-salt is completely precipitated by neutral acetate of lead; the precipitate, which is at first brown red and very bulky, soon becomes dark violet-brown and pulverulent; it dissolves with purple colour in boiling water, and the solution deposits slender microscopic needles, which, after drying, are light brown-red with greenish iridescence, and detonate very sharply when heated. It is not completely decomposed by sulphydric acid, and on boiling the remaining mass with water, a yellowish-red solution is obtained, which deposits shining brown crystalline tufts having the composition of the original salt.

The *potassium-salt*, $\text{C}^6\text{H}^3\text{KN}^3\text{O}^6$ ($\text{C}^6\text{H}^3\text{KN}^3\text{O}^6$, according to *Bäyer*), has been already described.

The *silver-salt*, $\text{C}^6\text{H}^3\text{AgN}^3\text{O}^6$ (at 100°), separates from a solution of the potassium-salt, on addition of nitrate of silver, as a brown precipitate, which dries up to a dark-green mass possessing metallic lustre. It detonates when heated, and dissolves with purple colour in a large quantity of boiling water.

The *sodium-salt*, $\text{C}^6\text{H}^3\text{NaN}^3\text{O}^6$, is obtained, like the potassium-salt, by the action of cyanide of sodium on picric acid. It is dark-green with metallic lustre, dissolves in water much more easily than the potassium-salt, and is more difficult to crystallise: the solution is red.

The *strontium-salt* is obtained by adding nitrate of strontium to a solution of the potassium-salt, as a green, pulverulent, indistinctly crystalline precipitate, which deflagrates with a red flame when heated.

Hlasiwetz regards isopurpuric acid as dibasic, and the monometallic salts above described as acid salts. The neutral salts have not been obtained in definite form; but the solution of the monopotassic salt, mixed with caustic potash, acquires a dark-violet colour, and yields a precipitate which soon decomposes and turns brown. A similar change of colour, followed by rapid decomposition, is produced on triturating

the barium-salt with baryta-water. All the salts are very much like the corresponding purpurates; the ammonium-salt, according to Grailich's determinations, exactly resembles purpurate of ammonium (*murexid*), in its crystalline form and optical properties.

ISOPYRE (from *isos*, equal, and *πῦρ*, fire, because its appearance when fused is the same as in the natural state). A silicate of calcium, aluminium, and iron, found at St. Just, near Penzance, in Cornwall, in a quartzose granite, with tourmalin and tin ore; also in breccia, on the Calton Hill, Edinburgh. It bears considerable resemblance to obsidian, having a conchoidal fracture, no cleavage, a greyish-black to velvet-black colour, and vitreous lustre. Specific gravity, 2.912; hardness 6 to 6.5, nearly equal to that of orthoclase. Melts before the blowpipe to a black magnetic globule. Contains, according to Turner's analysis (Ed. N. Phil. J. iii. 263), 47.69 silica, 13.91 per cent. alumina, 15.43 lime, 20.07 ferric oxide, and 1.94 cupric oxide (loss 1.56 per cent.), agreeing nearly with the formula $\text{Ca}^2\text{O} \cdot \text{Al}^2\text{O}_3 \cdot 3\text{SiO}_2$, which is essentially the same as that of labradorite; but part of the iron in the mineral appears to be in the state of protoxide, and as long as this amount remains undetermined, the formula cannot be fixed with certainty.

ISOTARTARIC ACID and **ISOTARTRIDIC ACIDS**. See TARTARIC ACID, DERIVATIVES OF.

ISOTRIBROMHYDRIN. Syn. with tribromide of allyl (i. 141).

ISOTEREBENTHENE. See TURPENTINE.

ITACOLUMITE. A laminated granular quartz-rock, in which diamonds are generally found; it probably owes its lamination to tale or mica. It occurs in the mines of Brazil and the Ural; also in Georgia and North Carolina, where a few diamonds have been found. (Dana, ii. 24.)

ITACONIC ACID. $\text{C}^6\text{H}^4\text{O}^4$.—An acid obtained, together with citraconic acid (i. 992), by the dry distillation of citric acid. It bears a close resemblance to citraconic acid, but differs from it in solubility and in its reactions with nitric acid and with bromine. It is prepared by heating citric acid in a retort by a spirit-lamp, care being taken that the heat is applied at the bottom, and not on the sides, as in the latter case a portion would be converted into citraconic acid. The distillation is continued until empyreumatic vapours appear. The oily distillate is then dissolved in six parts of boiling water, and evaporated to crystallisation: the crystals which are first formed consist of itaconic acid; citraconic acid, which is always formed at the same time, remains dissolved in the mother liquor. Frequently the distillate solidifies on cooling. In this case the crystals are pressed between bibulous paper on a plate at 100° , and then between paper moistened with absolute alcohol, and lastly recrystallised from water.

Itaconic acid is inodorous, and has a strongly acid taste; when crystallised from water, it has the form of a rhombic octahedron. It dissolves in 17 pts. of water at 20° , and is much more soluble at a higher temperature. It is soluble in alcohol and in ether. It melts at 161° to a colourless liquid which crystallises on cooling; when further heated, it decomposes into citraconic anhydride and water. Unlike citraconic acid, it does not yield mesaconic acid when treated with nitric acid. When treated with bromine and water, it takes up 2 at. bromine without evolution of hydrobromic acid, and forms an acid having the composition of dibromo-pyrotartaric acid, $\text{C}^6\text{H}^2\text{Br}^2\text{O}^4$, (Kekulé, Ann. Ch. Pharm. Supp. i. 338; ii. 111; Cahours, Ann. Ch. Phys. [3], lxxvii. 129), and called *itadibromosuccinic acid* by Kekulé, *dibromitaconic acid* by Cahours (see PYROTARTARIC ACID, DERIVATIVES OF). Citraconic acid yields the same or an isomeric acid (Cahours). Itaconic acid treated with sodium-amalgam takes up 2 at. hydrogen and forms pyrotartaric acid, $\text{C}^6\text{H}^6\text{O}^4$ (Kekulé).

Itaconates. Itaconic acid is dibasic, forming acid salts, $\text{C}^6\text{H}^3\text{MO}^4$, and neutral salts, $\text{C}^6\text{H}^2\text{MO}^4$. The neutral itaconates of the alkali-metals do not crystallise. The acid potassium-salt is very soluble in water, and crystallises in lustrous laminae. It is obtained by neutralising the acid with potash, adding a quantity of acid equal to that already taken, and evaporating to crystallisation. The alkaline salts are soluble, and give white precipitates with the soluble salts of lead, mercury, and silver.

Amides of Itaconic acid. The amides of itaconic acid are not known, excepting perhaps *itaconamic acid*, which appears to be formed by heating itaconate of ammonium to 190° , whereby a brownish acid mass is obtained which forms a very soluble salt with ammonium. But some of the corresponding phenylamine-compounds have been investigated by Gottlieb (Ann. Ch. Pharm. lxxvii. 215), to whose researches the reader is referred for further details.

Phenylitaconamide, $\text{C}^7\text{H}^7\text{N}^2\text{O}^2$, is derived from neutral citraconate of phenylamine by the loss of two atoms of water:

It is obtained by heating itaconic acid with excess of phenylamine in a retort at a temperature a little above 180° . It crystallises in large thin plates with a pearly lustre.

Phenylitaconamic acid, $C^{11}H^{11}NO^2$, is derived from the acid itaconate of phenylamine by loss of water:

It is obtained by evaporating phenylamine to dryness with an excess of itaconic acid, and heating the residue a little above 100° . It forms large colourless needles, more soluble in alcohol than in water. Heated to 160° it is decomposed.

Itaconic Ether. $C^6H^4O^4 = C^6H^4(C^2H^3)^2O^4$. Itaconic acid is mixed with alcohol and hydrochloric acid, and the mixture distilled until about a third of the alcohol has passed over: water is then added to the residue, which separates the ether. It is a colourless, inodorous oil with a slight aromatic odour and bitter taste. It boils at 225° , but begins to decompose at this point. E. A.

ITTNERITE. A silicate occurring in monometric crystals, with dodecahedral cleavage, also granularly massive, in the dolerite of the Kaiserstuhl, near Freiberg; in basaltic dolerite at Sasbach; in phonolitic dolerite, with pyrites, titanite iron, and apatite, at Endingen. Hardness = 5.5. Specific gravity = 2.37 to 2.40. Colour dark-bluish or ash grey, or smoky grey. Lustre resinous. Translucent. Fracture imperfectly conchoidal. When heated in a tube, it gives off a large quantity of water, and before the blowpipe melts easily, with strong intumescence and evolution of sulphurous anhydride, forming a blebby opaque glass. Forms a clear glass with borax. Gelatinises easily with acids.

The composition of the mineral is shown by the following analyses: *a.* by C. Gmelin (Schw. J. xxxvi. 74), *b.* by Whitney (Pogg. Ann. lxx. 442).

	SiO ²	SO ³	Cl	Al ² O ³	Fe ² O ³	CaO	Na ² O	K ² O	Water and loss.*	
<i>a.</i>	34.02	2.86	0.73	28.40	0.61	7.26	12.15	1.56	10.76	= 98.35
<i>b.</i>	35.69	4.62	1.25	29.14	.	5.64	12.57	1.20	9.83	= 99.94

* Including sulphur undetermined.

According to the latter analysis, ittnerite may be regarded as a mixture of hydrated sodalite and haüyne (p. 15). (Dana, ii. 319; Rammelsberg, *Mineralchemie*, p. 712.)

IWAARITE. A black mineral from Iwaara in Finland, which crystallises in monometric forms, melts before the blowpipe to a black glass, and, according to Thoreld, consists of silica, titanite acid, lime, and ferric oxide: perhaps identical with schorlamite. (Rammelsberg, *Mineralchemie*, p. 887.)

IXIOLITE. A variety of tantalite from Kimito in Finland, containing considerable quantities of manganese and tin.

IXOLITE. A fossil resin found in a bed of bituminous coal at Oberhart, near Glogynitz. It is amorphous, with a fatty lustre and hyacinth-red colour, becoming yellowish when pulverised. It is subtranslucent in thin fragments. Fracture imperfectly conchoidal in the purer varieties. Specific gravity = 1.008. Hardness = 1. Softens at 76° , but is still tenacious at 100° . (Haidinger, Pogg. Ann. lvi. 345.)

J

JADE. See NEPHRITE and SAUSSURITE.

JALAP. This name is applied to the roots and tubers of certain plants of the convolvulaceous order, which yield purgative resins. The true or officinal jalap consists of the tubers of *Convolvulus Schiedanus* (or *Exogonia purga*, according to Pereira), which contains a strongly purgative resin called convolvulin. $C^{11}H^{14}O^{12}$ (i. 15), Kayser's *rhodocretin*.

Spurious, woody or fusiform jalap, jalap-wood, or jalap-stalks (*Stipites Jalapæ*), the root of *Convolvulus orizabensis*, is sometimes mixed with genuine jalap. Its characteristic principle is jalapin, $C^{11}H^{14}O^{12}$ (Kayser's *pararhodocretin*, p. 438), a resin homologous with convolvulin, and identical, or nearly so, with scammonin, the active principle of *Convolvulus Scammonia* (p. 438). The experiments of W. Mayer (Ann. Ch. Pharm. xcv. 161) seem to show that both convolvulin and jalapin exist in both kinds of jalap.

JALAPIC ACID. $C^8H^{10}O^{12}$? *Scammonic* or *Scammonic acid*. (W. Mayer, Ann. Ch. Pharm. xcii. 115; xcv. 129. Spargatis, *ibid.* cxvi. 289.)—An acid produced, with assimilation of water by dissolving jalapin in aqueous solutions of the alkalis or

alkaline earths. Jalapin is heated with baryta-water to the boiling point, until the whole is dissolved, and acids no longer form a precipitate in the solution; the baryta is then removed by sulphuric acid; the excess of this acid by hydrate of lead; and the dissolved lead, by sulphuric acid. The filtrate boiled to remove the sulphuric acid, and evaporated, deposits jalapic acid, which, in case it has become coloured, may be decolourised by treatment with animal charcoal, or by boiling it with a little hydrate of lead, and subsequently passing sulphuric acid through the liquid.

Jalapic acid is a translucent, amorphous, shining, yellowish, brittle mass, which does not soften below 100° , and at about 120° melts to a turbid, very hygroscopic syrup. It has no smell, but an irritating sweetish taste (Mayer), or a sourish irritating taste, with bitter after-taste (Spirgatis). It has a strong acid reaction; dissolves very easily in water, easily also in alcohol, less easily in ether. It contains, according to the mean of Mayer's analyses, 54.4 per cent. carbon and 8.3 hydrogen; according to Spirgatis, 54.6 carbon and 8.2 hydrogen: hence Mayer deduces the formula $C^{54.4}H^{8.3}O^{18}$, requiring 54.6 carbon and 7.9 hydrogen; the formula above given, which requires 54.0 carbon and 8.0 hydrogen, is perhaps more probable.

Jalapic acid decomposes at about 130° ; when heated on platinum foil, it burns with a bright sooty flame. When a concentrated aqueous solution is stirred for a long time with fuming hydrochloric acid, it splits up into jalapinol and glucose (Mayer):

The jalapic acid obtained from scammony forms jalapinolic acid, instead of jalapinol (Spirgatis; see p. 440). The same decomposition appears to be caused by emulsin (Mayer). Mayer obtained alphajalapic acid by boiling jalapic acid with dilute acids. By nitric acid jalapic acid is converted into ipomæic and oxalic acids. When melted with hydrate of sodium, it gives off hydrogen, and forms jalapinolic and oxalic acids.

Jalapates. Jalapic acid unites with bases, forming salts in which 1, 2, and 3 at. hydrogen are replaced by the same number of atoms of metal: mixtures of these different salts are, however, very apt to form. It displaces carbonic acid from the carbonates of the alkalis and alkaline earths. Even when neutralised with an alkali, it gives no precipitate with any metallic salt, except basic acetate of lead. The jalapates are amorphous.

Barium-salts. The monobarytic salt, $C^{54.4}H^{8.3}Ba^1O^{18}$, is obtained by mixing aqueous jalapic acid with a slight excess of baryta-water, removing the excess of baryta with carbonic acid, then warming and evaporating the filtrate. It resembles the tribarytic salt, and contains, according to Mayer's analysis, 49.7 per cent. C, 7.6 H, and 8.6 Ba, the above formula requiring 49.4 C, 7.1 H, and 8.3 Ba.

The tribarytic salt, $C^{54.4}H^{8.3}Ba^3O^{18}$, is prepared by boiling jalapin for 4 to 6 hours, with 2 pts. hydrate of barium and 4 pts. water (or mixing it with an equal weight of hydrate of barium, melted for half an hour in an air-bath, and then heated with water), and passing carbonic acid through the boiling solution, which is then filtered and evaporated down, and the residue dried at 100° in a current of air. It is an amorphous, neutral, slightly-coloured mass, having a slightly irritating, bitter-sweet taste. It melts at 100° , and decomposes with intumescence when strongly heated. It is soluble in water and alcohol, and is not decomposed by carbonic acid (Mayer, Spirgatis). It contains, according to Mayer, 42.1 per cent. C, 6.0 H, and 21.6 Ba, the preceding formula requiring 43.2 C, 6.0 H, and 21.8 Ba. [Mayer's formula, $C^{54.4}H^{8.3}Ba^3O^{18}$, requires 42.4 C, 5.9 H, and 21.3 Ba.]

A salt of intermediate composition, perhaps the dibarytic salt, appears also to be formed under certain circumstances (Mayer).

Jalapate of lead.—Recently precipitated hydrate of lead dissolves in boiling aqueous jalapic acid, forming an amorphous, easily soluble salt. When the aqueous acid is boiled for a long time with excess of hydrate of lead, a gummy, tumefied, basic salt is formed, which is insoluble in water, and very sparingly soluble in alcohol. The aqueous acid gives no precipitate with neutral acetate of lead, but copious white flakes with the basic acetate (Mayer, Spirgatis). Ammoniacal acetate of lead, or the basic acetate, throws down, from the aqueous acid, a flocculent precipitate, which may be purified by repeated solution in acetic acid, precipitation with ammonia, and washing. After being dried over oil of vitriol, it does not lose weight at 130° (Keller). It contains, according to Keller's analysis, 31.1 per cent. lead; the formula $C^{54.4}H^{8.3}Pb^1O^{18}$ requires 29.1 per cent. Keller's salt probably contained excess of base.

Alpha-jalapic acid. $C^{54.4}H^{8.3}O^{18}$. (W. Mayer, Ann. Chem. Pharm. xcv. 155.)—When dilute aqueous jalapic acid is boiled for not too long a time with hydrochloric or dilute sulphuric acid, one part of the jalapic acid is completely converted into jalapinol and sugar, another smaller part into alphajalapic acid, which, on cooling, separates out, with the jalapinol, as a soft, brown, semi-crystalline mass. By boiling this mass with baryta-water, removing the jalapinol of barium which separates on cooling, and concentrating the mother-liquor, white silky needles of alphajalapic acid

are obtained, while jalapinate of barium remains in solution. The needles are purified by recrystallisation from water; then dissolved in boiling water, and decomposed by acetic acid; and the alaphajalapic acid, which crystallises out on cooling, is collected and purified by washing, recrystallising from water, acidulation with acetic acid, solution in alcohol, and precipitation with hot water.

Alphajalapic acid forms white, flexible needles, exhibiting a silky lustre under water, melting below 80° to a pale yellow thin oil, and forming a crystalline solid on cooling. It has no smell, but an irritating taste, with sweetish after-taste, and is feebly acid. It dissolves sparingly in cold, more freely in boiling water, easily in alcohol and in ether.

When the barium-salt (or the acid itself) is heated, it is decomposed, with frothing, and gives off a brown acid oil, which solidifies on cooling, partly in the crystalline form. When treated with dilute acids, or boiled with nitric acid, or melted with hydrate of potassium, it exhibits the same reactions as jalapic acid. In the decomposition with dilute acids, however, only 4 at. sugar are formed to 1 at. jalapinol, whereas jalapic acid (p. 437) yields 6 at. sugar:

Alphajalapate of barium, prepared as above, forms white, glittering, brittle, crystalline needles, having a sweetish irritating taste, and melting easily, without loss of water, to a thin oil, soluble in water and in alcohol. It contains 10.5 per cent. barium, corresponding with the formula $C^{52}H^{102}Ba^2O^{26}$, which requires 10.4 per cent. barium.

JALAPIN. $C^{51}H^{104}O^{16}$. (J. Johnston, Phil. Trans. 1840, p. 342; Phil. Mag. [3], xvii. 183.—A. Kayser, Ann. Ch. Pharm. li. 101.—W. Mayer, *ibid.* xcv. 129.—On Jalapin from scammony-resin: Johnston, Phil. Trans. 1840, p. 340.—Fr. Keller, Ann. Ch. Pharm. civ. 63; further, with altered data, *ibid.* cix. 209.—Spargatis, *ibid.* cxvi. 289.)

This substance (Kayser's *Pararhodocortin*) occurs in the root-stalk of *Convolvulus* (or *Ipomœa*) *orizabensis*, the jalap-stalks or jalap-wood of commerce, and forms the principal portion (soluble in ether) of the jalap-resin prepared therefrom. [On the resin of tuberosa jalap-root, see ii. 15.]

The resin of jalap-stalks has been examined also by Hünle (Repert. xlviii. 365), and Planche (J. Pharm. xxiv. 169). According to Weppen (N. Br. Arch. lxxvii. 153), it resembles the resin of *Convolvulus arvensis*, which, like jalapin, assumes a fine purple-red colour with sulphuric acid, and is soluble in ether (contrary to the statement of Planche, J. Pharm. xiii. 165, who found it insoluble in ether). The same resin has been examined by Chevallier (J. Pharm. ix. 306). The resin of *Convolvulus Soldanella* appears, according to Planche, to be freely soluble in ether and alcohol, as also the portion of the tuberosa jalap-root which is soluble in ether: both these resins are therefore, perhaps, jalapin.

Commercial scammony resin, from *Convolvulus Scammonia*, was described some years ago by Bouillon-Lagrange and Vogel; also by Planche (J. Pharm. xiii. 165; xviii. 183). Cl. Marquart (N. Br. Arch. vii. 248; x. 139) described the resin obtained from the root, and believed he had separated from it a vegetable base (*convolvuline*). Johnston recognised the similarity between scammony-resin and the resin of the jalap-stalks; Spargatis showed that *scammonin*, the chief constituent of the former, is either identical with jalapin, or differs from it only in so far that, when decomposed by acids, it at once yields scammonolic (jalapinic) acid; whereas jalapin, according to Mayer, when treated in a similar manner, yields at first jalapinol (p. 439). These statements are, perhaps, better founded than the contrary statements of Keller and Kosmann (p. 440.)

According to Planche, the resin of *Convolvulus scutellariæ*, and according to Boutron and Charlard, that of *Conv. Turpethum* (J. Pharm. xiii. 131), are not soluble in ether, and may thus be distinguished from jalapin.

In what follows, the statements of Kayser and Mayer relate to jalapin from jalap stalks; those of Keller and Spargatis, to that from scammony.

Preparation.—a. From commercial *Resina Jalappæ ex stipitibus*. To a solution of the resin in a large quantity of alcohol, water is added, until it becomes slightly turbid; the whole is repeatedly boiled with animal charcoal, and the still-coloured filtrate is precipitated by neutral acetate of lead and a little ammonia, which produces a small greenish-brown precipitate. The liquid is filtered, and the filtrate freed from lead by passing sulphydric acid through it, then heating and filtering; the alcohol is again distilled off, and the resinous residuum repeatedly kneaded in boiling water, then dissolved in ether, from which it may be recovered by evaporation (Mayer). Or the alcoholic resin, after treatment with animal charcoal, is boiled for a long time with freshly-precipitated hydrated oxide of lead; the lead is separated from the filtrate by sulphydric acid; and the resin is three times separated by water from the alcoholic solution, then

well boiled in water and dissolved in ether (Mayer). Kayser exhausts the root with alcohol; evaporates the tincture; washes the resinous residue with hot water, dissolves it in alcohol, and treats the solution with animal charcoal; distills off the alcohol; boils the residue again with water; and dries it over a water-bath. Johnston examined a resin that was obtained either by dissolving the commercial resin in ether and evaporating the solution; or by exhausting the ground root of commerce with hot alcohol, evaporating the brown tincture, and extracting the residue with ether; or by extracting chips of the root with cold alcohol, evaporating, boiling the residue in water, dissolving the resinous residue in ether, and evaporating the solution.

b. From Scammony.—Coarsely-powdered scammony is exhausted with cold alcohol (boiling, according to Keller); the tincture is diluted with water till it becomes turbid, decolorised by animal charcoal, and filtered; the greater part of the alcohol is distilled off; and the residue mixed with water is heated in a water-bath, till the whole of the alcohol is driven off, after which the resin is treated for a long time in a water-bath, with frequently-renewed hot water, and at last dried up. The residue may be dissolved in ether and recovered by evaporation. (Spirgatis.)

The jalapin (obtained according to *a* or *b*) still contains a small quantity of a volatile acid (valerianic acid, according to Keller), which cannot be completely removed even by very long washing. It betrays itself by the smell which the jalapin emits when it is converted by bases into jalapic acid, and the resulting solution supersaturated with a mineral acid. Keller regards this acid, the bulk of which passes off in the water used in washing the jalapin, as an essential product of the decomposition of scammony; whereas Mayer and Spirgatis regard it as a mere contamination.

Properties.—Jalapin is a colourless, amorphous resin, translucent when in thin plates; at 100° it becomes brittle, and may be rubbed down to a white powder. It softens at 123°, and melts at 150° to a transparent, colourless, or pale-yellow syrup. It is tasteless and inodorous; in alcoholic solution it gives a scarcely perceptible acid reaction (Mayer, Spirgatis). It is but slightly soluble in water, but dissolves very easily and without decomposition in alcohol, wood-spirit, ether, and chloroform. It dissolves also in benzene, oil of turpentine, and petroleum.

The composition of jalapin dried at 100°, or in a vacuum at common temperatures, is shown by the following analyses.

		Analyses.				
	Calculation.		Kayser.	Mayer.	Keller.	Spirgatis.
34 C . .	408	56.66	58.13	56.52	56.05	56.47
56 H . .	56	7.77	8.07	8.18	8.39	7.93
16 O . .	256	35.57	33.80	35.30	34.96	35.60
$C^{34}H^{56}O^{16}$	720	100.00	100.00	100.00	100.00	100.00

Johnston found in the resin obtained from jalap-stalks, 55.76 to 56.65 per cent., in scammony-resin 54.06 to 55.32 per cent. carbon. Keller gives the formula $C^{34}H^{56}O^{16}$.

Decompositions.—1. Jalapin heated above 127° gives off carbon and hydrogen in the form of a volatile compound, which contains less oxygen than the residual resin (Johnston). Jalapin which melts at 150°, becomes brown when further heated, and acquires a pungent empyreumatic odour (Spirgatis).—2. When heated on platinum-foil, it takes fire, burns with a bright sooty flame and empyreumatic odour, and leaves charcoal.—3. It dissolves slowly in cold strong sulphuric acid, the solution, in five or ten minutes, acquiring a beautiful purple or maroon-red colour, then becoming brown, and finally black. On standing, or after dilution, a brown resin or a brown tallowy body separates from the liquid, while sugar remains dissolved (Kayser, Mayer, Spirgatis).—4. By heating with dilute mineral acids, jalapin (even that which has been dissolved in alkalis and thereby converted into jalapic acid) is decomposed into jalapinol and sugar (Mayer). When jalapin from scammony is treated in the same way, jalapinolic acid is obtained in place of jalapinol (Spirgatis). Formation of jalapinol:

Of jalapinolic acid:

If pure jalapin (or pure jalapic acid) has been used, no other bodies are produced than those just mentioned (Mayer, Spirgatis). According to Keller, when a solution (alkaline or alcoholic?) of scammonin is treated with strong sulphuric acid or with hydrochloric acid gas, and then left to itself, three decomposition-products result, and the formation of a fourth (formic acid or formic aldehyde) appears probable from the formulae. The products of this decomposition are—*a.* A neutral body, $C^{34}H^{56}O^4$, also separable by alkalis into scammonolic acid (jalapinolic acid), and an alcohol, $C^6H^{12}O^6$.—

b. Amylic aldehyde, which passes over as valerianic acid when scammony-resin is boiled with potash-ley, and then with dilute sulphuric acid.—c. A *carbo-hydrate*, $C^{12}H^{10}O^8$, which, however, is converted into sugar by simple boiling with dilute sulphuric acid. Keller gives the equation:

But, according to Spirgatis, the neutral body *a* must be regarded as ethyl-scammonolic ether: moreover, the valerianic acid is obtained only from impure scammonin, Kosmann (J. Pharm. [3], xxxviii. 83), by boiling scammony-resin with dilute sulphuric acid, obtains sugar and his *scammoncol*, as a soft, yellowish-white substance, having a silky lustre and acid reaction, and separating from the hot alkaline solution on cooling. He calculates, according to Johnston's analysis of scammony-resin, the formula $C^{22}H^{22}O^4$ for scammonin, and so arrives at the equation of decomposition:

—5. When jalapin is dissolved in aqueous solutions of *caustic alkalis*, *ammonia*, or *baryta-water*, or in boiling *alkaline carbonates*, water is assimilated, and jalapic acid, soluble in water, is formed (Mayer, Spirgatis), probably thus:

Even the purest jalapin yields also traces of jalapinolic acid and a volatile acid, but no sugar (Mayer). When jalapin is melted with *hydrate of sodium*, hydrogen is given off, and jalapinolic and oxalic acids are formed (Mayer). Keller, by boiling scammonin with alcoholic potash, obtained dark flakes (on account of impurities in the scammonin, according to Spirgatis); and on subsequently adding water to the solution, the compound, $C^{22}H^{22}O^4$ or $C^{14}H^{20}O^2$, was precipitated in white flakes, while valerate of potassium remained in solution. The body, $C^{14}H^{20}O^2$, regarded by Keller as an alcohol, is likewise formed, on boiling commercial jalapin (obtained from the resin of jalap-stalks) or scammony with baryta-water, or solution of potash; it evaporates with the water, and separates in gelatinous flakes from the distillate. At 40° it melts to an oil, crystallises on cooling, and contains, on the average, 78 per cent. C, 14.12 H, and 7.88 O. Keller regards this body as a product of the decomposition of scammonin (or more exactly of the neutral body, $C^{22}H^{22}O^4$ or $C^{14}H^{20}O^2$; Spirgatis regards it as a mixture of resins, since the greater portion of it is obtained on distilling the impure resin with water.

6. By *nitric acid*, jalapin is at first decomposed into jalapinol and sugar, and these products, when further subjected to the action of the nitric acid, are converted into ipomeic and oxalic acids (Mayer). A small quantity of nitric acid does not colour jalapin; but, in presence of gusiac-resin, a green colour is produced (Bull, Spirgatis).

—7. When *sulphurous anhydride* is passed through an ammoniacal alcoholic solution of scammony resin, silvery-shining plates are separated, containing perhaps an aldehyde in combination with acid sulphite of ammonium. (Keller.)

JALAPINOL. $C^{12}H^{10}O^7$. (W. Mayer, Ann. Ch. Pharm. xcv. 145.)—Jalapin and jalapic acid are resolved, by contact with mineral acids, slowly at ordinary, more quickly at elevated temperatures, into jalapinol and sugar (pp. 437, 439). Jalapinol and sugar were also produced, in one instance, when aqueous jalapic acid was left for 24 hours in contact with emulsion of almonds at 36° to 38° ; whereas, in a second experiment, pure emulsin did not effect the decomposition, perhaps because the solution was too strongly heated.

To prepare jalapinol, a moderately concentrated aqueous solution of jalapic acid is mixed with half its bulk of fuming hydrochloric acid, and left to itself for days, or till the clear mixture has solidified to a thick crystalline pulp; and the product, after being washed on a filter with cold water, is repeatedly melted under warm water, and purified by recrystallisation from alcohol, with help of animal charcoal.

Jalapinol forms white, cauliflower-like crystals, which melt at 62° or 62.5° ; and solidify at 59.5° to a hard, brittle, crystalline mass. It makes grease-spots on paper; is inodorous; has an irritating taste, and weak acid reaction. It is soluble in *alcohol* and in *ether*.

In contact with *caustic alkalis*, aqueous *ammonia*, or *baryta*, it is converted, with elimination of water, into a salt of jalapinolic acid:

JALAPINOLIC ACID. $C^6H^{10}O^4$.—An acid produced—1. By treating jalapinol with caustic alkalis, or with baryta (Mayer).—2. By the action of melting hydrate of potassium on jalapin or jalapic acid (Mayer). Jalapin and jalapic acid, prepared from scammony, are resolved by mineral acids into jalapinolic acid and sugar. (Spirgatis.)

Preparation.—1. Jalapin is added gradually and by small portions to hydrate of

sodium melted with $\frac{1}{8}$ th pt. of water (the mass then frothing up violently, giving off hydrogen and turning brown); the mixture is heated and stirred as long as hydrogen continues to escape; the crumbling light-yellow mass is dissolved in water after cooling; and the greater part of the alkali is neutralised with acid. The jalapinatol of sodium, which separates after some hours, is collected, washed, and decomposed by hot acidulated water; the separated acid is again repeatedly melted with pure water, then dissolved in alcohol and treated with animal charcoal; the somewhat concentrated filtrate is mixed with a large quantity of warm water; and the solid acid which separates on cooling is collected (Mayer). From the mother-liquor filtered from the jalapinatol of sodium, excess of acid still separates a small quantity of impure jalapinic acid (Mayer).—2. The hot aqueous solution of jalapinic acid (from scammony) is digested in the water-bath for a fortnight with dilute sulphuric acid; and the tallowy mass which separates on cooling, is freed from sulphuric acid by washing with hot water, and crystallised from ether with help of animal charcoal (Spirgatis).—3. Jalapin from scammony is added to boiling baryta-water; the liquid is heated till the whole is dissolved, and a sample of the filtrate is not rendered turbid, either by water or by hydrochloric acid; and the solution, after filtration, is mixed with one-third of its volume of fuming hydrochloric acid. The liquid becomes turbid in about 20 hours, and solidifies in the course of 10 days to a thick pulp, which is collected, washed with cold water, remelted with hot water, and recrystallised four or five times from aqueous alcohol.

Properties. Jalapinic acid forms white tufts of needles, appearing under a magnifying power of 300, as thin 4-sided prisms. It melts at 64° or 64.5° (60° to 61° , according to Kellor,) and solidifies at 61.5° or 62° (Mayer), at 60° (Spirgatis), to a white radio-crystalline, hard and brittle mass. It makes grease-spots on paper; is lighter than water; inodorous, but has an irritating taste and acid reaction (Mayer, Spirgatis). It is insoluble in water, but soluble in alcohol and in ether.

When heated above its melting point, it decomposes with intumescence, emitting a pungent odour which attacks the eyes and throat.—Nitric acid oxidises it to ipomeic acid and oxalic acid (Mayer, Spirgatis).

Jalapinatolates. The acid is monobasic, the general formula of its neutral salts being $C^{10}H^{15}MO^2$.

Jalapinatol of Ammonium, $C^{10}H^{15}(NH^4)O^2.C^{10}H^{15}O^2$.—By dissolving jalapinol or jalapinic acid in aqueous ammonia, an opalescent liquid is obtained which gives off ammonia when evaporated, solidifies to a crystalline mass when concentrated to a certain point, but if completely evaporated, leaves an amorphous neutral jelly soluble in water. The crystals are grouped like cauliflower-heads, and when strongly magnified, appear as long colourless needles. (Mayer.)

Jalapinatol of Barium, $C^{10}H^{15}Ba^2O^4$, is obtained by precipitating jalapinatol of ammonium with chloride of barium, or by boiling jalapinol or alcoholic jalapinic acid with baryta, and crystallises out on cooling, in microscopic, thin, white, lustreless needles, melting to a colourless liquid when heated. It is nearly insoluble in cold, sparingly soluble in boiling water, more easily in boiling aqueous alcohol. (Mayer, Spirgatis.)

Jalapinatol of ammonium precipitates aqueous chloride of calcium.

Jalapinatol of Copper. a. *Basic*.—When a slightly alkaline aqueous solution of the ammonium-salt is precipitated with cupric acetate, and the precipitate is washed and dried at 100° , a dark blue-green, amorphous, very loose mass is obtained, which melts, without loss of water, to a dark green liquid, and solidifies to a translucent brittle mass. It is insoluble in water, nearly soluble in alcohol, contains at 100° , 18.75 per cent. cupric oxide, and is therefore $2C^{10}H^{15}Cu^2O^4.Cu^2H^2O^2$ (calc. 18.24 per cent. CuO). (Mayer.)

b. *Neutral*.— $C^{10}H^{15}Cu^2O^4$. A hot aqueous solution of jalapinatol of sodium forms with hot aqueous cupric sulphate, a green-blue precipitate, which dries up to a light blue-green amorphous powder, melting to a dark green liquid when heated. (Spirgatis.) It gave by analysis 13.24 per cent. CuO, the formula requiring 13.28 per cent.

Jalapinatol of ammonium precipitates iron-salts.

Jalapinatol of Lead, $C^{10}H^{15}Pb^2O^4$, is obtained by precipitating alcoholic jalapinic acid mixed with a little ammonia, with neutral acetate of lead, and washing the white amorphous precipitate with dilute alcohol and water. It sinters together to an opaque mass at 120° . It is sparingly soluble in water and alcohol.

Jalapinatol of Potassium is obtained by dissolving jalapinol in boiling aqueous potash. The solution on cooling solidifies to a crystalline pulp, which, after washing, and recrystallisation from water or alcohol, forms slender, white, silky needles, melting without decomposition when heated. It is neutral, forms an opalescent solution with water, even when free alkali is present, and is soluble in alcohol.

Jalapinatol of Silver, $C^{10}H^{15}AgO^2$.—The alcoholic solution of the acid neutralised

with ammonia is precipitated by a warm solution of nitrate of silver, in flakes which have a scarcely perceptible crystalline character. (Keller.)

Jalapinolate of Sodium, $C^{16}H^{22}NaO^2$, crystallises in slender dazzling-white tufts of needles, which form a turbid solution with a small quantity of hot water, a clear neutral solution with a larger quantity, and are likewise soluble in alcohol. (Spirgatis.)
